Contents

Preface ix
Associate Editors x
Contributors x
Authors Emeritus from the 27th Edition xviii
Acknowledgements xix

PART 1: BASIC PRINCIPLES

1 **Metabolic response to injury** 1
Iain D. Anderson

2 **Shock, haemorrhage and transfusion** 11
Karim Brohi

3 **Wound healing and tissue repair** 24
Sarah L. Benyon and Kai Yuen Wong

4 **Tissue engineering and regenerative therapies** 38
Andrew W. McCaskie and Liam M. Grover

5 **Surgical infection** 50
H. Paul Redmond and Zeeshan Razzaq

6 **Tropical infections and infestations** 66
Sanjay De Bakshi and Pawanindra Lal

7 **Basic surgical skills** 94
Mark G. Coleman and Joshua Franklyn

8 **Diagnostic imaging** 117
Matthew Matson, Muaaze Z. Ahmad and Niall Power

9 **Gastrointestinal endoscopy** 143
Philip Woodland and Rohit Rao

10 **Principles of minimal access surgery** 162
Ara Darzi and Leanne Harling

11 **Tissue and molecular diagnosis** 177
Roger M. Feakins and Rondell P. Graham

12 **Principles of oncology** 198
Grant D. Stewart and Tim Eisen

13 **Surgical audit and research** 218
Thomas D. Pinkney and Birgit Whitman

14 **Ethics and law in surgical practice** 227
Robert Wheeler

15 **Human factors, patient safety and quality improvement** 236
Kenneth Mealy and Deborah A. McNamara

16 **Global health and surgery** 250
Nobhojit Roy and Christopher B.D. Lavy

PART 2: GENERAL PAEDIATRICS

17 **Paediatric surgery** 254
Anthony D. Lander

18 **Neonatal surgery** 263
Anna-May Long

19 **Trauma in children** 273
Elizabeth Gavens

20 **Paediatric urology** 278
Mohan S. Gundeti and Octavio Herrera

PART 3: PERIOPERATIVE CARE

21 **Preoperative care including the high-risk surgical patient** 285
Amy J. Thomas

22 **Day case surgery** 299
Kim E. Russon

23 **Anaesthesia and pain relief** 304
Vivek Mehta and Serene H.-L. Chang

24 **Postoperative care including perioperative optimisation** 315
Anand M. Sardesai and Anita Balakrishnan

25 **Nutrition and fluid therapy** 329
Anita Balakrishnan

PART 4: TRAUMA

26 **Introduction to trauma** 342
Robert C. Handley and Peter V. Giannoudis

27 **Early assessment and management of severe trauma** 354
Chris Moran and Dan Deakin

Bailey & Love

Digital resources to support your surgical training are available at: www.baileyandlove.tandf.co.uk

28 **Traumatic brain injury** 360
Harry J.C.J. Bulstrode and Antonio Belli

29 **Torso and pelvic trauma** 371
Kenneth D. Boffard and Mansoor Ali Khan

30 **The neck and spine** 388
John R. Crawford and Douglas S. Hay

31 **Maxillofacial trauma** 405
Peter A. Brennan and Rabindra P. Singh

32 **Extremity trauma** 416
Lee Van Rensburg and Jaikirty Rawal

33 **Disaster surgery** 446
Mamoon Rashid

34 **Conflict surgery** 461
Jon Clasper and Phill Pearce

PART 5: ELECTIVE ORTHOPAEDICS

35 **History taking and clinical examination in musculoskeletal disease** 472
Stephen M. McDonnell and Hemant G. Pandit

36 **Sports medicine and sports injuries** 500
Peter J. Millett and Joseph J. Ruzbarsky

37 **The spine** 508
Brian J.C. Freeman and Christopher B.D. Lavy

38 **The upper limb** 526
David Limb and Samuel R. Vollans

39 **The hip** 550
Vikas Khanduja and Karadi H. Sunil Kumar

40 **The knee** 562
Wasim S. Khan and Andrew J. Porteous

41 **The foot and ankle** 568
Bob Sharp

42 **Musculoskeletal tumours** 579
W. Paul Cool and Craig H. Gerrand

43 **Infection of the bones and joints** 595
Martin A. McNally

44 **Paediatric orthopaedics** 609
Deborah M. Eastwood

PART 6: SKIN, PLASTIC AND RECONSTRUCTIVE

45 **Skin and subcutaneous tissue** 639
Adam R. Greenbaum

46 **Burns** 664
John E. Greenwood and Lindsay L. Damkat-Thomas

47 **Plastic and reconstructive surgery** 681
James K.-K. Chan and Marc C. Swan

PART 7: HEAD AND NECK

48 **Cranial neurosurgery** 702
William P. Gray and Harry J.C.J. Bulstrode

49 **The eye and orbit** 724
Keith R. Martin

50 **Developmental abnormalities of the face, mouth and jaws: cleft lip and palate** 738
David A. Koppel and Mark F. Devlin

51 **The ear, nose and sinuses** 750
Iain F. Hathorn and Alex M.D. Bennett

52 **The pharynx, larynx and neck** 774
Vinidh Paleri and Anusha Balasubramanian

53 **Oral cavity cancer** 813
Andrew Schache and John Edward O'Connell

54 **Disorders of the salivary glands** 831
Prathamesh Pai, Deepa Nair and Manish D. Mair

PART 8: ENDOCRINE AND BREAST

55 **The thyroid gland** 850
Richard M. Adamson and Iain J. Nixon

56 **The parathyroid glands** 873
Ruth S. Prichard

57 **The adrenal glands and other abdominal endocrine disorders** 888
Michael J. Stechman and David M. Scott-Coombes

58 **The breast** 914
Anurag Srivastava, Suhani Suhani and Anita Dhar

PART 9: CARDIOTHORACIC

59 **Cardiac surgery** 944
Mustafa Zakkar

60 **The thorax** 974
Carol Tan and Ian Hunt

Bailey & Love

Digital resources to support your surgical training are available at: www.baileyandlove.tandf.co.uk

PART 10: VASCULAR

61 **Arterial disorders** 997
Robert S.M. Davies

62 **Venous disorders** 1025
Ian C. Chetter and Daniel Carradice

62A **Lymphatic disorders (available online at: www.baileyandlove.tandf.co.uk)**
Gnaneswar Atturu, David A. Russell, Shervanthi Homer-Vanniasinkam, Ian C. Chetter and Daniel Carradice

PART 11: ABDOMINAL

63 **History and examination of the abdomen** 1051
Dhananjaya Sharma

64 **The abdominal wall, hernia and umbilicus** 1058
Bruce R. Tulloh and Barbora East

65 **The peritoneum, mesentery, greater omentum and retroperitoneal space** 1083
J. Calvin Coffey

66 **The oesophagus** 1106
Simon Y.K. Law and Ian Y.H. Wong

67 **The stomach and duodenum** 1148
Timothy J. Underwood and John N. Primrose

68 **Bariatric and metabolic surgery** 1182
Richard Welbourn and Dimitri J. Pournaras

69 **The liver** 1191
Ashley R. Dennison and Guy J. Maddern

70 **The spleen** 1219
Pawanindra Lal

71 **The gallbladder and bile ducts** 1232
Avinash N. Supe and Ramkrishna Y. Prabhu

72 **The pancreas** 1260
Satyajit Bhattacharya

73 **Functional disorders of the intestine** 1288
Charles H. Knowles

74 **The small intestine** 1306
Gordon L. Carlson and Jonathan C. Epstein

75 **Inflammatory bowel disease** 1318
P. Ronan O'Connell and Nicola S. Fearnhead

76 **The vermiform appendix** 1335
Jürgen Mulsow

77 **The large intestine** 1354
Steven R. Brown and Catherine L. Boereboom

78 **Intestinal obstruction** 1375
James Hill

79 **The rectum** 1393
David G. Jayne and Aaron J. Quyn

80 **The anus and anal canal** 1417
Malcolm A. West and Karen P. Nugent

PART 12: GENITOURINARY

81 **Urinary symptoms and investigations** 1447
Rajeev Kumar and John K. Mellon

82 **The kidney and ureter** 1466
Nitin Kekre

83 **The urinary bladder** 1486
Sachin Malde

84 **The prostate and seminal vesicles** 1522
Anant Kumar and Oussama Elhage

85 **The urethra and penis** 1538
Sanjay B. Kulkarni

86 **The testis and scrotum** 1558
Tet L. Yap

87 **Gynaecology** 1575
Monica Mittal, Prasanna R. Supramaniam and Christian M. Becker

PART 13: TRANSPLANTATION

88 **Kidney transplantation and the principles of transplantation** 1595
Michael L. Nicholson

89 **Liver transplantation** 1608
Mohamed Rela and Abdul Rahman Hakeem

90 **Pancreas transplantation** 1621
James P. Hunter and Peter J. Friend

91 **Intestinal and multivisceral transplantation** 1629
Neil Russell and Andrew Butler

92 **Heart and lung transplantation** 1636
Stephen C. Clark

Preface to 28th Edition

It is a great privilege to have been entrusted with the responsibility of overseeing the 28th edition of Hamilton Bailey and McNeil Love's *Short Practice of Surgery*. When first published in 1932, almost a century ago, surgery was very different. Then, many surgical procedures, now taken for granted, had not been invented, there were no antibiotics available, and anaesthesia was in its infancy. Endoscopy, cross-sectional imaging, automated biochemical and molecular diagnostics had not been conceived, while open heart surgery, joint replacement and transplantation were still decades away. Yet after 28 editions '*Bailey & Love*' continues to find a place in every medical library. It remains a familiar friend, venerated by generations of medical students and surgeons young and old as a rite of passage and a repository of the core knowledge needed for safe surgical practice. The basic principles of careful history taking, observation, deductive reasoning, technical knowledge and postoperative patient care set out in the first edition, remain the cornerstones of safe clinical practice.

In developing the 28th edition, we have tried to retain the heritage and tradition of this great textbook, while ensuring that every chapter has been revised, and the most up-to-date content has been included in a familiar format, accessible to first time medical student readers while serving as an easy reference source for those more experienced and studying for postgraduate surgical examinations.

Conscious of the need to match content with both undergraduate and postgraduate curriculae, we have made every effort to cover core knowledge, highlighted in summary boxes throughout the text, while more senior readers will find links to supplementary materials online and links to core references and guidelines in the Further Reading sections. Throughout the text, we have endeavoured to highlight where major developments in surgical practice have occurred or are likely to transform surgical practice in the next decade. While surgery retains its prowess as a curative or restorative intervention, it increasingly is part of a multidisciplinary care pathway. Thus, throughout the text, there is particular emphasis on the importance of multidisciplinary team meetings and patient engagement in difficult decision making.

There is no more intense environment than an operating theatre, so how a surgical team interacts is crucial to the outcome for a patient undergoing a surgical procedure. In recent years regulation of medical practice has become tighter. Whereas in certain jurisdictions some may feel that this has become stifling, there is no doubt that regulation is here to stay. Needless to say, we should all be aware of our responsibilities to patients, both morally and ethically, and, although most need no reminding, the law is continually changing as test cases are brought before the courts. Hence, we draw the attention of the reader to the chapters on consent, ethics and the law, patient safety, human factors and quality improvement.

We are very conscious that *Bailey & Love* is popular throughout the world with a substantial readership in India, Nepal, Pakistan, Bangladesh, and Sri Lanka. We have consequently ensured that the 28th edition has an authorship reflective of the readership. Our new authors bring a refreshing enthusiasm and perspective while retaining much of the accumulated wisdom of authors from the 27th and earlier editions. We have worked to create a consistent layout and style of tables, graphics and diagrams. Where appropriate we have included algorithms to assist the reader in understanding patient care pathways. Additional material is included in the Digital Learning Resource, including more detailed descriptions of operative techniques, explanatory videos and hyperlinks to other information sources. We have of course kept the biographical details of individual scientists and practitioners, beloved of readers throughout the generations.

A book as comprehensive as this could never have been completed without the dedication and professionalism of our contributors. They have invariably answered our demands appreciating the responsibility that goes with informing the readership of such a respected and established textbook. We are extremely grateful for all their efforts. In bringing in new contributors, we must also say farewell to many who have contributed to previous editions. We are grateful to them for magnanimously stepping down and making way for 'new blood' and none more so than our previous editor-in-chief Professor Sir Norman Williams who has been an editor since the 22nd edition published in 1997. We thank Sir Norman for his 20-year association with *Bailey & Love* and for his wisdom and guidance. We are delighted to welcome Professor Robert Sayers as our new senior editor and associate editors Mr. Anthony D. Lander (General Paediatrics section), Dr. Anand M. Sardesai (Perioperative Care), Mr. Peter J. Conboy (Head and Neck section) and Professor Prokar Dasgupta (Genitourinary section).

Readers of *Bailey & Love* have always been an integral part of the development of the book over the years and the present editorial group appreciate your feedback, which we know from experience will be forthcoming. Such input is vital if the book is to continue to reach the very high standards expected from each new edition. This has been a labour of love for all of us involved and we do hope it fulfils your needs, no matter whether you are an undergraduate student exploring the exciting world of surgical practice for the first time, a postgraduate trainee studying for exams or an established consultant who wishes to refresh his or her memory.

We wish you all well in your careers no matter which specialty you choose to practise, and we very much hope that the 28th and indeed subsequent editions of *Bailey & Love* accompany you on your travels through this most rewarding of professions.

Acknowledgements

In this day and age, it is impossible to produce a book like Bailey and Love without the contribution of numerous individuals. Although it is impractical to mention all those who have played a part in producing the 28th Edition, it would be remiss not to express our gratitude to all those who have made significant contributions in previous editions.

Chapter 1, *Metabolic response to injury*, contains some material from *Metabolic response to injury* by the late Kenneth Fearon. The material has been revised and updated by the current author.

Chapter 3, *Wound healing and tissue repair*, contains some material from *Wounds, healing and tissue repair* by Michael John Earley. The material has been revised and updated by the current authors.

Chapter 4, *Tissue engineering and regenerative therapies*, contains some material from *Tissue engineering and regeneration* by John Andrew Bradley. The material has been revised and updated by the current authors.

Chapter 5, *Surgical infection*, contains some material from *Surgical infection* by Peter Lamont. The material has been revised and updated by the current authors.

Chapter 6, *Tropical infections and infestations*, contains some material from *Tropical infections and infestations* by Pradip K. Datta. The material has been revised and updated by the current authors.

Chapter 9, *Gastrointestinal endoscopy*, contains some material from *Gastrointestinal endoscopy* by James O. Lindsay. The material has been revised and updated by the current authors.

Chapter 10, *Principles of minimal access surgery*, contains some material from *Principles of laparoscopic and robotic surgery* by Hutan Ashrafian. The material has been revised and updated by the current authors.

Chapter 12, *Principles of oncology*, contains some material from *Principles of oncology* by Robert J.C. Steele and Alastair Munro. The material has been revised and updated by the current authors.

Chapter 13, *Surgical audit and research*, contains some material from *Surgical audit and research* by Jonothan J. Earnshaw. The material has been revised and updated by the current authors.

Chapter 15, *Human factors, patient safety and quality improvement*, contains some material from *Human factors, patient safety and quality improvement* by Frank B.V. Keane. The material has been revised and updated by the current authors.

Chapter 16, *Global health and surgery*, contains some material from *Appendix 2: Fundamental principles in the operating theatre and the importance of global health* by Alan Norrish. The material has been revised and updated by the current authors.

Chapter 21, *Preoperative care including the high-risk surgical patient*, contains some material from *Preoperative care including the high-risk surgical patient* by Madha Vanarase-Pandit, Pierre Foex and Anand Sardesai. The material has been revised and updated by the current author.

Chapter 22, *Day case surgery*, contains some material from *Day case surgery* by Douglas McWhinnie and Ian Jackson. The material has been revised and updated by the current author.

Chapter 24, *Postoperative care*, contains some material from *Postoperative care* by Fay Gilder. The material has been revised and updated by the current authors.

Chapter 25, *Nutrition and fluid therapy*, contains some material from *Nutrition and fluid therapy* by John MacFie. The material has been revised and updated by the current author.

Chapter 29, *Torso and pelvic trauma*, contains some material from *Torso trauma* by Elias Degiannis. The material has been revised and updated by the current authors.

Chapter 31, *Maxillofacial trauma*, contains some material from *Maxillofacial trauma* by David A. Koppel. The material has been revised and updated by the current authors.

Chapter 36, *Sports medicine and sports injuries*, contains some material from *Sports medicine and sports injuries* by Gina Allen. The material has been revised and updated by the current authors.

Chapter 43, *Infection of the bones and joints*, contains some material from *Infection of the bones and joints* by Philippa C. Matthews. The material has been revised and updated by the current author.

Chapter 45, *Skin and subcutaneous tissue*, contains some material from *Skin and subcutaneous tissue* by Christopher L.H. Chan. The material has been revised and updated by the current author.

Chapter 46, *Burns*, contains some material from *Burns* by Michael P.H. Tyler and Sudip J. Ghosh. The material has been revised and updated by the current authors.

Chapter 47, *Plastic and reconstructive surgery*, contains some material from *Plastic and reconstructive surgery* by Tim

Goodacre. The material has been revised and updated by the current authors.

Chapter 50, *Developmental abnormalities of the face, mouth and jaws: cleft lip and palate*, contains some material from *Cleft lip and palate: developmental abnormities of the face, mouth and jaws* by William P. Smith. The material has been revised and updated by the current authors.

Chapter 51, *The ear, nose and sinuses*, contains some material from *The ear, nose and sinuses* by Iain J. Nixon. The material has been revised and updated by the current authors.

Chapter 52, *The pharynx, larynx and neck*, contains some material from *Pharynx, larynx and neck* by Terry M. Jones. The material has been revised and updated by the current authors.

Chapter 53, *Oral cavity cancer*, contains some material from *Oral cavity malignancy* by William P. Smith. The material has been revised and updated by the current authors.

Chapter 54, *Disorders of the salivary glands*, contains some material from *Disorders of the salivary glands* by William P. Smith, Mark McGurk and Leandros-Vassilios F. Vassiliou. The material has been revised and updated by the current authors.

Chapter 57, *The adrenal glands and other abdominal endocrine disorders*, contains some material from *The adrenal glands and other abdominal endocrine disorders* by Tom W.J. Lennard. The material has been revised and updated by the current authors.

Chapter 58, *The breast*, contains some material from *The breast* by Richard C. Sainsbury. The material has been revised and updated by the current authors.

Chapter 59, *Cardiac surgery*, contains some material from *Cardiac surgery* by Jonathan R. Anderson. The material has been revised and updated by the current author.

Chapter 61, *Arterial disorders*, contains some material from *Arterial disorders* by Rob Sayers. The material has been revised and updated by the current author.

Chapter 62, *Venous and lymphatic disorders*, contains some material from *Lymphatic disorders* by Gnaneswar Atturu, David A. Russell and Shervanthi Homer-Vanniasinkam. The material has been revised and updated by the current authors.

Chapter 63, *History and examination of the abdomen*, contains some material from *History and examination of the abdomen* by P. Ronan O'Connell. The material has been revised and updated by the current author.

Chapter 64, *The abdominal wall, hernia and umbilicus*, contains some material from *Abdominal wall, hernia and umbilicus* by Stephen J. Nixon. The material has been revised and updated by the current authors.

Chapter 65, *The peritoneum, mesentery, greater omentum and retroperitoneal space*, contains some material from *The peritoneum, omentum, mesentery and retroperitoneal space* by Charles H. Knowles. The material has been revised and updated by the current author.

Chapter 66, *The oesophagus*, contains some material from *The oesophagus* by Derek Alderson. The material has been revised and updated by the current authors.

Chapter 69, *The liver*, contains some material from *The liver* by Robert P. Jones and Graeme J. Poston. The material has been revised and updated by the current authors.

Chapter 70, *The spleen*, contains some material from *The spleen* by O. James Garden. The material has been revised and updated by the current author.

Chapter 71, *The gallbladder and bile ducts*, contains some material from *The gallbladder and bile ducts* by Kevin C.P. Conlon. The material has been revised and updated by the current authors.

Chapter 74, *The small intestine*, contains some material from *The small intestine* by Mattias Soop. The material has been revised and updated by the current authors.

Chapter 77, *The large intestine*, contains some material from *The large intestine* by Gordon Lawrence Carlson and Jonathan Epstein. The material has been revised and updated by the current authors.

Chapter 79, *The rectum*, contains some material from *The rectum* by Hiba Fatayer. The material has been revised and updated by the current authors.

Chapter 82, *The kidney and ureter*, contains some material from *Kidneys and ureters* by J. Kilian Mellon. The material has been revised and updated by the current author.

Chapter 83, *The urinary bladder*, contains some material from *The urinary bladder* by Freddie C. Hamdy. The material has been revised and updated by the current author.

Chapter 84, *The prostate and seminal vesicles*, contains some material from *The prostate and seminal vesicles* by David E. Neal and Greg Shaw. The material has been revised and updated by the current authors.

Chapter 85, *The urethra and penis*, contains some material from *Urethra and penis* by Ian Eardley. The material has been revised and updated by the current author.

Chapter 86, *The testis and scrotum*, contains some material from *Testis and scrotum* by Ian Eardley. The material has been revised and updated by the current author.

Part 13: Transplantation, contains some material from *Transplantation* by John Andrew Bradley. The material has been split into subsections, revised and updated by the current authors.

PART 1 | Basic principles

CHAPTER 1

Metabolic response to injury

Learning objectives

To understand:

- How the body responds to accidental injury and surgery
- Physiological and biochemical changes that occur during injury and recovery
- Mediators and pathways of the metabolic response to injury
- Avoidable factors that compound the metabolic response to injury
- How the metabolic response to injury influences surgical outcomes
- Concepts behind optimal perioperative care

INTRODUCTION

As surgeons we are inextricably linked with tissue injury and its effects, both from the damage which operating inevitably causes and from the treatment of accidental traumatic injury. The body responds to significant local tissue injury, whether surgical or accidental, with a series of systemic changes which affect the functions of vital organs. This surgical stress response is brought about by several pathways involving hormones, inflammation-related cytokines and neural circuits. It leads to alterations in body metabolism, wound healing and immunity and in the function of specific organs. These changes are known collectively as the metabolic response to injury. While these responses are designed to limit damage and begin repair processes, not all the effects are beneficial by any means. They can lead to complications, especially sepsis, which can then amplify and prolong the abnormal processes and lead to or prolong multiple organ dysfunction syndrome (MODS). Given that these metabolic effects of injury can have a significant impact on recovery and survival from many types of surgery and surgical illness, surgeons require an understanding of them in order to care optimally for their patients. Successful management of the metabolic response improves outcomes and forms the basis of modern perioperative care after major surgery as well as the treatment of severely injured and septic patients. This chapter will look primarily at the metabolic responses to injury while shock, fluid balance, sepsis and nutrition are covered in greater depth in *Chapters 2 and 25*.

Homeostasis

Homeostasis is the concept of maintaining a constant internal environment that allows cellular processes to function optimally. Many aspects of surgery, trauma and injury affect homeostasis and can lead to organ dysfunction. Traditionally the metabolic response to injury is divided into an initial period of catabolism (which may include a period of shock) followed by an anabolic phase of repair and tissue healing.

The catabolic phase begins at the time of injury and is characterised by hypovolaemia, decreased basal metabolic rate, reduced cardiac output, hypothermia and lactic acidosis. The main physiological role of this phase is to conserve both circulating volume and energy stores and thus maximise survival chances for future recovery. A series of neurohormonal responses accompany these effects and trigger a systemic inflammatory response syndrome (SIRS), where body stores are mobilised for recovery and repair. The catabolic effects include muscle breakdown, weight loss and hyperglycaemia, which themselves increase the risk of complications, especially sepsis. As the catabolic phase subsides, an anabolic (rebuilding) phase develops, which may last for weeks if extensive recovery and repair are required following serious injury.

Modern surgical care

The role of surgical critical care, including resuscitation and/or organ support, must be to work alongside the metabolic effects of injury while the patient is restored to a situation from which homeostatic mechanisms can achieve a return to normality. The systemic effects of injury still impact heavily on survival and complications through loss of muscle mass, sepsis and MODS. In fact, modern treatment of major trauma can now be so successful that the great majority of hospital deaths in developed countries occur after some days as a result of complex physiological processes, rather than as a direct and rapid consequence of organ damage or blood loss, although it is the initial injury and blood loss that sets the scene for the later systemic effects. Parallel with the catabolic effects introduced above, inflammatory-type processes cause immune suppression. While this inflammation is often initially sterile, the nature of surgery and injury predisposes to infection and sepsis. Impaired immunity as part of the metabolic response

compounds this risk and explains why sepsis and MODS/failure is a key part of perioperative care and a leading mode of death among our patients. Even in modern trauma systems, MODS carries a mortality of around 25%.

As a consequence of modern understanding of the metabolic response to injury, elective surgical practice now seeks to actively reduce the need for a homeostatic response by minimising the primary insult via minimal access surgery and by 'stress-free' perioperative care or enhanced recovery after surgery (ERAS). This chapter will review the mediators of the stress response, the physiological and biochemical pathway changes associated with surgical injury and the changes in body composition that occur following surgical injury. Emphasis is placed on why knowledge of these events is important to understand the rationale for modern 'stress-free' perioperative and critical care.

Summary box 1.1

Basic concepts

- Homeostasis is the foundation of normal physiology
- 'Stress-free' perioperative care helps to preserve homeostasis following elective surgery
- Resuscitation, surgical intervention and critical care can return the severely injured patient to a situation in which homeostasis becomes possible once again
- The metabolic response to surgery influences these processes profoundly, particularly through catabolic effects, MODS and impaired immunity

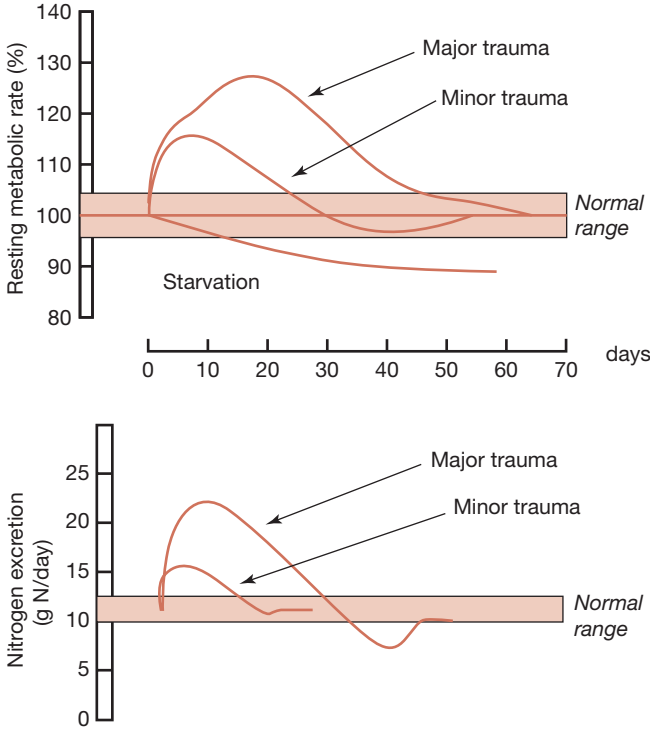

Figure 1.1 Hypermetabolism and increased nitrogen excretion are closely related to the magnitude of the initial injury and show a graded response.

THE MAGNITUDE OF THE INJURY RESPONSE

It is important to recognise that, in general or population terms, the metabolic response to injury is graded: the more severe the injury, the greater the response (***Figure 1.1***). This concept applies not only to physiological and metabolic changes but also to immunological changes and other sequelae. Thus, following major elective surgery, there may be a transient and modest rise in temperature, heart rate, respiratory rate, energy expenditure and peripheral white cell count. Following major trauma, emergency surgery, sepsis or burns, these changes are accentuated, resulting in SIRS, with hypermetabolism, marked catabolism, shock and even MODS. However, genetic variability also plays a key role in determining the intensity of the inflammatory response, with some individual patients responding much more dramatically than others to apparently similar conditions.

MEDIATORS OF THE METABOLIC RESPONSE TO INJURY

Tissue damage and inflammation

Tissue injury is sensed in several ways. Tissue damage causes the release of cellular and other molecular fragments known as damage-associated molecular patterns (DAMPs) or alarmins. These DAMPs are sensed by pattern recognition receptors (PRRs), such as Toll-like receptors and NOD-like receptors (or nucleotide-binding leucine-rich repeat receptors) on cells of the innate immune system, which includes macrophages, neutrophils and dendritic cells. These cells are attracted and activated, triggering the formation of complex intracellular proteins known as inflammasomes. This results in the activation of caspases; these are enzymes that, in turn, activate key inflammatory cytokines including interleukin-1 (IL-1), IL-6 and many others. PRR activation also leads to release of tumour necrosis factor alpha (TNF), interferons, chemokines and other mediators. Thus begins a sterile systemic inflammatory cascade that leads to local inflammation and, when sufficiently severe, to a clinically detectable SIRS. Once activated by DAMPs, inflammasomes also contribute to cell death, tissue damage and immune suppression. DAMPs can activate inflammasome formation in endothelial cells and platelets, resulting in leaky capillaries and coagulopathy; these are changes that can result in the production of more DAMPs owing to local ischaemia from microcirculatory effects. Local inflammation begins the process of tissue repair but SIRS, when uncontrolled or prolonged, becomes a risk factor for acute kidney injury, acute lung injury and coagulopathy, and hence for MODS and organ failure. Within the injured brain, secondary brain injury can occur.

DAMPs thought to be important in tissue trauma include heat shock proteins, high mobility group protein B1 (HMGB1), S100 proteins and fragments of nucleic acids. Commonly, DAMPs can activate several different receptors and pathways. This crossover, or redundancy as it is termed, is a characteristic of inflammation and has been one of the barriers to developing

effective therapeutic blockade of these mechanisms. Furthermore, DAMPs can be self-perpetuated during the complicated course of a surgical critical illness, amplifying and prolonging the inflammatory process and related organ dysfunction. Triggers to further release of DAMPs include sepsis, haemorrhage, massive transfusion, acidosis, surgery, crush syndrome and ischaemia–reperfusion. Thus the secondary insults of delayed or ineffective treatment of complications such as ongoing bleeding, ischaemia or sepsis will tend to maintain and amplify the inflammatory process and its resulting immune dysfunction. This can become a prolonged or self-perpetuating process (*Table 1.1*).

TABLE 1.1 Some secondary triggers of the metabolic response to injury.

Secondary triggers of inflammatory pathways in trauma and surgery
• Sepsis
• Haemorrhage
• Massive transfusion
• Acidosis
• Surgery
• Crush syndrome
• Ischaemia–reperfusion
These events can amplify or prolong the catabolic phase, leading to organ failure or immune dysfunction.

Neuroendocrine response to injury

Patients also respond rapidly to injury by the classical neuroendocrine pathways of the stress response, consisting of afferent nociceptive neurones, the spinal cord, thalamus, hypothalamus and pituitary (*Figure 1.2*). Nociceptive neurones are excited by the effects of local inflammation as well as by direct injury. The neurones terminate in the hypothalamus and release corticotropin-releasing factor (CRF). CRF stimulates adrenocorticotropic hormone (ACTH) release from the anterior pituitary, which then acts on the adrenals to increase the secretion of cortisol within hours of injury. Hypothalamic activation of the sympathetic nervous system causes release of adrenaline (epinephrine) and also stimulates release of glucagon. An intravenous infusion of a cocktail of these 'counter-regulatory' hormones (glucagon, glucocorticoids and catecholamines) reproduces many aspects of the metabolic response to injury. The metabolic effects of the acute rise in the levels of these hormones is to liberate glucose from carbohydrate stores and to begin the breakdown of fat and protein as metabolic substrates for energy and repair. There are, however, many other effects, including alterations in insulin release and sensitivity, hypersecretion of prolactin and growth hormone (GH) in the presence of low circulatory insulin-like growth factor-1 (IGF-1) and inactivation of peripheral thyroid hormones and gonadal function. Of note, GH has direct lipolytic, insulin-antagonising and proinflammatory properties.

Summary box 1.2

Neuroendocrine response to injury/critical illness

The neuroendocrine response to severe injury/critical illness is biphasic:

- **Acute phase** (hours) characterised by elevated counter-regulatory hormones (cortisol, glucagon, adrenaline). Changes are thought to be beneficial for short-term survival
- **Chronic phase** (days) associated with hypothalamic suppression and low serum levels of the respective target organ hormones. Changes may contribute to chronic wasting

As described above, the innate immune system (principally macrophages), once activated by DAMPs, interacts in a complex manner with the adaptive immune system (T cells, B cells) in co-generating the metabolic response to injury (*Figure 1.2*). Proinflammatory cytokines including IL-1, TNF alpha (TNFα), IL-6 and IL-8 are produced within the first 24 hours and act directly on the hypothalamus to cause pyrexia. Such cytokines also augment the hypothalamic stress response and act directly on skeletal muscle to induce proteolysis while inducing acute-phase protein production in the liver. Proinflammatory cytokines also play a complex role in the development of peripheral insulin resistance. Other important proinflammatory mediators include nitric oxide ([NO] via inducible nitric oxide synthetase [iNOS]) and a variety of prostanoids (via cyclooxygenase-2 [Cox-2]). Changes in organ function (e.g. renal hypoperfusion/impairment) may be induced by excessive vasoconstriction via endogenous factors such as endothelin-1. Complement and kinin pathways are also activated and processes of programmed cell death and phagocytosis are triggered to clear damaged tissues.

There are many complex interactions among the neuroendocrine, cytokine and metabolic axes. For example, although cortisol is immunosuppressive at high levels, it acts synergistically with IL-6 to promote the hepatic acute-phase response. ACTH release is enhanced by proinflammatory cytokines and the noradrenergic system. The resulting rise in cortisol levels may form a weak feedback loop, attempting to limit the proinflammatory stress response. Finally, hyperglycaemia may aggravate the inflammatory response in the mitochondria, causing the formation of excess oxygen free radicals and also altering gene expression to enhance cytokine production.

At the molecular level, the changes that accompany systemic inflammation are extremely complex. In one study using network-based analysis of changes in mRNA expression in leukocytes following exposure to endotoxin, there were changes in the expression of more than 3700 genes, with over half showing decreased expression and the remainder increased expression. The cell surface receptors, signalling mechanisms and transcription factors that initiate these events are also complex. Although the detailed mechanisms are being steadily identified, specific molecular therapies remain elusive and certainly subservient to optimal clinical care.

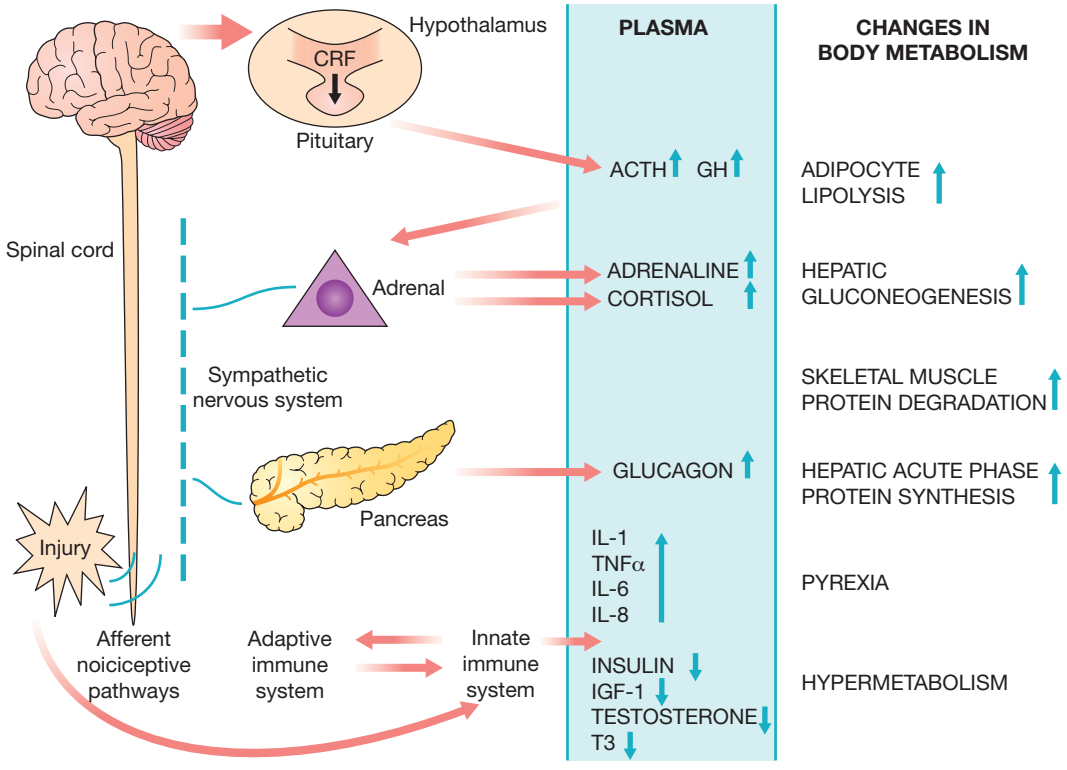

Figure 1.2 The integrated response to surgical injury (first 24–48 hours): there is a complex interplay between the neuroendocrine stress response and the proinflammatory cytokine response of the innate immune system. ACTH, adrenocorticotropic hormone; GH, growth hormone; IGF, insulin-like growth factor; IL, interleukin; T3, triiodothyronine; TNFα, tumour necrosis factor alpha.

Agonists and antagonists: an uncertain balance

Within hours of the upregulation of proinflammatory cytokines, endogenous cytokine antagonists enter the circulation (e.g. interleukin-1 receptor antagonist [IL-1Ra] and TNF-soluble receptors [TNF-sR-55 and 75]) and act to control the initial proinflammatory response and limit any systemic organ damage caused by it. A complex further series of adaptive changes includes the development of a counter-inflammatory response regulated by IL-4, -5, -9 and -13 and transforming growth factor beta (TGFβ). Within inflamed tissue the duration and magnitude of acute inflammation as well as the return to homeostasis are influenced by a group of local mediators known as specialised pro-resolving mediators (SPMs), which include essential fatty acid-derived lipoxins, resolvins, protectins and maresins. These endogenous resolution agonists orchestrate the uptake and clearance of apoptotic polymorphonuclear neutrophils and microbial particles, reduce proinflammatory cytokines and lipid mediators as well as enhance the removal of cellular debris. Thus, both at the systemic level (endogenous cytokine antagonists – see earlier) and at the local tissue level, the body attempts to limit the inflammatory response, but further tissue damage, sepsis or other complications challenge these processes of resolution. As with the initial inflammatory response to tissue injury, it appears that the degree of the secondary anti-inflammatory response varies between individuals, probably on a genetic basis. If the anti-inflammatory response dominates or is accentuated and prolonged in critical illness, it is characterised as a compensatory anti-inflammatory response syndrome (CARS), resulting in immunosuppression and an increased susceptibility to opportunistic (nosocomial) infection. Further sepsis, with its associated catabolism, results. CARS can be prolonged by ongoing critical illness as part of an ongoing vicious cycle of chronic critical illness (also known as Persistent Inflammation, Immunosuppression and Catabolism) syndrome. Thus both the initial inflammatory response to tissue injury and the secondary modulating responses can be seen to differing degrees in different individuals or at different stages of the critical illness. Either circumstance can cause harm, and rapid restoration of homeostasis and preventing secondary inflammation or sepsis are key therapeutic principles that influence late outcomes as well as immediate ones.

Summary box 1.3

The metabolic response to surgery and injury: key characteristics

- Rapid onset driven by proinflammatory cytokines (e.g. IL-1, IL-6 and TNFα)
- Broadly related to injury severity; most severe in sepsis, burns and major trauma
- Varies in severity between individuals (genetic)
- Causes catabolism, muscle breakdown, immunosuppression and organ dysfunction/failure
- Counterbalanced by antagonist response but the balance may be imperfect
- Prolonged by sepsis and other secondary insults
- Can become chronic
- Associated with most late deaths from injury or surgery in developed health systems

METABOLIC CHANGES AFTER SURGERY AND TRAUMA

The catabolic phase begins at the time of injury and lasts for approximately 24–48 hours. It may be attenuated by proper resuscitation and is characterised by hypovolaemia, decreased basal metabolic rate, reduced cardiac output, hypothermia and lactic acidosis. The predominant hormones regulating the catabolic phase are catecholamines, cortisol and aldosterone (following activation of the renin–angiotensin system). The magnitude of this neuroendocrine response depends on the degree of tissue damage, blood loss and the stimulation of somatic afferent nerves at the site of injury. The main physiological role of the catabolic phase is to conserve both circulating volume and energy stores for later recovery and repair.

Following resuscitation, the catabolic phase evolves into a hypermetabolic flow phase, which corresponds to SIRS. This phase involves the mobilisation of body energy stores for recovery and repair, and the subsequent replacement of lost or damaged tissue. It is characterised by tissue oedema (from vasodilatation and increased capillary leakage), increased basal metabolic rate (hypermetabolism), increased cardiac output, raised body temperature, leukocytosis, increased oxygen consumption and increased gluconeogenesis.

During the catabolic phase, the increased production of counter-regulatory hormones (including catecholamines, cortisol and glucagon) and inflammatory cytokines (e.g. IL-1, IL-6 and TNFα) results in significant fat and protein mobilisation, leading to significant weight loss and increased urinary nitrogen excretion. During shock, insulin levels do not rise as expected to combat the hyperglycaemia that occurs in response to stress hormone release and plasma insulin can even fall after severe injury. Within a few days, insulin production is increased but is associated with significant insulin resistance and, therefore, injured patients often exhibit poor glycaemic control. Importantly, the combination of pronounced or prolonged catabolism in association with insulin resistance places patients within this phase at increased risk of septic and other complications. Obviously, the development of complications will further aggravate the neuroendocrine and inflammatory stress responses, thus creating a vicious catabolic cycle and management of blood sugar levels remains an important step.

Summary box 1.4

Purpose of neuroendocrine changes following surgery or trauma

The constellation of neuroendocrine changes following surgery or trauma acts to:

- Provide essential substrates for survival from tissue breakdown
- Postpone anabolism
- Optimise host defence

These changes may be helpful in the short term, but may be harmful in the long term, especially to the severely injured or critically ill patient.

MANAGING THE CATABOLIC STRESS RESPONSE

There are several key elements that determine the extent of catabolism and thus govern the metabolic and nutritional care of the surgical patient. It must be remembered that, during the response to injury, not all tissues are catabolic. Indeed, the essence of this coordinated response is to allow the body to reprioritise limited resources away from peripheral tissues (muscle, adipose tissue, skin) and towards key viscera (liver, immune system) and the wound (*Figure 1.3*). However the damage to skeletal muscle can be catastrophic.

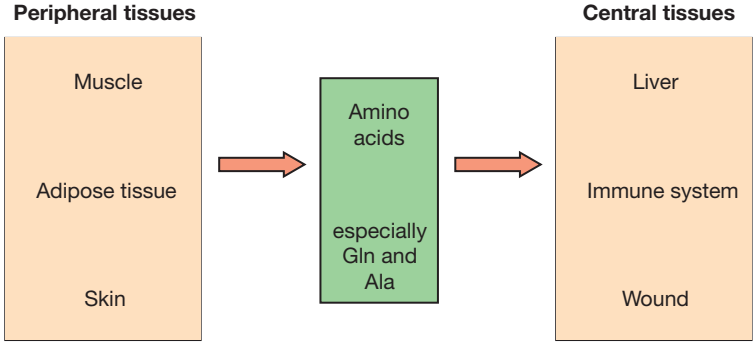

Figure 1.3 During the metabolic response to injury, the body reprioritises protein metabolism away from peripheral tissues and towards key central tissues such as the liver, immune system and wounds. One of the main reasons why the reutilisation of amino acids derived from muscle proteolysis leads to net catabolism is that the increased glutamine and alanine efflux from muscle is derived, in part, from the irreversible degradation of branched chain amino acids. Ala, alanine; Gln, glutamine.

Hypermetabolism

The majority of trauma patients (except possibly those with extensive burns, in whom a greater effect can be seen) demonstrate energy expenditures approximately 15–25% above predicted healthy resting values. The predominant cause appears to be a complex interaction between the central control of metabolic rate and peripheral energy utilisation. In particular, central thermodysregulation (caused by the proinflammatory cytokine cascade), increased sympathetic activity, abnormalities from wound circulation (ischaemic areas produce lactate, which must be metabolised by the adenosine triphosphate [ATP]-consuming hepatic Cori cycle; hyperaemic areas cause an increase in cardiac output), increased protein turnover and nutritional support may all increase patient energy expenditure. Theoretically, patient energy expenditure could rise even higher than observed levels following surgery or trauma, but several features of standard intensive care (including bed rest, paralysis, ventilation and external temperature regulation) limit the hypermetabolic driving forces of the stress response. Furthermore, the skeletal muscle wasting experienced by patients with prolonged catabolism actually limits the volume of metabolically active tissue (see ***Alterations in skeletal muscle protein metabolism***).

Alterations in skeletal muscle protein metabolism

Muscle protein is continually synthesised and broken down with a turnover rate in humans of 1–2% per day. Under normal circumstances, synthesis equals breakdown and muscle bulk remains constant. Physiological stimuli that promote net muscle protein increase include feeding (especially extracellular amino acid concentration) and exercise. Paradoxically, during exercise, skeletal muscle protein synthesis is depressed, but it increases again during rest and feeding.

During the catabolic phase of the stress response, muscle wasting occurs as a result of an increase in muscle protein degradation (via enzymatic pathways), coupled with a decrease in muscle protein synthesis. The major site of protein loss is peripheral skeletal muscle, but it also occurs in the respiratory muscles (predisposing the patient to hypoventilation and chest infections) and in the gut (reducing gut motility). Cardiac muscle appears to be mostly spared. The predominant mechanism involved in the wasting of skeletal muscle is the ATP-dependent ubiquitin–proteasome pathway (***Figure 1.4***), although the lysosomal cathepsins and the calcium–calpain pathway play facilitatory and accessory roles.

Under extreme conditions of catabolism (e.g. major sepsis), urinary nitrogen losses can reach 14–20 g/day; this is equivalent to the loss of 500 g of skeletal muscle per day. Muscle catabolism cannot be inhibited fully by providing artificial nutritional support as long as the stress response continues. Hyperalimentation (excess feeding beyond requirements) was once in vogue to try and match the large losses, but it is now recognised that hyperalimentation represents a metabolic stress in itself and that nutritional support should be at a modest level to attenuate rather than replace energy and protein losses. Treating underlying sepsis adequately is fundamental to limiting protein catabolism and is an essential part of effective nutritional support. This includes searching for and treating recurrent septic episodes in the critically ill.

Clinically, a patient with skeletal muscle wasting will experience weakness, fatigue, reduced functional ability, decreased quality of life and an increased risk of morbidity and mortality. In critically ill patients, muscle weakness may be further worsened by the development of critical illness myopathy, a multifactorial condition that is associated with impaired excitation–contraction coupling.

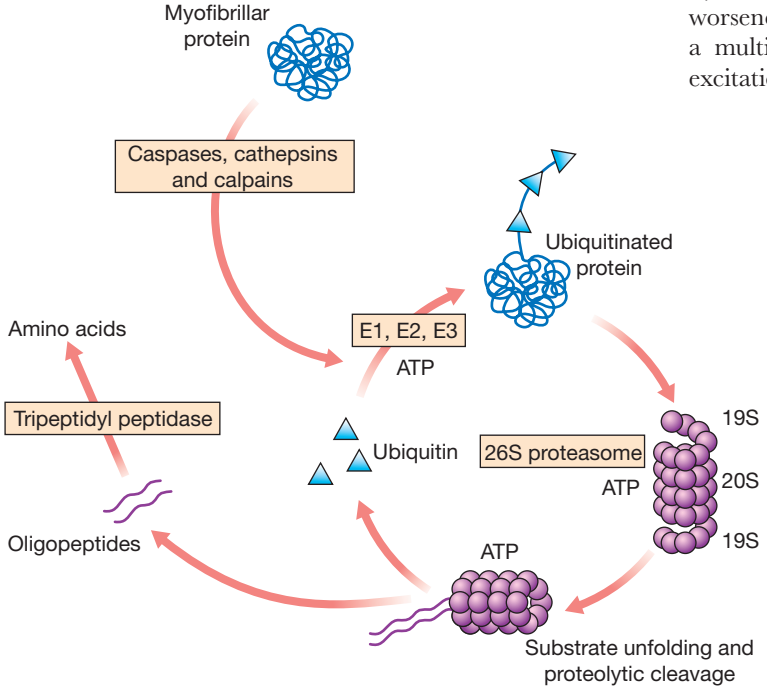

Figure 1.4 The intracellular effector mechanisms involved in degrading myofibrillar protein into free amino acids. The ubiquitin–proteasome pathway is a complex multistep process. ATP, adenosine triphosphate; E1, ubiquitin-activating enzyme; E2, ubiquitin-conjugating enzyme; E3, ubiquitin ligase.

Carl Ferdinand Cori, 1896–1984, and his wife **Gerty Theresa Cori**, 1896–1957, Professors of Biochemistry, Washington University Medical School, St Louis, MI, USA, were awarded a share of the 1947 Nobel Prize for Medicine.

Summary box 1.5

Skeletal muscle wasting

- Provides amino acids for the metabolic support of central organs/tissues
- Is mediated at a molecular level mainly by activation of the ubiquitin–proteasome pathway
- Is inevitable to some degree but is prolonged by sepsis in particular
- Can result in immobility and contribute to prolonged recovery, poor healing, hypostatic pneumonia and death if prolonged and excessive

Alterations in hepatic protein metabolism: the acute-phase protein response

The liver and skeletal muscle together account for >50% of daily body protein turnover. Skeletal muscle has a large mass but a low turnover rate (1–2% per day), whereas the liver has a relatively small mass (1.5 kg) but a much higher protein turnover rate (10–20% per day). Hepatic protein synthesis is divided roughly 50:50 between renewal of structural proteins and synthesis of export proteins. Albumin is the major export protein produced by the liver and is renewed at the rate of about 10% per day. The transcapillary escape rate (TER) of albumin is about 10 times the rate of synthesis, and short-term changes in albumin concentration are most probably due to increased vascular permeability. Albumin TER may be increased threefold following major injury/sepsis. In response to inflammatory conditions, including surgery, trauma and sepsis, proinflammatory cytokines, including IL-1, IL-6 and TNFα and in particular IL-6, promote the hepatic synthesis of positive acute-phase proteins, e.g. fibrinogen and C-reactive protein (CRP). The acute-phase protein response represents a 'double-edged sword' for surgical patients as it provides proteins important for recovery and repair but only at the expense of valuable lean tissue and energy reserves. In contrast to the positive acute-phase reactants, the plasma concentrations of other liver export proteins (the negative acute-phase reactants) fall acutely following injury, e.g. albumin. However, rather than representing a reduced hepatic synthesis rate, the fall in plasma concentration of negative acute-phase reactants is thought principally to reflect increased transcapillary escape, secondary to an increase in microvascular permeability.

Summary box 1.6

Hepatic acute-phase response

The hepatic acute-phase response represents a reprioritisation of body protein metabolism towards the liver and is characterised by:

- **Positive** reactants (e.g. CRP): plasma concentration ↑
- **Negative** reactants (e.g. albumin): plasma concentration ↓

Insulin resistance

Following surgery or trauma, postoperative hyperglycaemia develops as a result of increased glucose production combined with decreased glucose uptake in peripheral tissues. Decreased glucose uptake is a result of insulin resistance, which is temporarily induced within the stressed patient. Suggested mechanisms for this phenomenon include the action of proinflammatory cytokines and the decreased responsiveness of insulin-regulated glucose transporter proteins. The degree of insulin resistance is proportional to the magnitude of the injurious process. Following routine upper abdominal surgery for example, insulin resistance may persist for approximately 2 weeks but this period will extend with prolonged sepsis. Postoperative patients with insulin resistance behave in a similar manner to individuals with type 2 diabetes mellitus. In intensive care, the mainstay of management of insulin resistance is intravenous insulin infusion, which is used to keep blood glucose level within reasonable limits on the basis that this will reduce both morbidity and mortality. However, unduly tight control can increase the risk of significant hypoglycaemia. It should be noted that patients with diabetes whose glycaemic control has been poor prior to their critical illness pose a particular challenge.

CHANGES IN BODY COMPOSITION FOLLOWING INJURY

The average 70 kg male can be considered to consist of fat (13 kg) and fat-free mass (or lean body mass: 57 kg). In such an individual, the lean tissue is composed primarily of protein (12 kg), water (42 kg) and minerals (3 kg) (***Figure 1.5***). The protein mass can be considered as two basic compartments: skeletal muscle (4 kg) and non-skeletal muscle (8 kg), which includes the visceral protein mass. The water mass (42 litres) is divided into intracellular (28 litres) and extracellular (14 litres) spaces. Most of the mineral mass is contained in the bony skeleton.

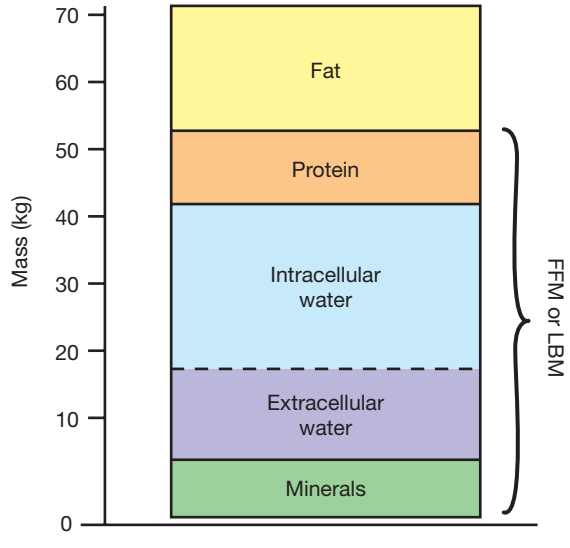

Figure 1.5 The chemical body composition of a normal 70 kg male. FFM, fat-free mass; LBM, lean body mass.

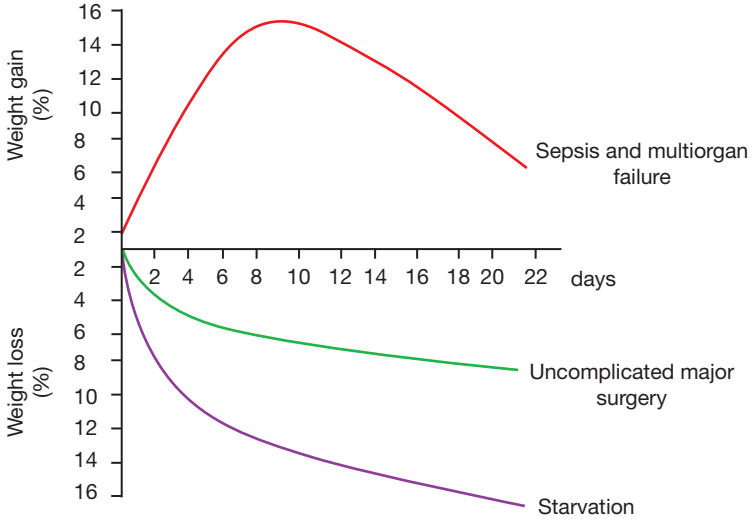

Figure 1.6 Changes in body weight that occur in serious sepsis, after uncomplicated surgery and in total starvation.

The main labile energy reserve in the body is fat, and the main labile protein reserve is skeletal muscle. While fat mass can be reduced without major detriment to function, loss of protein mass results not only in skeletal muscle wasting but also in depletion of visceral protein status. Within lean tissue, each 1 g of nitrogen is contained within 6.25 g of protein, which is contained in approximately 36 g of wet weight tissue. Thus, the loss of 1 g of nitrogen in urine is equivalent to the breakdown of 36 g of wet weight lean tissue. Protein turnover in the whole body is of the order of 150–200 g per day. A normal human ingests about 70–100 g protein per day, which is metabolised and excreted in urine as ammonia and urea (i.e. approximately 14 g N/day). During total starvation, urinary loss of nitrogen is rapidly attenuated by a series of adaptive changes. Loss of body weight follows a similar course (***Figure 1.6***), thus accounting for the survival of hunger strikers for a period of 50–60 days. Following major injury, and particularly in the presence of ongoing septic complications, this adaptive change fails to occur and there is a state of 'auto-cannibalism', resulting in continuing urinary nitrogen losses of 10–20 g N/day (equivalent to 500 g of wet weight lean tissue per day). As with total starvation, once loss of body protein mass has reached 30–40% of the total, survival is unlikely.

Critically ill patients admitted to the intensive care unit with severe sepsis or major blunt trauma undergo massive changes in body composition (***Figure 1.7***). Body weight increases immediately on resuscitation with an expansion of extracellular water by 6–10 litres within 24 hours. Thereafter, even with optimal metabolic care and nutritional support, total body protein will diminish by 15% in the next 10 days, and body weight will reach negative balance as the expansion of the extracellular space resolves. In marked contrast, it is now possible to maintain body weight and nitrogen equilibrium following major elective surgery. This can be achieved by blocking the neuroendocrine stress response with epidural analgesia/other related techniques and providing early oral/enteral feeding. Moreover, the early fluid retention phase can be avoided by careful intraoperative management of fluid balance, with avoidance of excessive administration of intravenous saline.

Summary box 1.7

Changes in body composition following major surgery/critical illness

- Catabolism leads to a decrease in fat mass and skeletal muscle mass
- Body weight may paradoxically increase because of expansion of fluid within the extracellular fluid space

AVOIDABLE FACTORS THAT COMPOUND THE RESPONSE TO INJURY

There are several factors that prolong the acute-phase response to injury (***Table 1.1***) and keep the patient in a catabolic state. Other factors can exacerbate or compound the metabolic stress response both in elective surgery and in the emergency setting. These include anaesthesia, dehydration, starvation (including preoperative fasting), acute medical illness, frailty, chronic diseases or even severe psychological stress (***Figure 1.7***). Attempts to limit or control these factors can also be beneficial to the patient.

Summary box 1.8

Avoidable factors that compound the metabolic response to injury during elective surgery

- Continuing haemorrhage/volume loss
- Hypothermia
- Tissue oedema
- Tissue underperfusion
- Starvation
- Immobility

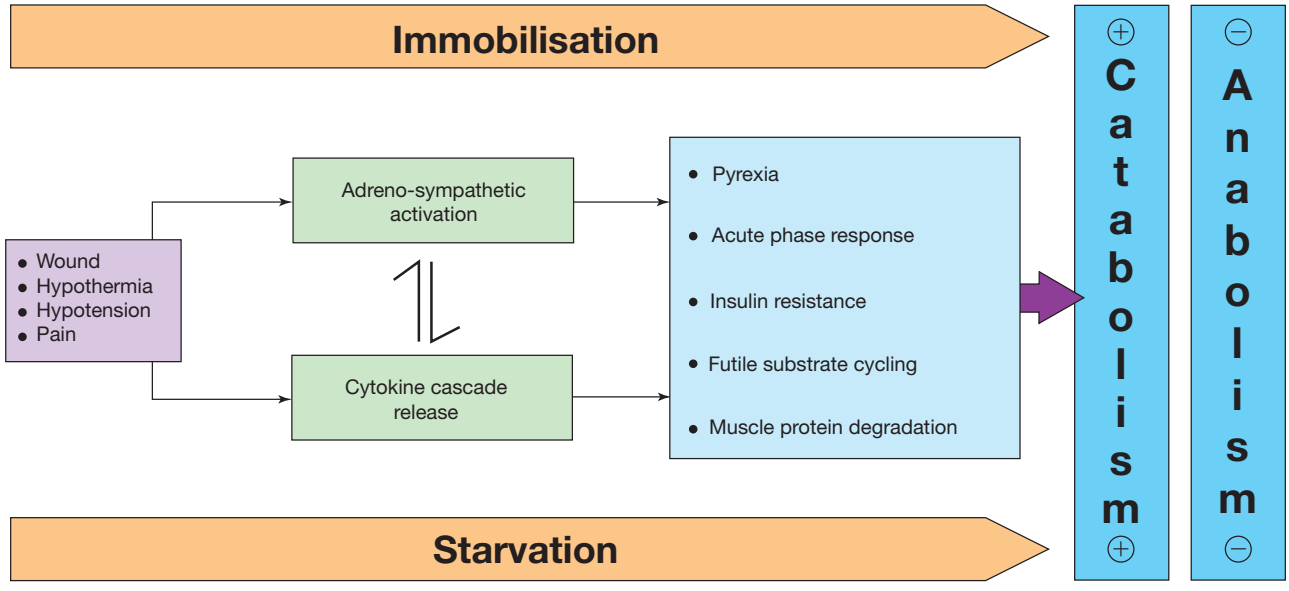

Figure 1.7 Factors that exacerbate the metabolic response to surgical injury include hypothermia, uncontrolled pain, starvation, immobilisation, sepsis and medical complications.

Volume loss

During simple haemorrhage, baroreceptors in the carotid artery and aortic arch and volume receptors in the wall of the left atrium initiate afferent nerve input to the central nervous system, resulting in the release of both aldosterone and antidiuretic hormone (ADH). Pain can also stimulate ADH release. ADH acts directly on the kidney to cause fluid retention. Decreased pulse pressure stimulates the juxtaglomerular apparatus in the kidney and directly activates the renin–angiotensin system, which in turn increases aldosterone release.

Aldosterone causes the renal tubule to reabsorb sodium (and consequently conserve water). ACTH release also augments the aldosterone response. The net effects of ADH and aldosterone result in the natural oliguria observed after surgery and conservation of sodium and water in the extracellular space. The tendency towards water and salt retention is exacerbated by resuscitation with saline-rich fluids. Salt and water retention can result in not only peripheral oedema but also visceral oedema (e.g. in the stomach). Such visceral oedema has been associated with reduced gastric emptying, delayed resumption of food intake and prolonged hospital stay. Careful limitation of intraoperative administration of balanced crystalloids so that there is no net weight gain following elective surgery has been proven to reduce postoperative complications and length of stay.

Hypothermia

Hypothermia results in increased production of adrenal steroids and catecholamines. When compared with normothermic controls, even mild hypothermia results in a two- to threefold increase in postoperative cardiac arrhythmias and increased catabolism. Randomised trials have shown that maintaining normothermia during surgery by an upper body forced-air heating cover reduces wound infections, cardiac complications and bleeding and transfusion requirements.

Tissue oedema

During systemic inflammation, fluid, plasma proteins, leukocytes, macrophages and electrolytes leave the vascular space and accumulate in the tissues as oedema. The oedema can diminish the alveolar diffusion of oxygen and may also impair renal function. Increased capillary leak is mediated by a wide variety of mediators, including cytokines, prostanoids, bradykinin and nitric oxide. Cellular hypoxia and dysfunction can occur. Intracellular volume decreases, and this provides part of the volume necessary to replenish intravascular and extravascular extracellular volume.

Systemic inflammation and tissue underperfusion

The vascular endothelium controls vasomotor tone and microvascular flow and regulates trafficking of nutrients and biologically active molecules. When endothelial activation is excessive, compromised microcirculation and subsequent cellular hypoxia contribute to the risk of organ failure. Controlling the blood sugar appropriately with insulin infusion during critical illness has been proposed to protect the endothelium, probably, in part, via inhibition of excessive iNOS-induced NO release.

Starvation

During starvation, the body is faced with an obligate need to generate glucose to sustain cerebral energy metabolism (100 g of glucose per day). This is achieved in the first 24 hours by mobilising glycogen stores and thereafter by hepatic gluconeogenesis from amino acids, glycerol and lactate. The energy metabolism of other tissues is sustained by mobilising fat from adipose tissue. Such fat mobilisation is mainly dependent on a fall in circulating insulin levels. Eventually, accelerated loss of

lean tissue (the main source of amino acids for hepatic gluconeogenesis) is reduced as a result of the liver converting free fatty acids into ketone bodies, which can serve as a substitute for glucose for cerebral energy metabolism. Provision of 2 litres of intravenous 4% dextrose/0.18% sodium chloride as maintenance intravenous fluids for surgical patients who are fasted provides 80 g of glucose per day and has a significant protein-sparing effect. Avoiding unnecessary fasting in the first instance and early oral/enteral/parenteral nutrition form the platform for avoiding loss of body mass as a result of the varying degrees of starvation observed in surgical patients. Modern guidelines on fasting prior to anaesthesia allow intake of clear fluids up to 2 hours before surgery. Administration of a carbohydrate drink at this time reduces perioperative anxiety and thirst and decreases postoperative insulin resistance.

Immobility

Immobility has long been recognised as a potent stimulus for inducing muscle wasting. Inactivity impairs the normal meal-derived amino acid stimulation of protein synthesis in skeletal muscle. Avoidance of unnecessary bed rest and active early mobilisation are essential measures to avoid muscle wasting as a consequence of immobility. Pre-habilitation programmes provide a better starting point before surgery.

ENHANCED RECOVERY AFTER SURGERY

Modern understanding of the metabolic response to surgical injury and the mediators involved has led to a complete reappraisal of traditional perioperative care and the process known as ERAS. ERAS is evidence based on the strong scientific rationale for avoiding unmodulated exposure to stress, prolonged fasting and excessive administration of intravenous (saline) fluids (***Figure 1.8***). ERAS principles are now applied by protocol to many types of major surgery, bringing considerable benefit in terms of improved outcomes. Reductions in length of hospital stay after surgery of 30–50% are common, with associated savings in healthcare costs. ERAS depends on a multimodal approach where the combined effects of several interventions achieve significant benefits. The widespread adoption of minimal access (e.g. laparoscopic) surgery is a key change in surgical practice that can reduce the magnitude of surgical injury and enhance the rate of patients' return to homeostasis and recovery. Modulating the stress/inflammatory response at the time of surgery may have long-term sequelae over periods of months or longer. For example, β-blockers are associated with improved short- and long-term survival after major surgery, perhaps by modulating the effects of the hyperadrenergic state induced by surgical stress. Equally, in 'open' surgery the use of epidural analgesia to reduce pain, block the cortisol stress response and attenuate postoperative insulin resistance may, via effects on the body's protein economy, favourably affect many of the patient-centred outcomes that are important to postoperative recovery. However, because of the reduction in wound size and tissue trauma, it should be noted that epidural analgesia is no longer recommended for laparoscopic surgery. Patient-controlled analgesia is usually sufficient and avoids the fluid shifts and hypotension seen with epidurals. Adjuncts such as 'one-shot' spinal diamorphine and/or a 6–12-hour infusion of intravenous lidocaine have been suggested to be opiate sparing, to improve gut function and to enhance overall recovery.

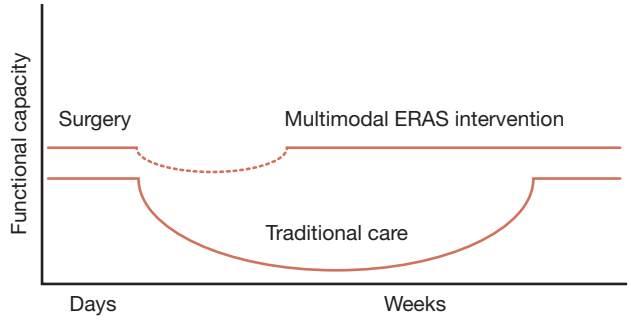

Figure 1.8 Enhanced recovery after surgery (ERAS) programmes use multimodal techniques to limit pain, fluid shifts and tissue damage and to enhance nutrition and rehabilitation in order to minimise the stress response. They have been hugely successful in improving outcomes.

Summary box 1.9

A proactive ERAS approach to prevent unnecessary aspects of the surgical stress response

- Minimal access techniques
- Blockade of afferent painful stimuli (e.g. epidural analgesia, spinal analgesia, wound catheters)
- Minimal periods of starvation
- Early mobilisation

PART 1 | Basic principles

CHAPTER 2

Shock, haemorrhage and transfusion

Learning objectives

To understand:

- The pathophysiology of shock
- The different patterns of shock and the principles and priorities of resuscitation
- Appropriate monitoring and end points of resuscitation
- Recognition and management of bleeding
- Use of blood and blood products, the benefits and risks of blood transfusion

INTRODUCTION

Shock is the most common cause of death of surgical patients. Death may occur rapidly because of a profound state of shock or may occur later because of the consequences of organ ischaemia and reperfusion injury. It is important therefore that every surgeon understands the pathophysiology, diagnosis and priorities in management of shock and haemorrhage.

SHOCK

Shock is a systemic state of low tissue perfusion that is inadequate for normal cellular respiration. With insufficient delivery of oxygen and glucose, cells switch from aerobic to anaerobic metabolism. If perfusion is not restored in a timely fashion, cell death ensues.

Pathophysiology

Cellular

As perfusion to the tissues is reduced, cells are deprived of oxygen and must switch from aerobic to anaerobic metabolism. The product of anaerobic respiration is not carbon dioxide but lactic acid. When enough tissue is underperfused the accumulation of lactic acid in the blood produces a systemic metabolic acidosis.

As glucose within cells is exhausted, anaerobic respiration ceases and there is failure of sodium/potassium pumps in the cell membrane and intracellular organelles. Intracellular lysosomes release autodigestive enzymes and cell lysis ensues. Intracellular contents, including potassium, are released into the bloodstream.

Microvascular

As tissue ischaemia progresses, changes in the local milieu result in activation of the immune and coagulation systems. Hypoxia and acidosis activate complement and prime leukocytes, resulting in the generation of oxygen free radicals and cytokine release. These mechanisms lead to injury of the capillary endothelial cells. These, in turn, further activate the immune and coagulation systems. Damaged endothelium loses its integrity and becomes 'leaky'. Spaces between endothelial cells allow fluid to leak out and tissue oedema ensues, exacerbating cellular hypoxia.

Ischaemic cell death releases potassium into the circulation, leading to systemic hyperkalaemia and acidosis, as well as further damage to molecules that systemically activate the immune system.

Systemic

Cardiovascular

As preload and afterload decrease, there is a compensatory baroreceptor response, resulting in increased sympathetic activity and release of catecholamines into the circulation. This results in tachycardia and systemic vasoconstriction (except in sepsis – see ***Distributive shock***).

Respiratory

The metabolic acidosis and increased sympathetic response result in an increased respiratory rate and minute ventilation to increase the excretion of carbon dioxide (and so produce a compensatory respiratory alkalosis).

Renal

Decreased perfusion pressure in the kidney leads to reduced filtration at the glomerulus and a decreased urine output. The renin–angiotensin–aldosterone axis is stimulated, resulting in further vasoconstriction and increased sodium and water reabsorption by the kidney.

Endocrine

As well as activation of the adrenal and renin–angiotensin systems, vasopressin (antidiuretic hormone) is released in

response to decreased preload and results in vasoconstriction and resorption of water in the renal collecting system. Cortisol is also released from the adrenal cortex, contributing to the sodium and water resorption and sensitising cells to catecholamines.

Classification of shock

There are numerous ways to classify shock, but the most common and most clinically applicable is one based on the initiating mechanism. All states are characterised by systemic tissue hypoperfusion, and different states may coexist within the same patient.

Summary box 2.1

Classification of shock

- Haemorrhagic/hypovolaemic shock
- Cardiogenic shock
- Obstructive shock
- Distributive shock
- Endocrine shock

Haemorrhagic and hypovolaemic shock

Hypovolaemic shock is due to a reduced circulating volume. Hypovolaemia may be due to haemorrhagic or non-haemorrhagic causes. Non-haemorrhagic causes include poor fluid intake (dehydration), excessive fluid loss due to vomiting, diarrhoea, urinary loss (e.g. diabetes), evaporation or 'third-spacing', where fluid is lost into the gastrointestinal tract and interstitial spaces, as for example in bowel obstruction or pancreatitis.

Hypovolaemia is the most common form of shock, and to some degree is a component of all other forms of shock. Absolute or relative hypovolaemia must be excluded or treated in the management of the shocked state, regardless of cause.

Cardiogenic shock

Cardiogenic shock is due to primary failure of the heart to pump blood to the tissues. Causes of cardiogenic shock include myocardial infarction, cardiac dysrhythmias, valvular heart disease, blunt myocardial injury and cardiomyopathy. Cardiac insufficiency may also be due to myocardial depression caused by endogenous factors (e.g. bacterial and humoral agents released in sepsis) or exogenous factors, such as pharmaceutical agents or drug abuse. Evidence of venous hypertension with pulmonary or systemic oedema may coexist with the classical signs of shock.

Obstructive shock

In obstructive shock there is a reduction in preload owing to mechanical obstruction of cardiac filling. Common causes of obstructive shock include cardiac tamponade, tension pneumothorax, massive pulmonary embolus or air embolus. In each case, there is reduced filling of the left and/or right sides of the heart, leading to low cardiac output.

Distributive shock

Distributive shock describes the pattern of cardiovascular responses characterising a variety of conditions, including septic shock, anaphylaxis and spinal cord injury. Inadequate organ perfusion is accompanied by vascular dilatation with hypotension, low systemic vascular resistance, inadequate afterload and a resulting abnormally high cardiac output.

In anaphylaxis, vasodilatation is due to histamine release, while in high spinal cord injury there is failure of sympathetic outflow and adequate vascular tone (neurogenic shock). The cause in sepsis is less clear but is related to the release of bacterial products (endotoxin) and the activation of cellular and humoral components of the immune system. There is maldistribution of blood flow at a microvascular level, with arteriovenous shunting and dysfunction of cellular utilisation of oxygen.

In the later phases of septic shock there is hypovolaemia from fluid loss into interstitial spaces and there may be concomitant myocardial depression, complicating the clinical picture (*Table 2.1*).

Endocrine shock

Endocrine shock may present as a combination of hypovolaemic, cardiogenic or distributive shock. Causes of endocrine shock include hypo- and hyperthyroidism and adrenal insufficiency. Hypothyroidism causes a shock state similar to that of neurogenic shock due to disordered vascular and cardiac responsiveness to circulating catecholamines. Cardiac output falls as a result of low inotropy and bradycardia. There may also be an associated cardiomyopathy. Thyrotoxicosis may cause a high-output cardiac failure.

Adrenal insufficiency leads to shock due to hypovolaemia and a poor response to circulating and exogenous

TABLE 2.1 Cardiovascular and metabolic characteristics of shock.

	Hypovolaemic	Cardiogenic	Obstructive	Distributive
Cardiac output	Low	Low	Low	High
Systemic vascular resistance	High	High	High	Low
Venous pressure	Low	High	High	Low
Mixed venous saturation	Low	Low	Low	High
Base deficit	High	High	High	High

catecholamines. Adrenal insufficiency may be due to pre-existing Addison's disease or be a relative insufficiency due to a pathological disease state, such as systemic sepsis.

Clinical consequences of shock

Unresuscitatable shock

Patients who are in profound shock for a prolonged period of time become 'unresuscitatable'. Cell death follows from cellular ischaemia and the ability of the body to compensate is lost. In the heart there is myocardial cell death from poor coronary perfusion and myocardial depression from severe acidaemia and hyperkalaemia. This leads to poor cardiac output and limited response to fluids or inotropic therapy. Peripherally there may also be loss of the ability to maintain systemic vascular resistance and further hypotension ensues. The peripheries no longer respond appropriately to vasopressor agents. Once patients enter this stage of systemic ischaemic injury, death is inevitable.

Ischaemia–reperfusion and the systemic inflammatory response syndrome (SIRS)

During the period of systemic hypoperfusion, cellular and organ damage progresses owing to the direct effects of tissue hypoxia and local activation of inflammation. Further injury occurs once normal circulation is restored to these tissues. The acid and potassium load that has built up can lead to direct myocardial depression, vascular dilatation and further hypotension. Molecules released from the interior of cells are released into the circulation. These are sensed by and activate leukocytes. These, together with cellular and humoral elements activated by the hypoxia (complement, neutrophils, microvascular thrombi), overwhelm the local anti-inflammatory response and are flushed back into the systemic circulation, where they cause injury to distant organs such as the lungs and the kidneys. This leads to acute lung injury, acute renal injury, cerebral oedema, multiple organ failure and death. Reperfusion injury can currently only be attenuated by reducing the extent and duration of tissue hypoperfusion.

Multiple organ failure

As techniques of resuscitation have improved, more and more patients are surviving shock. Where intervention is timely and the period of shock is limited, patients may make a rapid, uncomplicated recovery. However, the result of prolonged systemic ischaemia and reperfusion injury is end-organ damage and multiple organ failure.

Multiple organ failure is defined as two or more failed organ systems. There is no specific treatment for multiple organ failure. Management is support of organ systems, with ventilation, cardiovascular support and haemofiltration/dialysis until there is recovery of organ function. Multiple organ failure currently carries a mortality of 60%; thus, prevention is vital by early aggressive identification and reversal of shock.

Summary box 2.2

Effects of organ failure

- Cardiac: Cardiovascular failure
- Lung: Acute respiratory distress syndrome
- Kidney: Acute renal insufficiency
- Liver: Liver failure and coagulopathy
- Brain: Cerebral swelling and dysfunction

Recognition and diagnosis of shock

Shock may be profound and easily recognised or it may be subtle and only diagnosed with directed clinical examination and cardiovascular and metabolic monitoring.

Compensated shock

As shock progresses, the body's cardiovascular and endocrine compensatory responses reduce flow to non-essential organs to preserve preload and flow to the lungs and brain. In compensated shock, there is adequate cardiovascular compensation to maintain central blood volume and preserve flow to the kidneys, lungs and brain. Apart from a tachycardia and cool peripheries (vasoconstriction, circulating catecholamines), there may be no other clinical signs of hypovolaemia.

However, this cardiovascular state is only maintained by reducing perfusion to the skin, muscle and gastrointestinal tract. These organs are underperfused: their cells are respiring anaerobically and sustaining ischaemic damage. There is systemic metabolic acidosis and both local and systemic activation of humoral and cellular inflammation.

Although clinically occult, this state will lead to multiple organ failure and death if prolonged. Patients with occult hypoperfusion (metabolic acidosis despite normal urine output and cardiorespiratory vital signs) for more than 12 hours have a significantly higher mortality, infection rate and incidence of multiple organ failure (see *Multiple organ failure*).

Decompensation

Further loss of circulating volume overloads the body's compensatory mechanisms and there is progressive renal, respiratory and cardiovascular decompensation. In general, loss of around 15% of the circulating blood volume is within normal compensatory mechanisms. Blood pressure is usually well maintained and only falls after 30–40% of circulating volume has been lost.

Mild (compensated) shock

Initially there is tachycardia, tachypnoea, a mild reduction in urine output and the patient may exhibit mild anxiety. Blood pressure is maintained, although there is a decrease in pulse pressure. The peripheries are cool and sweaty with prolonged capillary refill times (except in septic distributive shock).

Thomas Addison, 1799–1860, physician, Guy's Hospital, London, UK, described the effects of disease of the suprarenal capsules in 1849.

TABLE 2.2 Clinical features of shock.

	Compensated	Uncompensated	
	Mild	Moderate	Severe
Lactic acidosis	+	++	+++
Urine output	Normal	Reduced	Anuric
Conscious level	Mild anxiety	Drowsy	Comatose
Respiratory rate	Increased	Increased	Laboured
Pulse rate	Increased	Increased	Increased
Blood pressure	Normal	Mild hypotension	Severe hypotension

Moderate shock

As shock progresses, renal compensatory mechanisms fail, renal perfusion falls and urine output dips below 0.5 mL/kg/hour. There is further tachycardia, and now the blood pressure starts to fall. Patients become drowsy and mildly confused.

Severe shock

In severe shock, there is profound tachycardia and hypotension. Urine output falls to zero and patients are unconscious with laboured respiration.

Clinical features

The classic cardiovascular responses described (***Table 2.2***) are not seen in every patient. It is important to recognise the limitations of the clinical examination and to recognise patients who are in shock despite the absence of classic signs.

Capillary refill

Most patients in hypovolaemic shock will have cool, pale peripheries, with prolonged capillary refill times. However, the actual capillary refill time varies so much in adults that it is not a specific marker of whether a patient is shocked, and patients with short capillary refill times may be in the early stages of shock. In distributive (septic) shock, the peripheries will be warm and capillary refill will be brisk, despite profound shock.

Tachycardia

Tachycardia may not always accompany shock. Patients who are on β-blockers or who have implanted pacemakers are unable to mount a tachycardia. A pulse rate of 80 in a fit young adult who normally has a pulse rate of 50 is very abnormal. Furthermore, in some young patients with penetrating trauma, where there is haemorrhage but little tissue damage, there may be a paradoxical bradycardia rather than tachycardia accompanying the shocked state.

Blood pressure

It is important to recognise that hypotension is one of the last signs of shock. Children and fit young adults are able to maintain blood pressure until the final stages of shock by dramatic increases in stroke volume and peripheral vasoconstriction. These patients can be in profound shock with a normal blood pressure.

Elderly patients who are normally hypertensive may present with a 'normal' blood pressure for the general population but be hypovolaemic and hypotensive relative to their usual blood pressure. β-blockers or other medications may prevent a tachycardic response. The diagnosis of shock may be difficult unless one is alert to these pitfalls.

HAEMORRHAGE

Uncontrolled bleeding will lead to a hypovolaemic shock state, or haemorrhagic shock. While haemorrhage and shock often coexist, they are not the same. Patients who are actively bleeding may not yet be in shock. Conversely, patients may be in shock as a consequence of haemorrhage, but they may no longer be actively bleeding.

Resuscitation is very different if patients are actively bleeding or if they are not bleeding. In patients who are bleeding, the priority is to stop bleeding. In patients who are not bleeding, the priority shifts to normalising end-organ perfusion (correcting the shock state). Thus it is vital to recognise patients who are actively bleeding, and this is different from recognising that a patient is in shock.

Haemorrhage must be recognised and managed rapidly and decisively to reduce the severity and duration of shock. Haemorrhage is treated by arresting the bleeding – not by fluid resuscitation or blood transfusion. Although necessary as supportive measures to maintain organ (especially cardiac) perfusion, repeated volume resuscitation of patients who have ongoing haemorrhage will lead to physiological exhaustion (profound coagulopathy, acidosis and hypothermia) and subsequently death.

Pathophysiology

In trauma and surgery, the combination of tissue trauma and hypovolaemic shock leads to the development of an endogenous coagulopathy called acute traumatic coagulopathy (ATC). Up to 25% of all trauma patients develop ATC within minutes of injury and it is associated with a fourfold increase in mortality. ATC is characterised by systemic hyperfibrinolysis, low fibrinogen levels and platelet dysfunction.

ATC evolves into a more complex, multifactorial 'trauma-induced coagulopathy' owing to further derangements induced by resuscitation (***Figure 2.1***). Fluid and red blood cell transfusions lead to dilution of coagulation factors, which worsens the pre-existing coagulopathy. Underperfused muscle is unable to generate heat and hypothermia ensues, again worsened by cold fluid or blood transfusion. Further heat is lost by opening

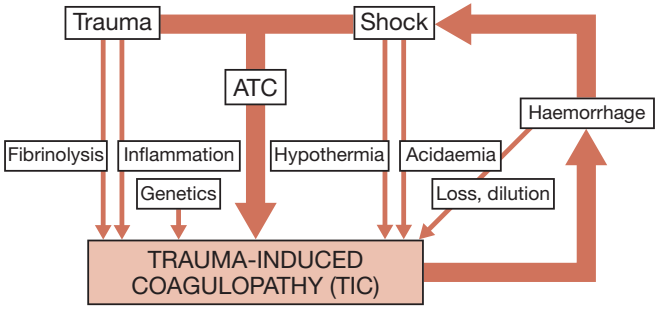

Figure 2.1 Trauma-induced coagulopathy. ATC, acute traumatic coagulopathy.

body cavities during surgery. Severe acidosis and hypothermia both inhibit coagulation proteases and reduce coagulation function. These then lead to further bleeding and a downward spiral, leading to physiological exhaustion and death.

Definitions

Revealed and concealed haemorrhage

Haemorrhage may be revealed or concealed. Revealed haemorrhage is obvious external haemorrhage, such as exsanguination from an open arterial wound or from massive haematemesis from a duodenal ulcer.

Concealed haemorrhage is contained within the body cavity and must be suspected, actively investigated and controlled. In trauma, haemorrhage may be concealed within the chest, abdomen, pelvis, retroperitoneum or in the limbs with contained vascular injury or associated with long-bone fractures. Examples of non-traumatic concealed haemorrhage include occult gastrointestinal bleeding or ruptured aortic aneurysm.

Primary, reactionary and secondary haemorrhage

Primary haemorrhage is haemorrhage occurring immediately as a result of an injury (or surgery).

Reactionary haemorrhage is delayed haemorrhage (within 24 hours) and is usually due to dislodgement of a clot by resuscitation, normalisation of blood pressure and vasodilatation. Reactionary haemorrhage may also be due to technical failure, such as slippage of a ligature.

Secondary haemorrhage is due to sloughing of the wall of a vessel. It usually occurs 7–14 days after injury and is precipitated by factors such as infection, pressure necrosis (such as from a drain) or malignancy.

Surgical and non-surgical haemorrhage

Surgical haemorrhage is due to a direct injury and is amenable to surgical control (e.g. suture ligation) or other techniques such as angioembolisation.

Non-surgical haemorrhage is general bleeding from raw surfaces and mucous membranes due to coagulopathy and cannot be stopped by surgical means (except packing). Treatment requires correction of the coagulation abnormalities.

Diagnosis of active bleeding: response to fluid therapy

The mode of resuscitation is determined by whether patients are actively bleeding, which requires a dynamic assessment of the blood pressure response to volume infusion. Patients who are 'non-responders' or 'transient responders' are still bleeding and must have the site of haemorrhage identified and controlled.

Responder

There is a good and sustained improvement in blood pressure in response to a bolus transfusion.

Transient responder

There is an improvement in the blood pressure but this is not sustained. The rate of haemorrhage is less than the rate of volume administration.

Non-responder

There is no improvement in the blood pressure to a bolus transfusion. The rate of haemorrhage is greater than the rate of volume administration.

Degree of haemorrhage and classification

The adult human has approximately 5 litres of blood (70 mL/kg for children and adults, 80 mL/kg for neonates). Estimation of the amount of blood that has been lost is difficult, inaccurate and usually underestimates the actual value.

External haemorrhage is obvious, but it may be difficult to estimate the actual volume lost. In the operating theatre, blood collected in suction apparatus can be measured and swabs soaked in blood weighed.

The haemoglobin level is a poor indicator of the degree of haemorrhage because it represents a concentration and not an absolute amount. In the early stages of rapid haemorrhage, the haemoglobin concentration is unchanged (as whole blood is lost). Later, as fluid shifts from the intracellular and interstitial spaces into the vascular compartment, the haemoglobin and haematocrit levels will fall.

TABLE 2.3 Traditional classification of haemorrhagic shock.

	Class			
	1	2	3	4
Blood volume lost as percentage of total	<15%	15–30%	30–40%	>40%

The amount of haemorrhage is historically classified into classes 1–4 based on the estimated blood loss required to produce certain physiological compensatory changes (*Table 2.3*). Although conceptually useful, this classification system is never applied clinically, and indeed is difficult if not impossible to determine. There is variation in clinical response across ages (the young compensate well, the old very poorly), variation among individuals (e.g. athletes versus the obese) and variation owing to confounding factors (e.g. concomitant medications, pain).

HAEMORRHAGE RESUSCITATION

The conduct and goals of resuscitation change depending on whether the patient is actively bleeding. In this case, the resuscitation focuses on achieving rapid haemostasis and maintaining the ability of the blood to clot. This paradigm is called damage control resuscitation (see *Damage control resuscitation*).

If the patient is not actively bleeding, has stopped bleeding or the cause of shock is not haemorrhage, then resuscitation is directed at correcting the shock state and restoring perfusion to end organs.

Identify haemorrhage

External haemorrhage may be obvious, but the diagnosis of concealed haemorrhage may be more difficult. Any shock should be assumed to be hypovolaemic until proven otherwise and, similarly, hypovolaemia should be assumed to be due to haemorrhage until this has been excluded.

Once haemorrhage has been identified, the institution's major haemorrhage protocol should be activated, which will specify the approach to damage control resuscitation. Immediate resuscitative measures include the assessment of airway and breathing and control of life-threatening issues as necessary. Large-bore intravenous access should be instituted and blood drawn for cross-matching (see *Cross-matching*). Transfusion should start with emergency (type O) blood (see *Transfusion*).

Once haemorrhage has been considered, the site of haemorrhage must be rapidly identified. Note that this is not to identify the exact location definitively, but rather to define the next step in haemorrhage control (operation, angioembolisation, endoscopic control). Clues may be in the history (previous episodes, known aneurysm, non-steroidal therapy for gastrointestinal bleeding) or examination (nature of blood – fresh, melaena; abdominal tenderness, etc.). For shocked trauma patients, the external signs of injury may suggest internal haemorrhage, but haemorrhage into a body cavity (thorax, abdomen) must be excluded with rapid investigations (chest and pelvis radiographs, abdominal ultrasound).

Investigations for blood loss must be appropriate to the patient's physiological condition. Rapid bedside tests such as ultrasound are more appropriate for profound shock and exsanguinating haemorrhage than investigations such as computed tomography. Patients who are not actively bleeding can have a more methodical, definitive work-up.

Damage control resuscitation

Damage control resuscitation (DCR), also known as haemostatic resuscitation, is a paradigm that prioritises haemorrhage control in patients who are still actively bleeding. The rationale is that no aspect of the shock state – end-organ perfusion, blood pressure, temperature, lactic acidosis – can be corrected

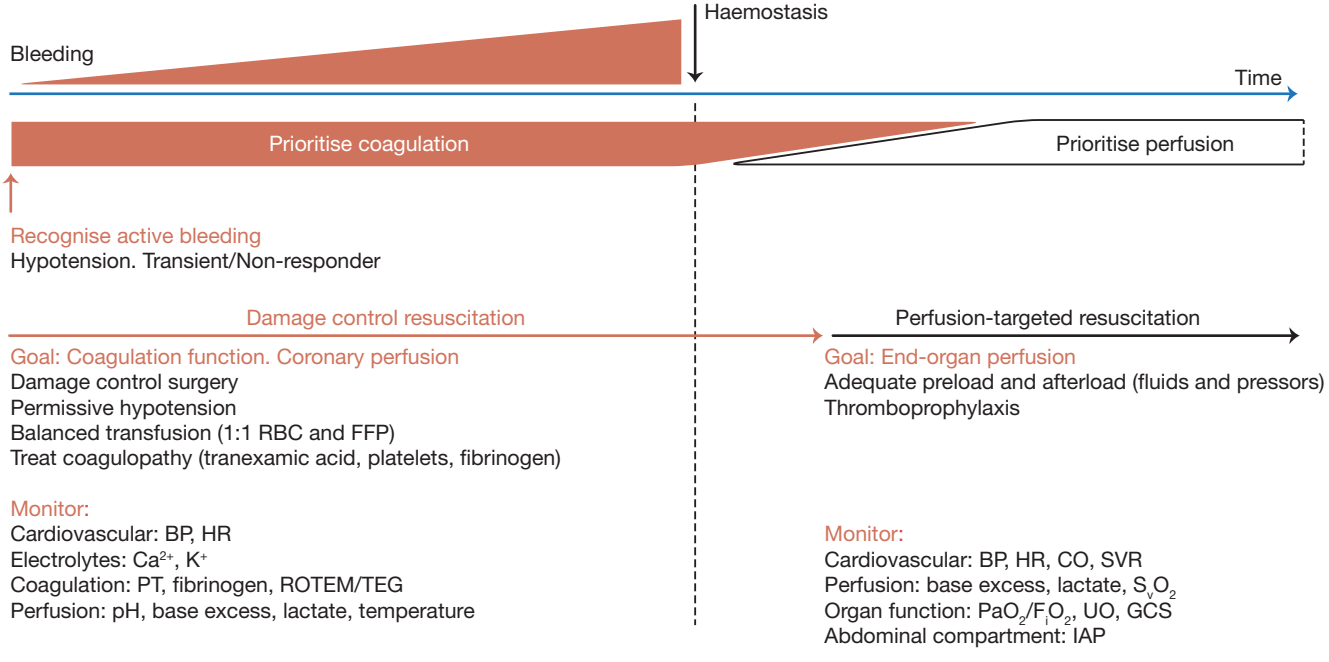

Figure 2.2 Haemorrhage resuscitation. BP, blood pressure; CO, cardiac output; FFP, fresh-frozen plasma; F_iO_2, fraction of inspired oxygen; GCS, Glasgow Coma Scale score; HR, heart rate; IAP, intra-abdominal pressure; PaO_2, arterial oxygen tension; PT, prothrombin time; RBC, red blood cells; ROTEM, rotational thromboelastometry; SVR, systemic vascular resistance; S_vO_2, mixed venous oxygen saturation; TEG, thromboelastography; UO, urine output.

while patients are bleeding, and repeated cycles of volume resuscitation will exacerbate coagulopathy, hypothermia and metabolic derangements (acidosis, hyperkalaemia, hypocalcaemia). The introduction of DCR has been associated with substantial reductions in mortality from haemorrhagic shock in the last decade.

DCR applies only while patients are bleeding and is based on four key principles – rapid haemorrhage control; permissive hypotension; avoiding dilutional coagulopathy; and treating existing coagulation deficits (***Figure 2.2***).

Rapid haemorrhage control

At all times, control of bleeding is the priority. Direct pressure should be placed over the site of external haemorrhage. Temporary bleeding control should be achieved with tourniquets, balloon occlusion or other techniques. Intracavitary haemorrhage should be suspected and searched for, and the pathway should actively move patients forwards to the operating theatre or interventional radiology room to achieve this.

The damage control approach is extended to the conduct of surgery to prioritise rapid bleeding control. In damage control surgery, surgical intervention is limited to the minimum necessary to stop bleeding and control sepsis, in order to avoid additional tissue damage, bleeding and physiological stress. More definitive repairs can be delayed until the patient is haemodynamically stable and physiologically capable of sustaining the procedure. Thus the operation is tailored to match the patient's physiology, and is not focused on reconstructing anatomy. 'Damage control' is a term borrowed from the military: it ensures continued functioning of a damaged ship above conducting complete repairs, which would prevent rapid return to battle.

Summary box 2.3

Damage control surgery

- Arrest haemorrhage
- Control sepsis
- Protect from further injury
- Nothing else

Permissive hypotension

Permissive hypotension allows the patient to set their own blood pressure while bleeding and avoids continued volume resuscitation in the vain attempt to normalise perfusion while bleeding. This reduces blood loss from bleeding sites and reduces dilutional coagulopathy and hypothermia induced by fluids. It is important to maintain baseline perfusion of the coronary arteries at minimum, and thus a palpable central pulse (mean arterial pressure above ~50 mmHg) must be maintained by whatever means are available.

Avoid dilutional coagulopathy

Avoid dilutional coagulopathy by avoiding clear fluids (crystalloids or colloids) and by giving a transfusion that approximates whole blood – usually administered as equal volumes of packed red blood cells and plasma.

Treat existing coagulation deficits

Treat existing coagulopathies either empirically or by regular coagulation testing and acting on the results. Tranexamic acid should be given as soon as possible in almost all bleeding patients to stop hyperfibrinolysis. Blood component concentrates should be given to correct existing deficits, such as cryoprecipitate for low fibrinogen levels or platelet transfusions for platelet dysfunctions.

After haemorrhage control

Once haemorrhage is controlled, patients should be definitively resuscitated, warmed and have coagulopathy corrected. Attention should be paid to fluid responsiveness and the end points of resuscitation to ensure that patients are fully resuscitated and to reduce the incidence and severity of organ failure (***Figure 2.2*** and ***Shock resuscitation***).

SHOCK RESUSCITATION

Immediate resuscitation manoeuvres for patients presenting in shock are to ensure a patent airway and adequate oxygenation and ventilation. Once 'airway' and 'breathing' are assessed and controlled, attention is directed to cardiovascular resuscitation. Haemorrhagic shock resuscitation should proceed as damage control resuscitation while bleeding continues (as discussed earlier). After bleeding is controlled, and for all other causes, shock resuscitation is guided by measures of tissue perfusion, as described in ***Monitoring***.

Conduct of resuscitation

Resuscitation should not be delayed in order to definitively diagnose the source of the shocked state. However, the timing and nature of resuscitation will depend on the type of shock and the timing and severity of the insult. Rapid clinical examination will provide adequate clues to make an appropriate first determination, even if a source of bleeding or sepsis is not immediately identifiable. If there is initial doubt about the cause of shock, it is safer to assume the cause is hypovolaemia and begin with fluid resuscitation, and then assess the response.

Correction of shock is important in the pre- and perioperative period for all cases of urgent surgery. For example, a patient with bowel obstruction and hypovolaemic shock must be adequately resuscitated before undergoing surgery. If not, the additional surgical injury and hypovolaemia induced during the procedure will increase the physiological demand on the heart, increasing the risk of myocardial infarction; will exacerbate the inflammatory activation and thus the incidence and severity of organ damage (especially acute kidney injury); will increase susceptibility to infection and venous thromboembolism; and will prolong the period of gut dysfunction and overall recovery from surgery.

Fluid therapy

In all cases of shock, regardless of classification, hypovolaemia and inadequate preload must be addressed before other therapy is instituted. Administration of inotropic or chronotropic agents to an empty heart will rapidly and permanently deplete the myocardium of oxygen stores and dramatically reduce diastolic filling and therefore coronary perfusion. Correction of preload by ensuring adequate volume resuscitation should be prioritised before introducing vasopressors or inotropic agents.

First-line therapy, therefore, is intravenous access and administration of intravenous fluids. Access should be through short, wide-bore catheters that allow rapid infusion of fluids as necessary. Long, narrow lines, such as central venous catheters, have too high a resistance to allow rapid infusion and are more appropriate for monitoring than fluid replacement therapy.

Type of fluids

As a general rule, the ideal replacement fluid is one that approximates the fluid lost by the underlying cause of shock. If blood is being lost, the replacement fluid is whole blood or its equivalent in components – although crystalloid therapy may be required while awaiting blood products. Other causes of shock will require crystalloid resuscitation with appropriate electrolyte supplementation.

In most studies of shock resuscitation there is no overt difference in response or outcome between crystalloid solutions (normal saline, Hartmann's solution, Ringer's lactate) and colloids (albumin or commercially available products). Furthermore, there is less volume benefit to the administration of colloids than had previously been thought, with only 1.3 times more crystalloid than colloid administered in blinded trials. On balance, there is little evidence to support the administration of colloids, which are more expensive and have worse side-effect profiles.

Hypotonic solutions (e.g. dextrose) are poor volume expanders and should not be used in the treatment of shock unless the deficit is free water loss (e.g. diabetes insipidus) or patients are sodium overloaded (e.g. cirrhosis).

Vasopressor and inotropic support

Vasopressor or inotropic therapy is not indicated as first-line therapy in hypovolaemia. Administration of these agents in the absence of adequate preload rapidly leads to decreased coronary perfusion and depletion of myocardial oxygen reserves.

Vasopressor agents (phenylephrine, noradrenaline [norepinephrine]) are indicated in distributive shock states (sepsis, neurogenic shock) where there is peripheral vasodilatation and a low systemic vascular resistance, leading to hypotension despite a high cardiac output. Where the vasodilatation is resistant to catecholamines (e.g. absolute or relative steroid deficiency), vasopressin may be used as an alternative vasopressor.

In cardiogenic shock, or where myocardial depression has complicated a shock state (e.g. severe septic shock with low cardiac output), inotropic therapy may be required to increase cardiac output and therefore oxygen delivery. The inodilator dobutamine is the agent of choice.

Monitoring

The **minimum** standard for monitoring of the patient in shock is continuous heart rate and oxygen saturation monitoring, frequent non-invasive blood pressure monitoring and hourly urine output measurements. Most patients will need more aggressive invasive monitoring, including central venous pressure (CVP) and invasive blood pressure monitoring.

Summary box 2.4

Monitoring for patients in shock

Minimum	Additional modalities
• ECG	• Central venous pressure
• Pulse oximetry	• Invasive blood pressure
• Blood pressure	• Cardiac output
• Urine output	• Base deficit and serum lactate

Cardiovascular

Cardiovascular monitoring at minimum should include continuous heart rate (electrocardiogram, oxygen saturation and pulse waveform and non-invasive blood pressure). Patients whose state of shock is not rapidly corrected with a small amount of fluid should have CVP monitoring and continuous blood pressure monitoring through an arterial line.

Central venous pressure

There is no 'normal' CVP for a shocked patient, and reliance cannot be placed on an individual pressure measurement to assess volume status. Some patients may require a CVP of 5 cmH_2O, whereas some may require a CVP of 15 cmH_2O or higher. Further, ventricular compliance can change from minute to minute in the shocked state, and CVP is a poor reflection of end-diastolic volume (preload).

CVP measurements should be assessed dynamically as the response to a fluid challenge. A fluid bolus (250–500 mL) is infused rapidly over 5–10 minutes.

The normal CVP response is a rise of 2–5 cmH_2O, which gradually drifts back to the original level over 10–20 minutes. Patients with no change in their CVP are empty and require further fluid resuscitation. Patients with a large, sustained rise in CVP have high preload and an element of cardiac insufficiency or volume overload.

Alexis Frank Hartmann, 1898–1964, paediatrician, St Louis, MO, USA, described the solution; should not be confused with the name of Henri Albert Charles Antoine Hartmann, French surgeon, who described the operation that goes by his name.
Sidney Ringer, 1835–1910, Professor of Clinical Medicine, University College Hospital, London, UK.

Cardiac output

Cardiac output monitoring allows assessment of not only the cardiac output but also the systemic vascular resistance and, depending on the technique used, end-diastolic volume (preload) and blood volume. Use of invasive cardiac monitoring with pulmonary artery catheters is becoming less frequent as new non-invasive monitoring techniques, such as Doppler ultrasound, pulse waveform analysis and indicator dilution methods, provide similar information without many of the drawbacks of more invasive techniques.

Measurement of cardiac output, systemic vascular resistance and preload can help distinguish the types of shock present (hypovolaemia, distributive, cardiogenic), especially when they coexist. The information provided guides fluid and vasopressor therapy by providing real-time monitoring of the cardiovascular response.

Measurement of cardiac output is desirable in patients who do not respond as expected to first-line therapy or who have evidence of cardiogenic shock or myocardial dysfunction. Early consideration should be given to instituting cardiac output monitoring for patients who require vasopressor or inotropic support.

Systemic and organ perfusion

Ultimately, the goal of treatment is to restore cellular and organ perfusion. Ideally, therefore, monitoring of organ perfusion should guide the management of shock. The best measure of organ perfusion and the best monitor of the adequacy of shock therapy remains the urine output. However, this is an hourly measure and does not give a minute-to-minute view of the shocked state. The level of consciousness is an important marker of cerebral perfusion, but brain perfusion is maintained until the very late stages of shock and hence is a poor marker of adequacy of resuscitation (***Table 2.4***).

Currently, the only clinical indicators of perfusion of the gastrointestinal tract and muscular beds are the global measures of lactic acidosis (lactate and base deficit) and the mixed venous oxygen saturation.

Base deficit and lactate

Lactic acid is generated by cells undergoing anaerobic respiration. The degree of lactic acidosis, as measured by serum lactate level and/or the base deficit, is sensitive for both diagnosis of shock and monitoring the response to therapy. Patients with a base deficit of more than 6 mmol/L have a much higher morbidity and mortality than those with no metabolic acidosis. Furthermore, the length of time in shock with an increased base deficit is important, even if all other vital signs have returned to normal (see occult hypoperfusion below under ***End points of resuscitation***).

These parameters are measured from arterial blood gas analyses, and therefore the frequency of measurements is limited and they do not provide minute-to-minute data on systemic perfusion or the response to therapy. Nevertheless, the base deficit and/or lactate should be measured routinely in these patients until they have returned to normal levels.

Mixed venous oxygen saturation

The percentage saturation of oxygen returning to the heart from the body is a measure of the oxygen delivery and extraction by the tissues. Accurate measurement is via analysis of blood drawn from a long central line placed in the right atrium. Estimations can be made from blood drawn from lines in the superior vena cava, but these values will be slightly higher than those of a mixed venous sample (as there is relatively more oxygen extraction from the lower half of the body). Normal mixed venous oxygen saturation levels are 50–70%. Levels below 50% indicate inadequate oxygen delivery and increased oxygen extraction by the cells. This is consistent with hypovolaemic or cardiogenic shock.

High mixed venous saturations (>70%) are seen in sepsis and some other forms of distributive shock. In sepsis, there is disordered utilisation of oxygen at the cellular level and

TABLE 2.4 Monitors for organ/systemic perfusion.

	Clinical	Investigational
Systemic perfusion		Base deficit
		Lactate
		Mixed venous oxygen saturation
Organ perfusion		
Muscle	–	Near-infrared spectroscopy
		Tissue oxygen electrode
Gut	–	Sublingual capnometry
		Gut mucosal pH
		Laser Doppler flowmetry
Kidney	Urine output	–
Brain	Conscious level	Tissue oxygen electrode
		Near-infrared spectroscopy

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the Doppler principle in 1842.

arteriovenous shunting of blood at the microvascular level. Therefore, less oxygen is presented to the cells, and those cells cannot utilise what little oxygen is presented. Thus, venous blood has a higher oxygen concentration than normal.

Patients who are septic should therefore have mixed venous oxygen saturations above 70%; below this level, they are not only in septic shock but also in hypovolaemic or cardiogenic shock. Although the S_vO_2 level is in the 'normal' range, it is low for the septic state, and inadequate oxygen is being supplied to cells that cannot utilise oxygen appropriately. This must be corrected rapidly. Hypovolaemia should be corrected with fluid therapy, and low cardiac output due to myocardial depression or failure should be treated with inotropes (dobutamine) to achieve a mixed venous saturation greater than 70% (normal for the septic state).

New methods for monitoring regional tissue perfusion and oxygenation are becoming available, the most promising of which are muscle tissue oxygen probes, near-infrared spectroscopy and sublingual capnometry. While these techniques provide information regarding perfusion of specific tissue beds, it is as yet unclear whether there are significant advantages over existing measurements of global hypoperfusion (base deficit, lactate).

End points of resuscitation

It is much easier to know when to start resuscitation than when to stop. Traditionally, patients have been resuscitated until they have a normal pulse, blood pressure and urine output. However, these parameters are monitoring organ systems whose blood flow is preserved until the late stages of shock. A patient therefore may be resuscitated to restore central perfusion to the brain, lungs and kidneys and yet continue to underperfuse the gut and muscle beds. Thus, activation of inflammation and coagulation may be ongoing and lead to reperfusion injury when these organs are finally perfused, and ultimately multiple organ failure.

This state of normal vital signs and continued underperfusion is termed 'occult hypoperfusion'. With current monitoring techniques, it is manifested only by a persistent lactic acidosis and low mixed venous oxygen saturation. The time spent by patients in this hypoperfused state has a dramatic effect on outcome. Patients with occult hypoperfusion for more than 12 hours have two to three times the mortality of patients with a limited duration of shock. Resuscitation algorithms directed at correcting global perfusion end points (base deficit, lactate, mixed venous oxygen saturation) rather than traditional end points have been shown to improve mortality and morbidity in high-risk surgical patients.

However, it is also clear that aggressive crystalloid resuscitation regimens can lead to tissue oedema and organ failure, especially acute respiratory distress syndrome, abdominal compartment syndrome and cerebral oedema. Some patients cannot be resuscitated to normal parameters within 12 hours by fluid resuscitation alone and care must be taken with all patients to be judicious in the approach to all therapies as end points are approached.

TRANSFUSION

The transfusion of blood and blood products has become commonplace since the first successful transfusion in 1818. Although the incidence of severe transfusion reactions and infections is now very low, in recent years it has become apparent that there is an immunological price to be paid for the transfusion of heterologous blood, leading to increased morbidity and decreased survival in certain population groups (trauma, malignancy). Supplies are also limited, and therefore the use of blood and blood products must always be judicious and justifiable for clinical need (*Table 2.5*).

TABLE 2.5 History of blood transfusion.

1492	Pope Innocent VIII suffers a stroke and receives a blood transfusion from three 10-year-old boys (paid a ducat each). All three boys died, as did the pope later that year
1665	Richard Lower in Oxford conducts the first successful canine transfusions
1667	Jean-Baptiste Denis reports successful sheep–human transfusions
1678	Animal–human transfusions are banned in France because of the poor results
1818	James Blundell performs the first successful documented human transfusion in a woman suffering postpartum haemorrhage. She received blood from her husband and survived
1901	Karl Landsteiner discovers the ABO system
1914	The Belgian physician Albert Hustin performed the first non-direct transfusion, using sodium citrate as an anticoagulant
1926	The British Red Cross instituted the first blood transfusion service in the world
1939	The rhesus system was identified and recognised as the major cause of transfusion reactions

Blood and blood products

Blood is collected from donors who have been previously screened before donating to exclude any donor whose blood may have the potential to harm the patient or to prevent possible harm that donating a unit of blood may have for the donor. In the UK, up to 450 mL of blood is drawn, a maximum of three times each year. Each unit is tested for evidence of hepatitis B, hepatitis C, human immunodeficiency virus (HIV)-1, HIV-2 and syphilis. Donations are leukodepleted as a precaution against variant Creutzfeldt–Jakob disease (this may also reduce the immunogenicity of the transfusion).

Karl Landsteiner, 1868–1943, Professor of Pathological Anatomy, University of Vienna, Austria. In 1909 he classified the human blood groups into A, B, AB and O. For this he was awarded the Nobel Prize in Physiology or Medicine in 1930.
Hans Gerhard Creutzfeldt, 1885–1946, neurologist, Kiel, Germany.
Alfons Maria Jakob, 1884–1931, neurologist, Hamburg, Germany.

The ABO and rhesus D blood groups are determined, as well as the presence of irregular red cell antibodies. The blood is then processed into subcomponents.

Whole blood

Whole blood is now rarely available in civilian practice because it has been seen as an inefficient use of the limited resource. However, whole blood transfusion has significant advantages over packed cells as it is coagulation factor rich and, if fresh, more metabolically active than stored blood.

Packed red cells

Packed red blood cells are spun-down and concentrated packs of red blood cells. Each unit is approximately 330 mL and has a haematocrit of 50–70%. Packed cells are stored in a SAG-M (saline–adenine–glucose–mannitol) solution to increase shelf life to 5 weeks at 2–6°C. (Older storage regimes included storage in CPD [citrate–phosphate–dextrose] solutions, which have a shelf life of 2–3 weeks.)

Fresh-frozen plasma

Fresh-frozen plasma (FFP) is rich in coagulation factors and is removed from fresh blood and stored at −40°C to −50°C with a 2-year shelf life. It is the first-line therapy in the treatment of coagulopathic haemorrhage (see ***Management of coagulopathy***). Rhesus D-positive FFP may be given to a rhesus D-negative woman, although it is possible for seroconversion to occur with large volumes owing to the presence of red cell fragments and Rh-D immunisation should be considered.

Cryoprecipitate

Cryoprecipitate is a supernatant precipitate of FFP and is rich in fibrinogen, factor VIII and factor XIII. It is stored at −30°C with a 2-year shelf life. It is given in low-fibrinogen states or factor VIII deficiency.

Platelets

Platelets are supplied as a pooled platelet concentrate and contain about 250×10^9/litre. Platelets are stored on a special agitator at 20–24°C and have a shelf life of only 5 days. Platelet transfusions are given to patients with thrombocytopenia or with platelet dysfunction who are bleeding or undergoing surgery.

Patients are increasingly presenting on antiplatelet therapy such as aspirin or clopidogrel for reduction of cardiovascular risk. Aspirin therapy rarely poses a problem but control of haemorrhage on the more potent platelet inhibitors can be extremely difficult. Patients on clopidogrel who are actively bleeding and undergoing major surgery may require almost continuous infusion of platelets during the course of the procedure. Arginine vasopressin or its analogues (DDAVP) have also been used in this patient group, although with limited success.

Prothrombin complex concentrates

Prothrombin complex concentrates are highly purified concentrates prepared from pooled plasma. They contain factors II, IX and X. Factor VII may be included or produced separately. It is indicated for the emergency reversal of anticoagulant (warfarin) therapy in uncontrolled haemorrhage.

Autologous blood

It is possible for patients undergoing elective surgery to pre-donate their own blood up to 3 weeks before surgery for re-transfusion during the operation. Similarly, during surgery blood can be collected in a cell saver, which washes and collects red blood cells that can then be returned to the patient.

Indications for blood transfusion

Blood transfusions should be avoided if possible, and many previous uses of blood and blood products are now no longer considered appropriate. The indications for blood transfusion are as follows:

- Acute blood loss, to replace circulating volume and maintain oxygen delivery;
- Perioperative anaemia, to ensure adequate oxygen delivery during the perioperative phase;
- Symptomatic chronic anaemia, without haemorrhage or impending surgery.

Transfusion trigger

Historically, patients were transfused to achieve a haemoglobin >10 g/dL. This has now been shown not only to be unnecessary but also to be associated with an increased morbidity and mortality compared with lower target values. A haemoglobin level of 6 g/dL is acceptable in patients who are not actively bleeding, those who are not about to undergo major surgery and those who are not symptomatic. There is some controversy as to the optimal haemoglobin level in some patient groups, such as those with cardiovascular disease, sepsis and traumatic brain injury. Although, conceptually, a higher haemoglobin level improves oxygen delivery, there is little clinical evidence at this stage to support higher levels in these groups (***Table 2.6***).

TABLE 2.6 Perioperative red blood cell transfusion criteria.

Haemoglobin level (g/dL)	Indications
<6	Probably will benefit from transfusion
6–8	Transfusion unlikely to be of benefit in the absence of bleeding or impending surgery
>8	No indication for transfusion in the absence of other risk factors

Blood groups and cross-matching

Human red cells have on their cell surface many different antigens. Two groups of antigens are of major importance in surgical practice – the ABO and rhesus systems.

ABO system

These proteins are strongly antigenic and are associated with naturally occurring antibodies in the serum. The system consists of three allelic genes – A, B and O – which control synthesis of enzymes that add carbohydrate residues to cell surface glycoproteins. A and B genes add specific residues while the O gene is an amorph and does not transform the glycoprotein.

TABLE 2.7 ABO blood group system.

Phenotype	Genotype	Antigens	Antibodies	Frequency (%)
O	OO	O	Anti-A, anti-B	46
A	AA or AO	A	Anti-B	42
B	BB or BO	B	Anti-A	9
AB	AB	AB	None	3

The system allows for six possible genotypes although there are only four phenotypes. Naturally occurring antibodies are found in the serum of those lacking the corresponding antigen (*Table 2.7*).

Blood group O is the universal donor type as it contains no antigens to provoke a reaction. Conversely, group AB individuals are 'universal recipients' and can receive any ABO blood type because they have no circulating antibodies.

Rhesus system

The rhesus D (Rh(D)) antigen is strongly antigenic and is present in approximately 85% of the population in the UK. Antibodies to the D antigen are not naturally present in the serum of the remaining 15% of individuals, but their formation may be stimulated by the transfusion of Rh-positive red cells or they may be acquired during delivery of a Rh(D)-positive baby.

Acquired antibodies are capable, during pregnancy, of crossing the placenta and, if present in a Rh(D)-negative mother, may cause severe haemolytic anaemia and even death (hydrops fetalis) in a Rh(D)-positive fetus *in utero*. The other minor blood group antigens may be associated with naturally occurring antibodies, or may stimulate the formation of antibodies on relatively rare occasions.

Transfusion reactions

If antibodies present in the recipient's serum are incompatible with the donor's cells, a transfusion reaction will result. This usually takes the form of an acute haemolytic reaction. Severe immune-related transfusion reactions due to ABO incompatibility result in potentially fatal complement-mediated intravascular haemolysis and multiple organ failure. Transfusion reactions from other antigen systems are usually milder and self-limiting.

Febrile transfusion reactions are non-haemolytic and are usually caused by a graft-versus-host-response from leukocytes in transfused components. Such reactions are associated with fever, chills or rigors. The blood transfusion should be stopped immediately. This form of transfusion reaction is rare with leukodepleted blood.

Cross-matching

To prevent transfusion reactions, all transfusions are preceded by ABO and rhesus typing of both donor and recipient blood to ensure compatibility. The recipient's serum is then mixed with the donor's cells to confirm ABO compatibility and to test for rhesus and any other blood group antigen–antibody reaction.

Full cross-matching of blood may take up to 45 minutes in most laboratories. In more urgent situations, 'type-specific' blood is provided; this is only ABO/rhesus matched and can be issued within 10–15 minutes. Where blood must be given in an emergency, group O (universal donor) blood is given (O– to females, O+ to males).

When blood transfusion is prescribed and blood is administered, it is essential that the correct patient receives the correct transfusion. Two healthcare personnel should check the patient's details against the prescription and the label of the donor blood. In addition, the donor blood serial number should also be checked against the issue slip for that patient. Provided these principles are strictly adhered to, the number of severe and fatal ABO incompatibility reactions can be minimised.

Complications of blood transfusion

Complications from blood transfusion can be categorised as those arising from a single transfusion and those related to massive transfusion.

Complications from a single transfusion

Complications from a single transfusion include:

- incompatibility haemolytic transfusion reaction;
- febrile transfusion reaction;
- allergic reaction;
- infection:
  - bacterial infection (usually due to faulty storage);
  - hepatitis;
  - HIV;
  - malaria;
- air embolism;
- thrombophlebitis;
- transfusion-related acute lung injury (usually from FFP).

Complications from massive transfusion

Complications from massive transfusion include:

- coagulopathy;
- hypocalcaemia;
- hyperkalaemia;
- hypokalaemia;
- hypothermia.

In addition, patients who receive repeated transfusions over long periods of time (e.g. patients with thalassaemia) may develop iron overload. (Each transfused unit of red blood cells contains approximately 250 mg of elemental iron.)

Management of coagulopathy

Correction of coagulopathy is not necessary if there is no active bleeding and haemorrhage is not anticipated (not due for surgery). However, coagulopathy will occur during major haemorrhage and should be anticipated and managed actively.

Prevention of dilutional coagulopathy is central to the damage control resuscitation of patients who are actively bleeding. This is the prime reason for delivering balanced transfusion regimes that deliver a resuscitation which approximates that of whole blood. In most practice this means delivering matched units of red blood cells, plasma and platelets in a 1:1:1 ratio. Crystalloids and colloids should be avoided if at all possible.

The balanced transfusion approach will not correct an established coagulopathy. Most bleeding patients are hyperfibrinolytic, and should be empirically given tranexamic acid, an antifibrinolytic agent, as quickly as possible.

Low fibrinogen levels are very common, and fibrinogen is vital to clot formation and stabilisation. Cryoprecipitate can be given empirically or guided by laboratory or point-of-care tests of clotting (e.g. thromboelastometry). Similarly platelet concentrates are given for low platelet counts or observed platelet dysfunction. Clotting function should be assayed frequently during haemorrhage and acted upon until bleeding has been controlled.

Blood substitutes

Blood substitutes are an attractive alternative to the costly process of donating, checking, storing and administering blood, especially given the immunogenic and potential infectious complications associated with transfusion.

There are several oxygen-carrying blood substitutes under investigation in experimental animal or early clinical trials. Blood substitutes are either biomimetic or abiotic. Biomimetic substitutes mimic the standard oxygen-carrying capacity of the blood and are haemoglobin based. Abiotic substitutes are synthetic oxygen carriers and are currently primarily perfluorocarbon based.

Haemoglobin is seen as the obvious candidate for developing an effective blood substitute, and one free haemoglobin solution is available in some countries where blood components are not readily available. Various other engineered molecules are under clinical trials and are based on human, bovine or recombinant technologies. Second-generation perfluorocarbon emulsions are also showing potential in clinical trials.

PART 1 | Basic principles

CHAPTER 3

Wound healing and tissue repair

Learning objectives

To understand:

- Normal wound healing and how it can be adversely affected
- Types of healing and how to classify wounds
- The principles of wound management
- The principles of scar management

INTRODUCTION

Wound healing is a complex and dynamic biological process. In human adults, the normal response to injury across all organ systems typically results in fibrosis and scar formation. Fibrotic healing causes tissue dysfunction and its potential impact on patients is often underappreciated. This contrasts with early gestation when fetal tissues can remarkably heal without fibrosis. Regenerative medicine is therefore an exciting field of research. A better understanding of the mechanisms involved can potentially help reduce the global burden of disease associated with wound healing. This chapter describes the pathophysiology of wound healing, the types of healing and how to classify wounds. Clinical judgement is crucial in managing wounds. A framework is provided to better understand the key principles of wound and scar management.

NORMAL WOUND HEALING IN SKIN

Classically, wound healing has been arbitrarily described in three overlapping but distinct stages, including inflammation, proliferation and remodelling (***Figure 3.1***). An additional stage, haemostasis, is often described as the immediate phase occurring before inflammation.

Haemostasis

Disruption of the vascular endothelium following injury causes vasoconstriction and exposure of the subendothelial extracellular matrix. This encourages platelets to adhere, activate and aggregate, resulting in a platelet plug, which also helps limit further blood loss.

Platelet adhesion results in their activation and release of granules. Alpha granules contain hundreds of proteins, including cytokines and growth factors; for example, transforming growth factor beta, platelet-derived growth factor, fibroblast growth factor, epidermal growth factor and vascular endothelial growth factor. These are involved in the deposition of extracellular matrix, chemotaxis, epithelialisation and the formation of new blood vessels (angiogenesis).

Platelet aggregation occurs once platelets become activated. At the same time, tissue factor at the site of injury initiates the coagulation cascade (***Figure 3.2***), resulting in the formation of thrombin. Thrombin performs various functions, including fibrin generation, which helps to stabilise the platelet plug and form a scaffold for infiltrating cells.

Inflammation

In the early inflammatory phase (days 1–2), platelet activation causes an influx of inflammatory cells led by polymorphonuclear leukocytes, particularly neutrophils. The latter are important for minimising bacterial contamination of the wound. Platelets and the local injured tissue also release vasoactive amines such as histamine and serotonin, which increase vascular permeability, thereby aiding infiltration of inflammatory cells.

During the late inflammatory phase (days 2–3) monocytes appear in the wound and differentiate into macrophages. Macrophages play a vital role in wound healing. They function as phagocytic cells and release proteolytic enzymes to help debride the wound. They are also the primary producer of cytokines and growth factors promoting fibroblast proliferation and angiogenesis.

Historically, this phase has been described by *rubor* (redness), *tumor* (swelling), *calor* (heat) and *dolor* (pain).

Proliferation

The proliferative phase starts around day 3 and lasts for 2–4 weeks. It consists mainly of fibroblast activity with the production of ground substance (glycosaminoglycans and proteoglycans), collagen, angiogenesis and re-epithelialisation of the wound.

The wound tissue formed in the early part of this phase is called granulation tissue. It has a pink and granular appearance. In the later part of this phase, there is an increase in the

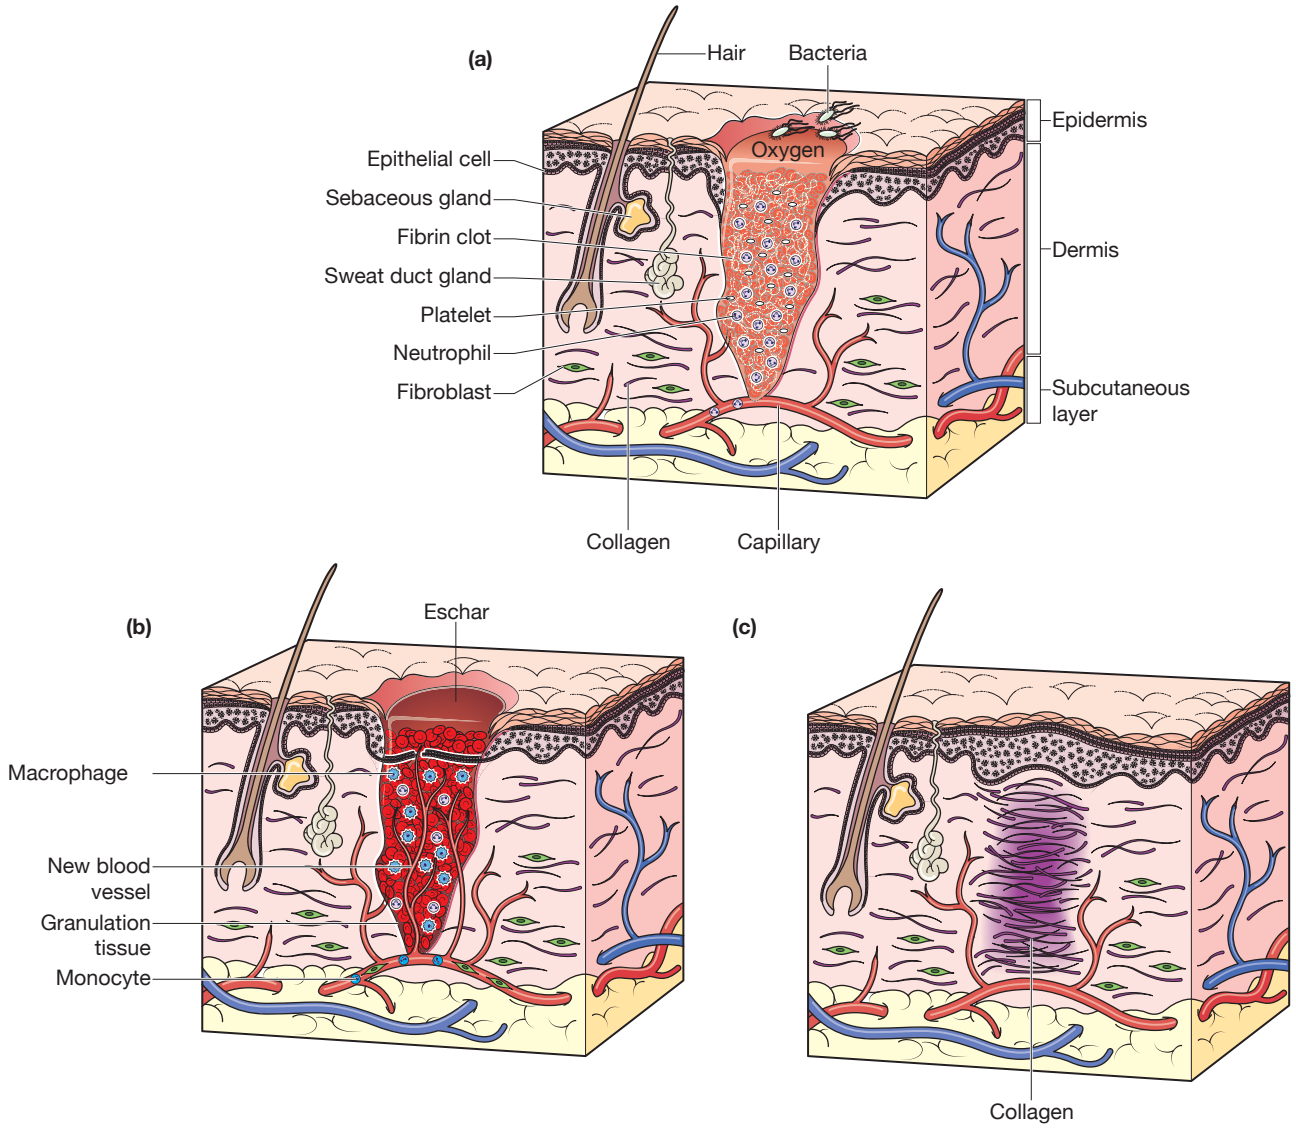

Figure 3.1 Classic stages of wound healing. **(a)** Inflammation. **(b)** Proliferation. **(c)** Remodelling. (Adapted by permission from Springer: Gurtner G, Werner S, Barrandon Y *et al*. Wound repair and regeneration. *Nature* 2008; **453**: 314–21. 2008).

tensile strength of the wound as a result of increased collagen synthesised by fibroblasts. Some fibroblasts differentiate into myofibroblasts, which are contractile cells. These play an important role in contraction to bring the edges of the wound together.

Remodelling

The remodelling phase begins 2–3 weeks after injury and lasts for a year or more. This phase is characterised by maturation of collagen. Type III collagen, which is prevalent during proliferation, is replaced by stronger type I collagen until the normal skin ratio of 4:1 type I to type III collagen is re-established. The collagen becomes more cross-linked and uniformly aligned. This maturation of collagen leads to increased tensile strength in the wound, which is maximal 12 weeks post injury and represents approximately 80% of the uninjured skin strength.

NORMAL HEALING IN OTHER SPECIFIC TISSUES

Bone

Bone healing occurs in similar phases to those for skin but with some differences (*Figure 3.3*). Most fractures heal by callus formation, which involves intramembranous and endochondral ossification. This is known as indirect or secondary bone healing and typically occurs in non-operative fracture management. A haematoma forms at the fracture site and there is an inflammatory response. The fracture haematoma is gradually replaced by a soft callus. This fibrocartilage callus then undergoes endochondral ossification to form hard callus, which is woven bone helping to stabilise the fracture. Intramembranous ossification also occurs directly adjacent to the distal and proximal fracture ends. Hard callus formation is

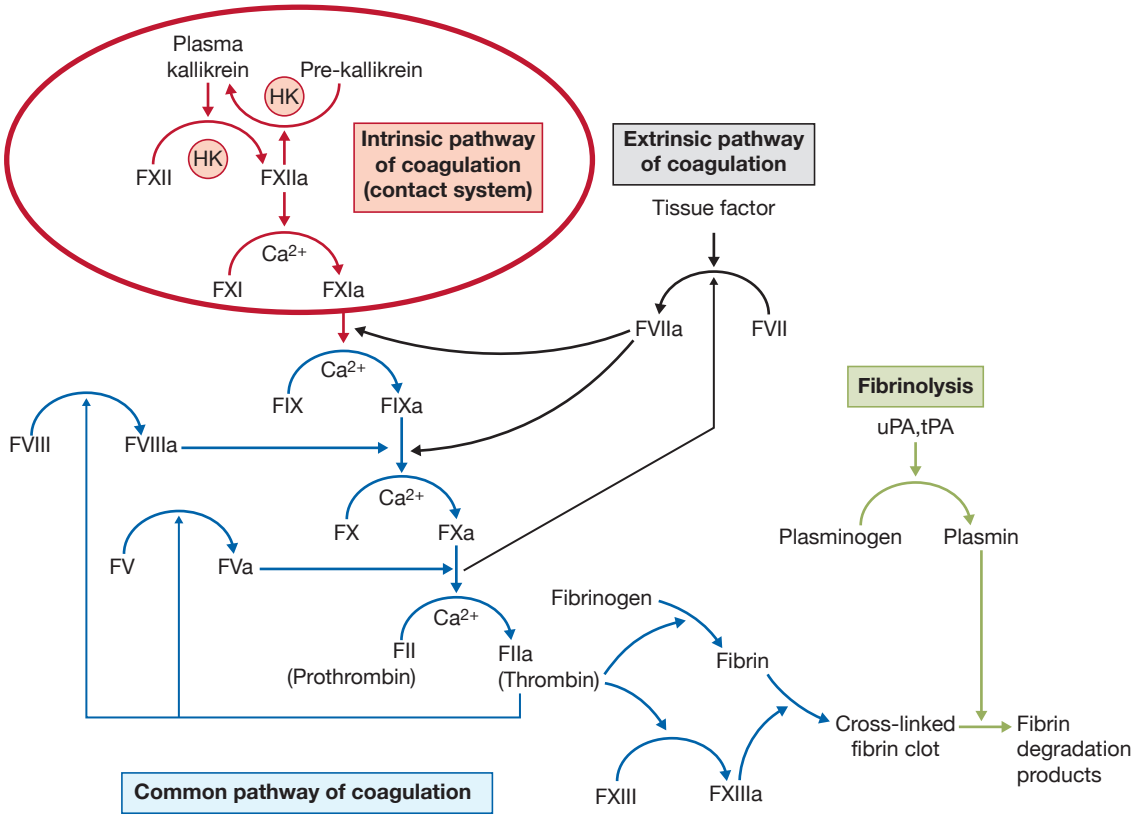

Figure 3.2 Schematic representation of the coagulation cascade and the fibrinolytic system. The coagulation cascade (blue arrows) can be activated during haemostasis via the intrinsic pathway (contact system; red arrows) or the extrinsic pathway (black arrows), which ultimately converge on the common pathway of coagulation. Both pathways lead to the activation of factor X and subsequently of thrombin, which is required for the conversion of fibrinogen into fibrin and for activation of factor XIII. The fibrin clot is cross-linked and stabilised by factor XIII. Fibrinolysis (green arrows) is activated at the same time as the coagulation system but operates more slowly and is important for the regulation of haemostasis. During fibrinolysis, plasminogen is converted into plasmin, which degrades the fibrin network. Coagulation factors are indicated by 'F' followed by a roman numeral; an additional 'a' denotes the activated form. HK, high-molecular-weight kininogen; tPA, tissue plasminogen activator; uPA, urokinase plasminogen activator. (Adapted with permission from Loof TG, Deicke C, Medina E. The role of coagulation/fibrinolysis during *Streptococcus pyogenes* infection. *Front Cell Infect Microbiol* 2014; **4**: 128. 2014. http://creativecommons.org/licenses/by/4.0/)

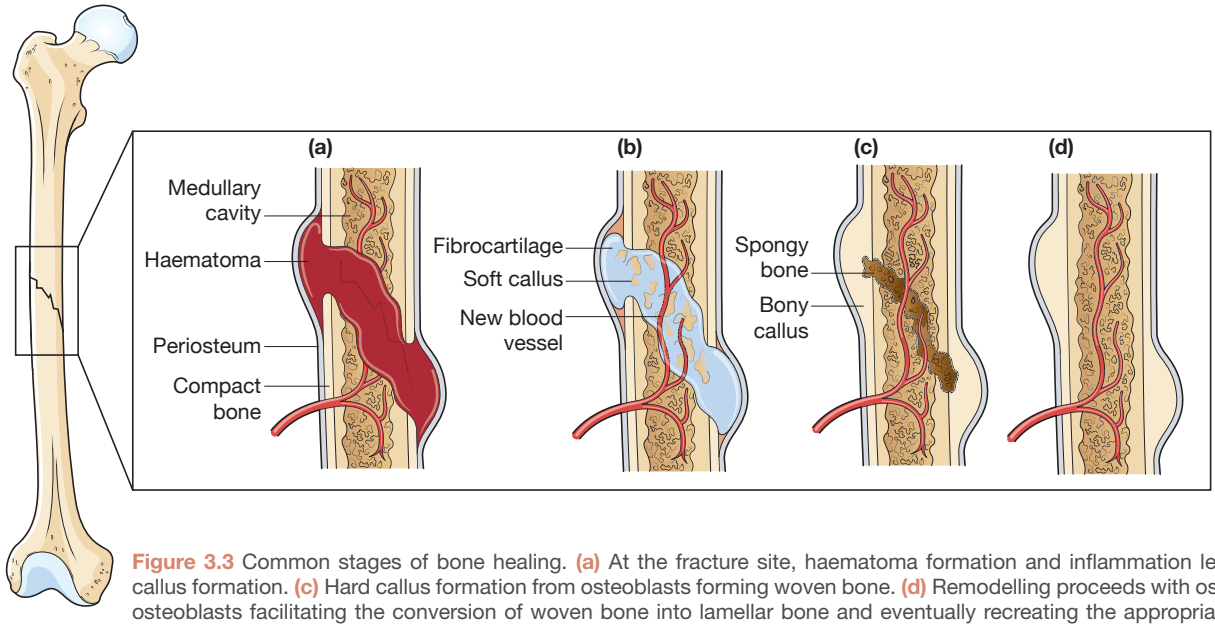

Figure 3.3 Common stages of bone healing. **(a)** At the fracture site, haematoma formation and inflammation lead to **(b)** soft callus formation. **(c)** Hard callus formation from osteoblasts forming woven bone. **(d)** Remodelling proceeds with osteoclasts and osteoblasts facilitating the conversion of woven bone into lamellar bone and eventually recreating the appropriate anatomical shape. (Adapted with permission from Li J, Kacena MA, Stocum DL. Fracture healing. In: Burr DB, Allen MR (eds). *Basic and applied bone biology*, 2nd edn. London: Academic Press, 2019: 235–53.)

followed by bony remodelling, where woven bone is replaced by lamellar bone.

Primary bone healing is a direct bone union process involving intramembranous ossification without callus formation. It does not commonly occur in the natural process of healing since it requires fracture ends to be directly apposed and rigidly fixed with absolute stability. If a gap exists, then secondary healing may lead to delayed union, non-union or malunion. Primary healing is therefore the aim of open reduction and internal fixation surgery. (See also *Chapter 32*) .

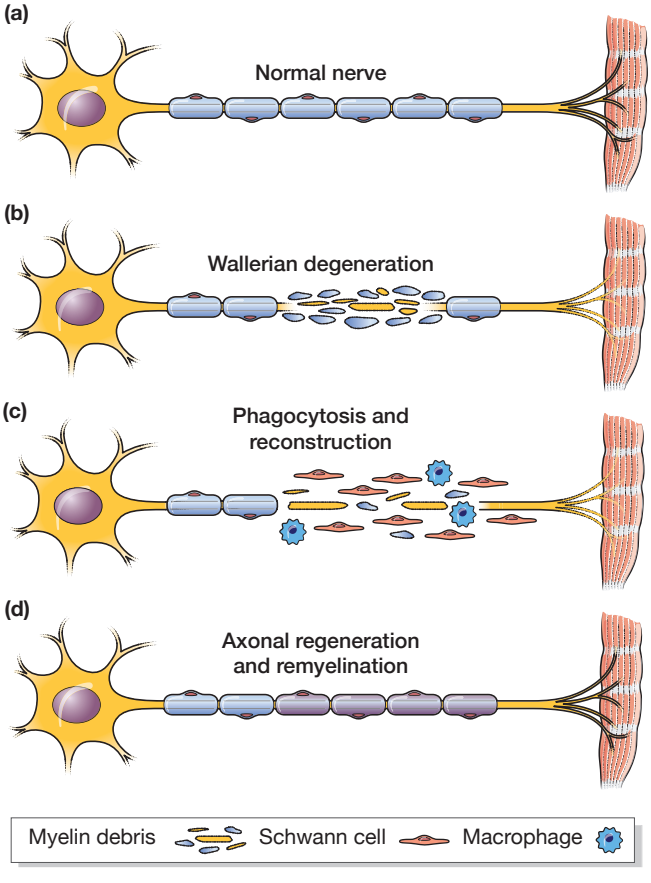

Figure 3.4 Schematic diagram illustrating the process of degeneration and regeneration after peripheral nerve injury. When normal nerves **(a)** suffer a physical injury, the portion of the lesion site and its distal stump undergo destruction and break down to produce myelin debris. This degenerative process is called Wallerian degeneration **(b)**. Then, Schwann cells (SCs) recruit macrophages to scavenge degenerated myelin fragments **(c)**. Meanwhile, SCs proliferate and migrate alone to the basal lamina to form bands of Büngner, which guide the axon to reinnervate towards the corresponding target **(d)**. (Adapted from Li R, Li DH, Zhang HY *et al*. Growth factor-based therapeutic strategies and their underlying signaling mechanisms for peripheral nerve regeneration. *Acta Pharmacol Sin* 2020; **41**: 1289–300. 2020. http://creativecommons.org/licenses/by/4.0/)

Nerve

Peripheral nerve degeneration and regeneration are summarised in *Figure 3.4*. Distal to nerve injury (neurotmesis), Wallerian degeneration occurs. Proximally, the nerve suffers degeneration as far as the nearest node of Ranvier. The regenerating nerve fibres are attracted to their receptors by neurotropism, which is mediated by growth factors, hormones and the extracellular matrix. Injury of the perineurium and inflammation can lead to neuroma formation, where the disorganised nerve regeneration leads to a painful lump.

Tendon

Although repair follows the normal pattern of wound healing, there are two main mechanisms whereby nutrients, cells and new vessels reach the severed tendon. Intrinsic healing consists of vincular blood flow and synovial diffusion. Extrinsic healing depends on the formation of fibrous adhesions between the tendon and the tendon sheath. Early active mobilisation following tendon repairs prevents adhesions limiting the range of motion and therefore promotes the more desired intrinsic healing. At the same time, tendon repairs must be protected by splintage to avoid rupture.

ABNORMAL WOUND HEALING

Various factors can adversely affect wound healing (*Summary box 3.1*). Some wounds fail to heal in a timely and orderly manner, resulting in chronic non-healing wounds, significant morbidity and poor cosmesis. On the other hand,

Summary box 3.1

Local and systemic factors influencing wound healing

- Local
  - Skin tension
  - Hypoxia and ischaemia
  - Vascular insufficiency
  - Lymphoedema
  - Contamination
  - Infection
  - Presence of foreign bodies
  - Radiotherapy
- Systemic
  - Advancing age
  - Obesity
  - Malnutrition
  - Smoking
  - Diseases (e.g. diabetes mellitus, connective tissue diseases)
  - Immunocompromised (e.g. acquired immunodeficiency syndrome)
  - Medications (e.g. steroids, immunosuppressants, chemotherapy)

Augustus Volney Waller, 1816–1870, general practitioner of Kensington, London, UK (1842–1851), subsequently worked as a physiologist in Bonn, Germany; Paris, France; Birmingham, UK; and Geneva, Switzerland.
Louis Antoine Ranvier, 1835–1922, physician and histologist who was a professor in the College of France, Paris, France, described these nodes in 1878.

aberrations of normal wound healing such as prolonged inflammation can result in excessive scar tissue, for example hypertrophic and keloid scars. These abnormal scars contain excess collagen, which is arranged in a disorganised pattern in keloid scars as opposed to a parallel pattern in hypertrophic scars.

Hypertrophic scars do not extend beyond the boundary of the original incision or wound and eventually regress. They are more common in areas of increased tension, wounds crossing tension lines, deep dermal burns and wounds left to heal by secondary intention (longer than 3 weeks).

Keloid scars extend beyond the boundaries of the original incision or wound (*Figure 3.5*), do not spontaneously regress and are difficult to treat. The aetiology is unknown but genetic predisposition is implicated. They often occur as a result of relatively minor trauma and mainly in those with darker skin pigmentation.

Figure 3.5 Multiple keloid scars.

TYPES OF WOUND HEALING

There are different types of healing (*Summary box 3.2*). Primary healing is also known as healing by first intention. This occurs when there is direct approximation of the wound edges and is the aim of treatment. When there are no adverse influences, these wounds heal well and leave the best scar. Delayed primary healing occurs when the wound edges are not opposed immediately, which may be necessary in contaminated or untidy wounds. After debridement of non-viable tissue and when the wound is clean, the wound edges may be surgically approximated. This is also called healing by tertiary intention.

Secondary healing or healing by secondary intention occurs in wounds that are left open and allowed to heal by granulation, contraction and re-epithelialisation.

Summary box 3.2

Classification of wound closure and healing

- Primary
  - Wound edges apposed
  - Normal healing
  - Minimal scar
- Secondary
  - Wound left open
  - Heals by granulation, contraction and re-epithelialisation
  - Increased inflammation and proliferation
  - Poor scar
- Tertiary (delayed primary)
  - Wound initially left open
  - Edges apposed later when healing conditions favourable

CLASSIFICATION OF WOUNDS

Wounds are diverse and there is no standard classification system that incorporates all relevant aspects for different clinical contexts. A wide variety of classifications (*Summary box 3.3*) are used and descriptors from more than one system are required to accurately describe a given wound.

A widely accepted wound classification was first introduced in 1964 by the US National Research Council[1] to describe the degree of bacterial load or contamination of surgical wounds at the time of surgery. It was subsequently adapted by the US Centers for Disease Prevention and Control[2] to classify wounds as clean, clean–contaminated, contaminated and dirty (*Table 3.1*). Although the simplicity of this classification has led to its widespread use, the definitions are not entirely clear and low interobserver reliability has been reported.[3,4]

Various grading and scoring systems exist for specific conditions such as pressure ulcers and diabetic ulcers. The National Nosocomial Infections Surveillance (NNIS) score is commonly used to predict surgical site infections (SSIs). It was established in recognition of the effectiveness of infection surveillance in reducing SSIs.[5] The NNIS score stratifies surgical wound infection rates by risk factors. This risk index score ranges from 0 (lowest SSI risk) to 3 (highest SSI risk) with a point allocated for the presence of each of the following risk factors:

TABLE 3.1 US Centers for Disease Prevention and Control surgical wound classification.[2]

Class I *Clean*	Uninfected operative wounds No inflammation is encountered Respiratory, alimentary, genital or uninfected urinary tracts are not entered Primarily closed and, if necessary, drained using a closed system
Class II *Clean–contaminated*	Respiratory, alimentary, genital or urinary tracts are entered under controlled conditions and without unusual contamination No evidence of infection or major break in technique is encountered
Class III *Contaminated*	Open, fresh, accidental wounds Operations with major breaks in sterile technique (e.g. open cardiac massage) or gross spillage from the gastrointestinal tract Incisions in which acute, non-purulent inflammation is encountered
Class IV *Dirty*	Old traumatic wounds with retained devitalised tissue and those that involve existing clinical infection or perforated viscera

- contaminated or dirty wound;
- American Society of Anesthesiologists score ≥3;
- operative time longer than the expected duration for similar procedures (>75th percentile).

Summary box 3.3

Synopsis of wound classification systems

- Aetiology
  - Clean, surgical
  - Shearing or degloving
  - Crush
  - Blast
  - Burn (thermal, electrical, chemical, radiation, mechanical)
  - Cold injury
  - Avulsion or traction
  - Low or high energy
  - Bite
- Depth
  - Epidermal
  - Dermal (superficial or deep)
  - Full thickness
- Contamination
  - Clean
  - Clean–contaminated
  - Contaminated
  - Dirty
  - Implant or non-implant
- Complexity
  - Simple
  - Complex
    - Significant soft-tissue loss
    - Open fracture or joint
    - Visceral involvement
  - Complicated
    - Infection
    - Necrosis
    - Haematoma
    - Gas gangrene
    - Compartment syndrome
- Chronic
  - Vascular ulcers (venous or arterial)
  - Pressure ulcers
  - Diabetic ulcers

WOUND MANAGEMENT

Assessment

Wound management is guided by the timing and mechanism of injury as well as factors affecting healing (***Summary box 3.1***). It is also important to assess the patient's ideas, concerns and expectations. Patient outcomes also rely on good postoperative compliance.

Assess the patient using Advanced Trauma Life Support principles to first identify and treat life- and then limb-threatening conditions. Some wounds require a multidisciplinary approach; for example, the involvement of orthopaedic surgeons and plastic surgeons in managing complex open lower limb fractures.[6]

Assess the site, size, geometry and nature of any wounds. Look for signs of contamination, infection, swelling and pulsatile bleeding. Deformities may suggest underlying fractures or dislocations. Has there been skin loss or degloving? What structures are visible? Thorough irrigation of wounds will allow better visualisation.

It is important to correlate the clinical examination with the mechanism of injury as seemingly innocuous wounds can lead to underestimation of tissue damage. For example, high-pressure injection injuries of the hand can cause significant mechanical and chemical tissue damage with risk of amputation. The injected substances can track proximally into the forearm. Urgent surgical exploration and debridement is required.

Before palpation, ensure that the patient has adequate analgesia or a local anaesthetic block. When possible, it is important to assess motor and sensory function before any local anaesthesia. Unless there are obvious muscle injuries, the purpose of testing specific muscle groups is to evaluate potential nerve or tendon injuries. Imaging is useful to exclude foreign bodies, fractures or dislocations where appropriate.

Principles

Clinical judgement is crucial in managing wounds. Some general principles of wound management are summarised in ***Table 3.2***. Antibiotic prophylaxis is needed for clean–contaminated, contaminated and dirty wounds. It may also be used in clean wounds when there is a high risk of infection or when the sequelae of infection are potentially disastrous. Tetanus prophylaxis should be given based on the type of wound (***Table 3.3***) and immunisation status (***Figure 3.6***).

TABLE 3.2 Principles of wound management.

Preparation	Antibiotic prophylaxis Tetanus prophylaxis Adequate analgesia/anaesthesia Wound irrigation
Wound	Early debridement and irrigation Exploration Repair structures Haemostasis
Closure	Skin closure without tension Consider reconstruction options Suture choice Consider drains Optimal dressings
Follow-up	Removal of sutures/splints Physiotherapy Monitoring for complications Scar management

TABLE 3.3 Tetanus-prone wounds.[7]

Tetanus-prone wounds	High-risk tetanus-prone wounds
• Puncture-type injuries in a contaminated environment • Bites • Compound fractures • Containing foreign bodies • Wounds or burns with systemic sepsis	Any tetanus-prone wound with: • Heavy contamination, e.g. soil or manure • Wound requiring surgery with >6-hour delay • Extensive devitalised tissue

Adapted from https://www.gov.uk/government/publications/tetanus-prone-wounds-posters.

Debridement is essential to remove any devitalised tissue and foreign material from the wound. Non-viable tissue must be excised until healthy bleeding occurs at the wound edges. The importance of thorough debridement is often

Post exposure management for Tetanus Prone Wounds

Immunisation Status	Immediate treatment				Later treatment
	Clean wound[1]	Tetanus prone		High risk tetanus prone	
Those aged 11 years and over, who have received an adequate priming course of tetanus vaccine[1] with the last dose within 10 years	None required	None required		None required	Further doses as required to complete the recommended schedule (to ensure future immunity)
Children aged 5-10 years who have received priming course and pre-school booster					
Children under 5 years who have received an adequate priming course					
Received adequate priming course of tetanus vaccine[3] but last dose more than 10 years ago	None required	Immediate reinforcing dose of vaccine		Immediate reinforcing dose of vaccine	One dose of human tetanus immunoglobulin[2] in a different site
Children aged 5-10 years who have received an adequate priming course but no pre-school booster					
(Includes UK born after 1961 with history of accepting vaccinations)					
Not received adequate priming course of tetanus vaccine[3] (Includes uncertain immunisation status and/or born before 1961)	Immediate reinforcing dose of vaccine	Immediate reinforcing dose of vaccine	One dose of human tetanus immunoglobulin[2] in a different site	Immediate reinforcing dose of vaccine	One dose of human tetanus immunoglobulin[2] in a different site

1 Clean wounds are defined as wounds less than six hours old, non-penetrating with negligible tissue damage.
2 If TIG is not available, HNIG may be used as an alternative.
3 At least three doses of tetanus vaccine at appropriate intervals. This definition of "adequate course" is for risk assessment of tetanus-prone wounds only. The full UK schedule is five doses of tetanus containing vaccine.

Patients who are severely immunosuppressed may not be adequately protected against tetanus, despite having been fully immunised and additional booster doses or treatment may be required.

Figure 3.6 Postexposure management for tetanus-prone wounds. (Redrawn with permission from https://www.gov.uk/government/publications/tetanus-prone-wounds-posters. © Crown copyright 2019. 2019TET02 10K OCT 2019 (APS).

underappreciated and is not as simple as is often perceived. The end points of surgical debridement can sometimes be difficult to determine. Healthy subcutaneous fat is yellow and soft. Muscle viability is judged by its colour, capacity to bleed and contractility. Contaminated, complex and complicated wounds often require more than one surgical debridement before definitive repair and closure; for example, blast injuries and necrotising fasciitis (see ***Part 4***). Other types of debridement are summarised in ***Table 3.4***.

TABLE 3.4 Types of debridement.

Surgical	Excision of non-viable tissue using surgical instruments such as a scalpel, curette, scissors or rongeur until healthy bleeding occurs at the wound edges
Mechanical	Non-selective debridement such as using irrigation, wet-to-dry dressings and hydrotherapy. Both non-viable and viable tissue may be removed
Autolytic	Using dressings such as hydrocolloids or transparent films to retain moisture and allow wound enzymes to selectively liquefy non-viable tissue
Enzymatic	Chemically liquefy necrotic tissue with enzymes using topical agents such as collagenase or papain–urea
Biological	Medical-grade larvae of *Lucilia sericata* release proteolytic and antimicrobial substances to remove necrotic tissue. They also directly promote wound healing

All wounds should be irrigated at the first available opportunity to reduce bacterial contamination. This also allows better visualisation for wound assessment. Warm normal saline

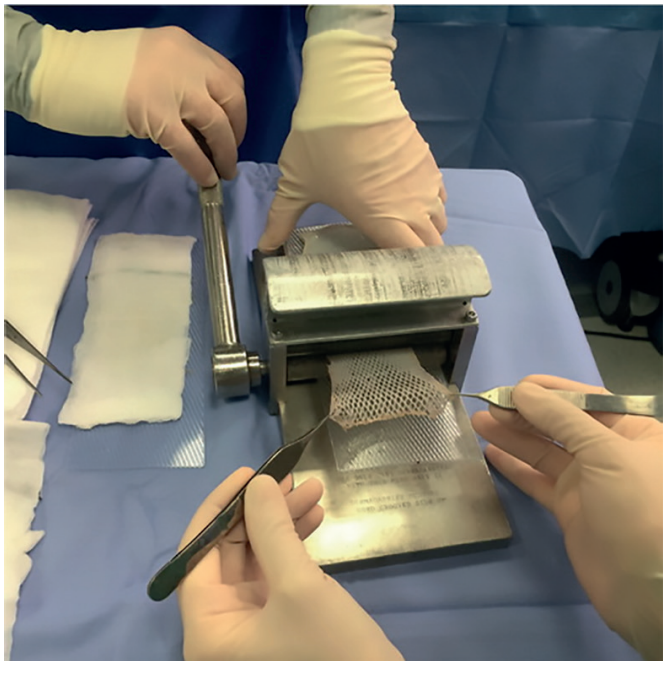

Figure 3.7 Meshing a split-thickness skin graft. (Reproduced with permission of MA Healthcare Limited from Hili S, Wong KY, Stephens P. Pretibial lacerations. *Br J Hosp Med* 2017; **78**: C162–6.)

is typically used, although other irrigation fluids are available such as water and antiseptic solutions. Irrigation can also be performed with a soft brush or sponge to clear particulate matter prior to preoperative application of skin antiseptic preparation.

Wounds should be explored to determine the extent of injury, including any damage to underlying neurovascular structures, tendons, joints and bones. Careful tissue handling and meticulous technique are important throughout. Repair of all damaged structures may be attempted once the wounds are clean. Repair of nerves and vessels should be performed under magnification using loupes or a microscope.

Skin closure should always be without tension. Direct closure is not always possible and other reconstruction methods should be considered. Historically, the reconstructive ladder and its variants such as the reconstructive elevator[8] have been used as a framework to consider the simplest means to achieve wound closure for the desired goal. Advances in technology and surgical techniques have led to ongoing adjustments of these frameworks. Although these frameworks do not guide the selection of a particular technique over another, they provide a useful reminder of the options available (***Summary box 3.4***).

A skin graft has no inherent blood supply and is dependent on a well-vascularised recipient site for survival and wound healing. Split-thickness skin grafts (***Figure 3.7***) consist of the epidermis and a small portion of dermis whereas full-thickness skin grafts consist of the epidermis and the majority of the dermis.

A flap contains tissue with its intrinsic blood supply that is transferred from one part of the body (donor) to another (recipient). The blood supply of the flap therefore does not rely on the recipient site like a skin graft. A free flap contains tissue with its vascular pedicle that is surgically detached and transferred from its original location to a distant recipient site (***Figure 3.8***). A microscope is used to perform microvascular anastomoses to connect the blood vessels in the free flap to blood vessels close to the recipient site.

Since its development in the 1990s, negative-pressure wound therapy (NPWT) is now widely used. It is not a replacement for definitive wound closure but is a useful adjunct

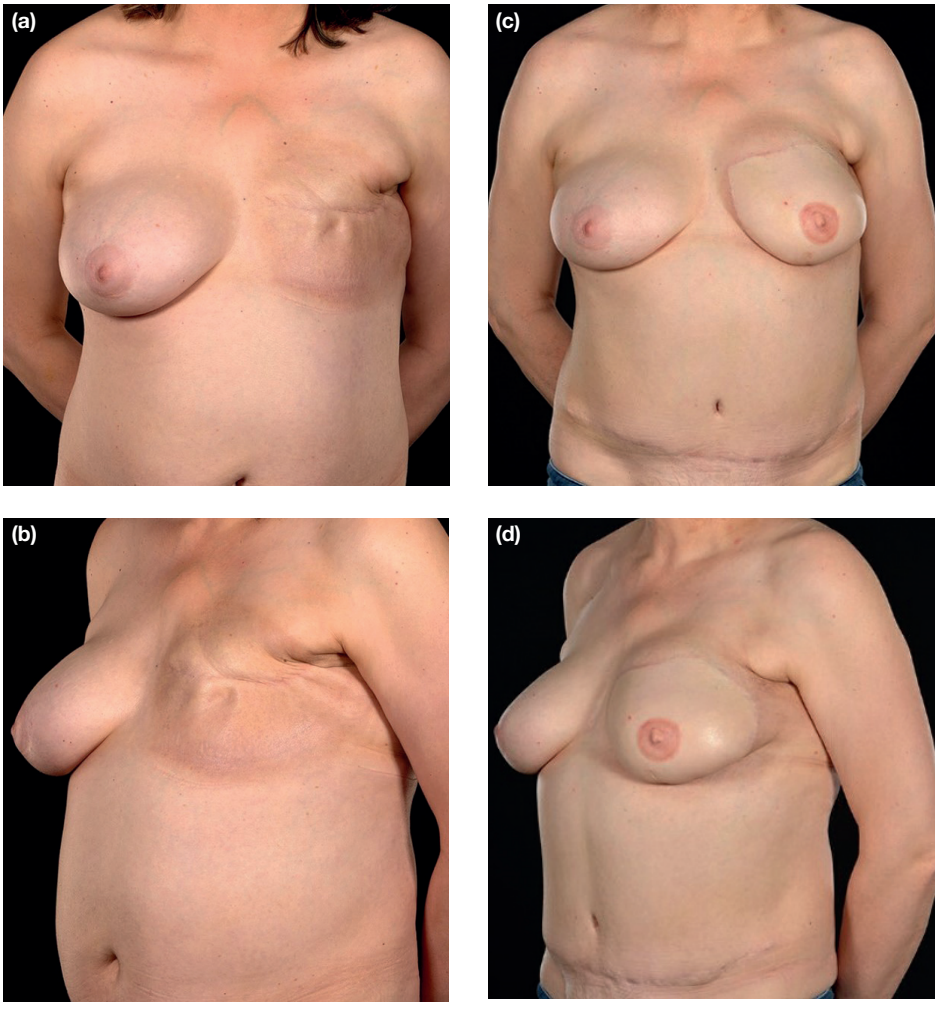

Figure 3.8 Left mastectomy **(a, b)** and delayed left breast reconstruction with a deep inferior epigastric artery perforator free flap and nipple reconstruction **(c, d)** (©Addenbrookes Hospital).

Figure 3.9 Negative-pressure wound therapy for a lower limb wound. (Reproduced with permission of MA Healthcare Limited from Hili S, Wong KY, Stephens P. Pretibial lacerations. *Br J Hosp Med* 2017; **78**: C162–6.)

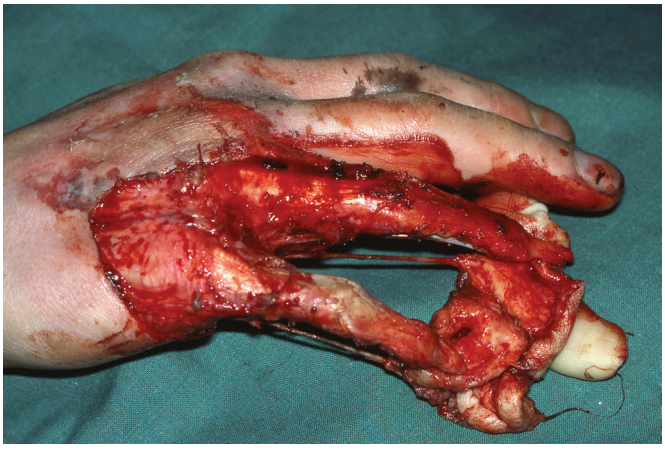

Figure 3.10 Degloving injury of the right little and ring fingers.

(*Figure 3.9*). Negative pressure helps draw the wound edges together, remove exudate, reduce oedema and promote granulation tissue formation. NPWT is not recommended in the setting of exposed vessels, malignancy, untreated osteomyelitis, necrotic tissue or non-enteric and unexplored fistulae.

ACUTE WOUNDS

Bites

Most bites involve either puncture wounds or avulsions. Wounds over the metacarpophalangeal joint should be treated as a human bite following a punch to the mouth until proven otherwise. Joint infections are a surgical emergency as they can result in articular cartilage destruction. They present as hot, swollen and tender joints with a limited range of motion.

Figure 3.11 Degloving buttock injury.

Summary box 3.4

Reconstruction options for wound closure

- Primary closure
- Secondary closure
- Tertiary (delayed primary) closure
- NPWT
- Split-thickness skin graft
- Full-thickness skin graft
- Dermal matrices
- Local, regional or pedicled flap
- Tissue expansion
- Free flap

Degloving

Degloving is the avulsion of skin and subcutaneous fat from the underlying fascia, muscle or bone. A degloving injury may be open or closed. An example of an open degloving is a finger avulsion injury with loss of skin (*Figure 3.10*).

Closed degloving injuries result from shearing forces, which may occur with motor vehicle collisions. The extent of these injuries is often underappreciated and much of the skin may be non-viable (*Figure 3.11*). Disruption of perforating vascular and lymphatic vessels may result in a characteristic haemolymphatic collection between the fascial planes called a Morel-Lavallée lesion (*Figure 3.12*). Although these lesions were originally described as occurring over the greater trochanter the term is also used now for similar lesions in other anatomical locations.

Assessing the viability of degloved tissue can be difficult and may therefore require more than one surgical exploration and debridement before definitive reconstruction. Non-viable skin may show fixed staining and thrombosis of subcutaneous veins. Most surgeons serially excise the degloved skin until punctate dermal bleeding is seen from viable tissue. Intravenous fluorescein may also help delineate non-viable tissue, but

Victor-Auguste-François Morel-Lavallée, 1811–1865, surgeon who first described this lesion in 1863.

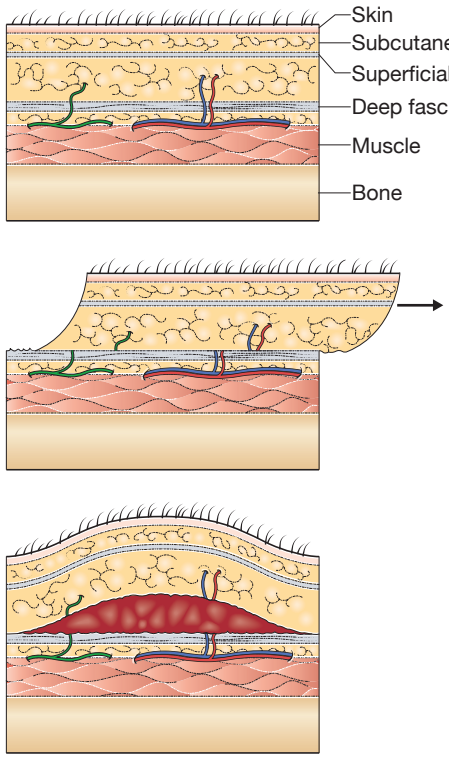

Figure 3.12 Mechanism of injury for Morel-Lavallée lesions. Cross-sectional illustrations of the layers of tissue from the skin to the bone demonstrate how a shearing force can cause the comparatively mobile subcutaneous tissues to move relative to the comparatively fixed underlying deep fascia, causing shearing of perforating arteries (red), veins (blue) and lymphatics (green) and ultimately leading to the formation of a haemolymphatic collection in this potential space. (Adapted with permission from Bonilla-Yoon I, Masih S, Patel DB *et al*. The Morel-Lavallée lesion: pathophysiology, clinical presentation, imaging features, and treatment options. *Emerg Radiol* 2014; **21**(1): 35–43.)

it requires specialist equipment and there is a small risk of anaphylaxis. More recently, the use of indocyanine green fluorescence has been reported.

A useful classification system to help guide management describes four patterns of degloving (***Summary box 3.5***).

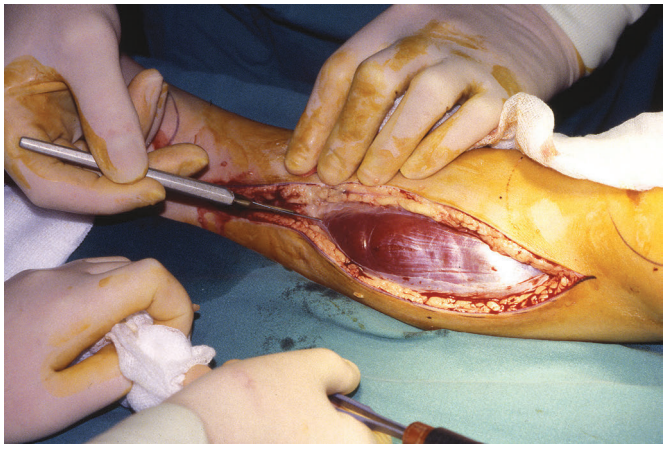

Figure 3.13 Fasciotomy of the leg.

It may be appropriate to offer primary amputation in cases of severe multiplanar degloving.

Summary box 3.5

Classification of degloving injuries in limb trauma[9]

1. Limited degloving with abrasion or avulsion
2. Non-circumferential degloving
3. Circumferential single plane degloving
4. Circumferential multiplanar degloving

Acute compartment syndrome

Acute compartment syndrome occurs when there is increased interstitial pressure within a closed osteofascial compartment, which results in microvascular compromise. It is a surgical emergency as delayed treatment may lead to irreversible muscle ischaemia and significant long-term morbidity.

Compartment syndrome most commonly occurs after lower limb fractures, both open and closed (see ***Chapter 32***). It also occurs in the upper limb, buttock and abdomen. Other causes include soft-tissue trauma, arterial injuries, burns and prolonged compression. It is characterised by pain out of proportion to the injury, particularly with passive movement of the affected compartment muscles. Paraesthesia is another early sign. Absent pulses are uncommon and suggest the possibility of vascular injury.

Compartment syndrome is generally a clinical diagnosis. It can be difficult to diagnose in the presence of impaired consciousness, in children and in patients with regional nerve blocks. Monitoring intracompartment pressures (ICPs) can sometimes help to guide management. A pressure of ≤30 mmHg between the diastolic pressure and ICP has been recommended as the threshold for fasciotomy.

Fasciotomy involves incising the skin and deep fascia with long axial incisions (***Figure 3.13***). If the compartment pressure was high, the muscle will then be seen bulging out through the fasciotomy opening. The lower limb is reliably decompressed via two incisions. A medial longitudinal incision 1–2 cm posterior to the medial border of the tibia decompresses the superficial and deep posterior compartments. A lateral longitudinal incision 2 cm lateral to the anterior tibial border decompresses the peroneal and anterior compartments.

Late diagnosis of compartment syndrome is a management dilemma as a late fasciotomy may result in rhabdomyolysis, infection, need for amputation and even death.

Necrotising fasciitis

This is a severe, rapidly progressing infection of the soft tissue and fascia associated with significant morbidity and mortality (***Figure 3.14***). Reported mortality rates vary widely but a Danish nationwide cohort study including over 1500 patients found 30-day and 1-year mortality rates of up to 26% and 40%, respectively.[10] The infection is commonly polymicrobial but monomicrobial presentation with *Streptococcus pyogenes* (group A streptococcus) is also frequent. Examples of other

Figure 3.14 Necrotising fasciitis of the anterior abdominal wall.

Figure 3.15 Pressure ulcer.

organisms include *Staphylococcus aureus*, *Escherichia coli*, *Pseudomonas*, *Clostridium* and *Bacteroides*.

There is usually a history of trauma or surgery with wound contamination. Diabetes mellitus is the most common comorbidity, although up to 30% of patients may not have any comorbidities.[10,11] Clinical features are shown in ***Summary box 3.6***. A scoring system to aid clinical decision making has been developed, but its performance remains questionable.[12] It remains primarily a clinical diagnosis and surgical treatment should not be delayed if suspicion is high.

Treatment consists of appropriate intravenous antibiotics with urgent radical surgical debridement. A *second look* operation is usually planned in 24–48 hours depending on clinical response. Multiple debridements may be required.

Summary box 3.6

Signs and symptoms of necrotising fasciitis

- Local
  - Unusual pain
  - Erythema, oedema, warmth
  - Crepitus
  - Blisters, bullae
  - Greyish drainage ('dishwater pus')
  - Fixed staining
  - Necrosis, gangrene
- Systemic
  - Fever, tachycardia, tachypnoea
  - Shock
  - Coagulopathy
  - Multiorgan failure

CHRONIC WOUNDS

These wounds fail to progress through the normal stages of wound healing in a timely manner. They are often characterised by a prolonged inflammatory phase and persistent infections. The management of chronic wounds therefore often involves debridement (***Table 3.4***), control of infection and inflammation and appropriately selected dressings to correct moisture imbalances. Chronic wounds can be categorised into vascular ulcers (venous or arterial), diabetic ulcers and pressure ulcers.

Leg ulcers

In developed countries, the most common chronic wounds are leg ulcers. An ulcer can be defined as a break in the epithelial continuity. A prolonged inflammatory phase leads to overgrowth of granulation tissue and attempts to heal by scarring leave a fibrotic margin. Necrotic tissue, often at the ulcer centre, is called slough. The more common aetiologies are listed in ***Summary box 3.7***.

A chronic ulcer that is unresponsive to dressings and simple treatments should be biopsied to rule out neoplastic change, a squamous cell carcinoma known as a Marjolin's ulcer being the most common. Effective treatment of any leg ulcer depends on treating the underlying cause, and diagnosis is therefore vital. Arterial and venous circulation should be assessed, as should sensation throughout the lower limb. Surgical treatment is only indicated if non-operative treatment has failed.

Summary box 3.7

Aetiology of leg ulcers

- Vascular (venous, arterial, mixed)
- Trauma (bites, self-inflicted, burns)
- Infection (bacterial, fungal, mycobacterial, syphilis)
- Metabolic disorders (diabetes mellitus, gout, calciphylaxis)
- Autoimmune disorders (vasculitis, systemic sclerosis, rheumatoid arthritis)
- Neoplastic (squamous cell carcinoma, basal cell carcinoma)

Pressure ulcers

Pressure ulcers occur over a bony prominence or under a medical or other device (***Figure 3.15***). A number of similar classifications exist. The US National Pressure Injury Advisory

Jean-Nicholas Marjolin, 1780–1850, surgeon, Paris, France, described the development of carcinomatous ulcers in scars in 1828.

Panel has replaced the term 'pressure ulcer' with 'pressure injury' in its staging system (*Table 3.5*) to provide a more accurate description of injuries to both intact and ulcerated skin.[13]

Pressure injuries should be regarded as preventable. There is a higher incidence in those who are severely ill, those who have impaired mobility or those with a significant loss of sensation. The most common sites are listed in *Summary box 3.8*.

TABLE 3.5 US National Pressure Injury Advisory Panel staging of pressure injuries.[13]

Stage	Description
1	Non-blanchable erythema of intact skin
2	Partial-thickness skin loss with exposed dermis
3	Full-thickness skin loss
4	Full-thickness skin and tissue loss
Unstageable full-thickness pressure injury	Obscured full-thickness skin and tissue loss
Deep tissue pressure injury	Persistent non-blanchable, deep red, maroon or purple discoloration

Summary box 3.8

Common sites for pressure injuries and ulcers

- Ischium
- Greater trochanter
- Sacrum
- Heel
- Malleolus
- Occiput

Prevention starts with assessing risk using a validated score to support clinical judgement such as the Braden scale, Waterlow score or Norton risk assessment scale. Patients at risk of developing pressure injuries should have a skin assessment, regular repositioning every 2–4 hours and the use of pressure-redistributing devices as appropriate. Patients should receive education on self-care and risk factors need to be addressed, such as providing nutritional support for any deficiencies.

The treatment of pressure ulcers should focus on patient optimisation especially any aspects of poor nutrition and ongoing poorly managed medical problems to address any risk factors. Preventative measures are used and debridement may be appropriate (*Table 3.4*). Dressings should be chosen to create an optimum wound-healing environment and appropriate antibiotics given if there are signs of infection. Surgery is not first-line treatment and is only considered when the above measures have been fully implemented. Patients must also be well motivated and able to fully comply with postoperative preventative measures.

Surgical management of pressure sores follows some of the same principles described for wound management in *Table 3.2*. Primary closure and skin grafting should be avoided as they are likely to fail. In suitable patients, successful reconstruction options include the use of large fasciocutaneous or musculocutaneous flaps. If possible, use a flap that can be advanced further if there is recurrence and that does not interfere with the planning of neighbouring flaps that may be used in the future.

SCAR MANAGEMENT

Principles

The remodelling and maturation phase of wound healing results in scar formation. The immature scar is at first pink, hard, raised and often itchy. As the collagen matures, the scar becomes almost acellular as the fibroblasts and blood vessels reduce. The external appearance of the scar becomes paler, while the scar becomes softer, flattens and its itchiness diminishes. Most of these changes occur over the first 3 months but a scar will continue to mature over 1–2 years, and sometimes more. Tensile strength will continue to increase but would not be expected to exceed around 80% that of normal skin.

There is well-established evidence for managing scars with pressure/compression therapy, silicone sheets and gels, intralesional corticosteroid injection and surgery.[14] Other treatment modalities include massage therapy, psychological counselling, laser therapy, radiotherapy, cryosurgery and intralesional injection of other products.

Prevention of adverse scar formation is better than treatment, so it is important to correctly manage wounds (*Table 3.2*). Optimal surgical management starts with careful planning, tissue handling and meticulous technique. For example, placing incisions along relaxed skin tension lesions where possible, and avoiding straight-line incisions across flexion creases. Early debridement reduces the risk of infection and allows for earlier wound closure. Dirt-ingrained (tattooed) scars are usually preventable by proper initial scrubbing and cleansing of the wound (*Figure 3.16*). It is important to recognise normal

Figure 3.16 Dirt-ingrained scar.

Barbara Braden, contemporary, developed the Braden scale with Nancy Bergstrom in 1987.
Judy Waterlow, contemporary, developed the Waterlow score in 1985.
Doreen Norton, 1922–2007, nurse, developed the Norton risk assessment scale in 1962.

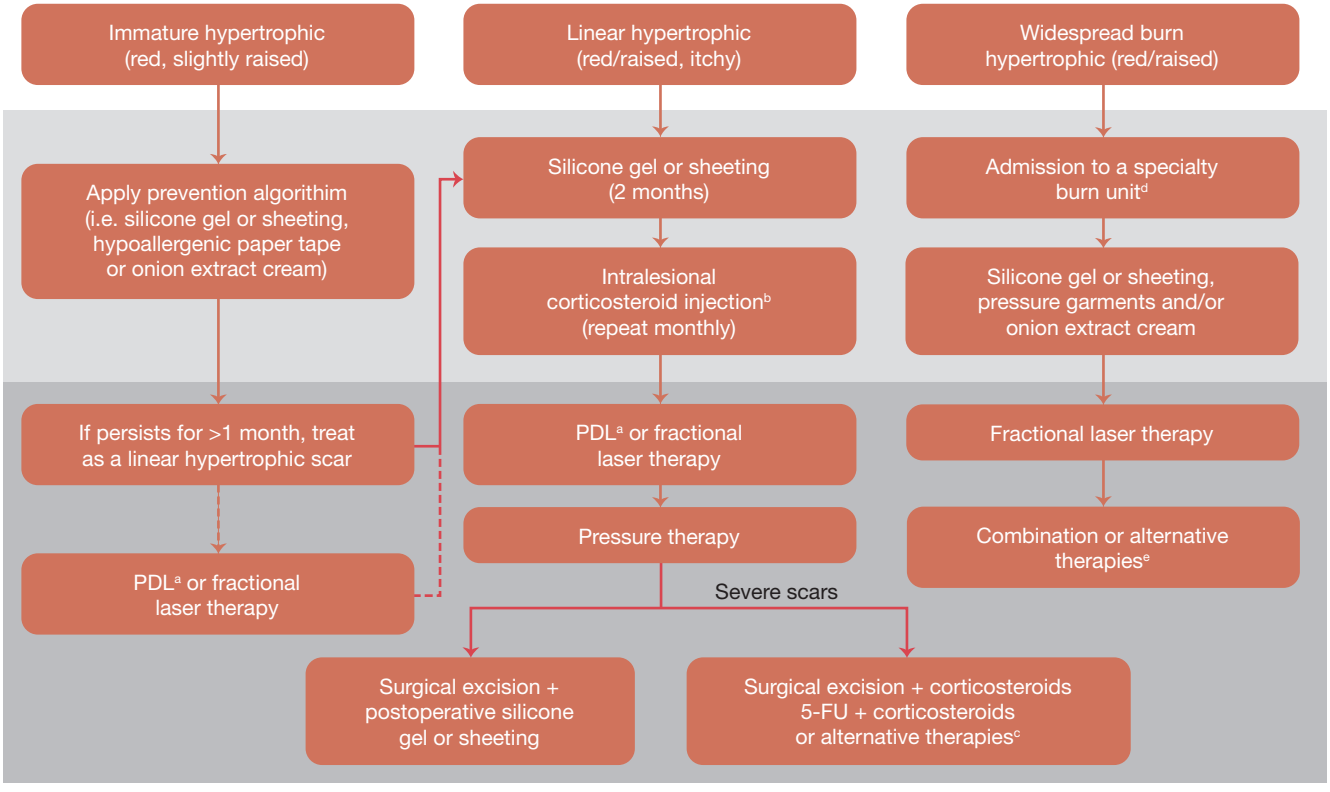

Figure 3.17 Management algorithm for hypertrophic scars. Light grey indicates initial management strategies; dark grey indicates secondary management options. [a]Preferred initial option. [b]2.5–20 mg/mL (face); 20–40 mg/mL (body). [c]Alternative therapy options for severe lesions include bleomycin, mitomycin C, laser therapy and cryotherapy. [d]Scar prevention and treatment should not begin before epithelium and wound stabilisation. [e]Combination and alternative therapies include massage, physical therapy, corticosteroids, tension-relieving surgical intervention, excision, grafting or flap coverage, hydrocolloid dressings, antihistamines and laser therapy. 5-FU, 5-fluorouracil; PDL, pulsed-dye laser. (Redrawn with permission from Gold MH, McGuire M, Mustoe TA *et al*. Updated international clinical recommendations on scar management: part 2–algorithms for scar prevention and treatment. *Dermatol Surg* 2014; **40**(8): 825–31.)

anatomical landmarks to avoid misaligned scars, such as at the lip vermilion border where even a 1-mm discrepancy is noticeable at a distance. Skin closure should be without tension and allow for postoperative oedema typically associated with injury and healing. Wounds should be sutured in layers unless they are very small. Deep dermal absorbable sutures hold the skin edges together to allow subsequent subcuticular or skin sutures. Large and deep wounds also require closure of the fascial layer, for example Scarpa's fascia in the abdomen. Subcuticular suturing avoids skin suture marks. If skin sutures are used, suture marks may be minimised by using monofilament sutures that are removed in a timely fashion depending on anatomical location. For example, sutures are typically removed by 5 days in the face versus 10–14 days in the lower limb.

Following wound closure, scar prevention measures include tension relief, taping, hydration and ultraviolet protection.[14] Silicone sheeting or gel is widely accepted as the first-line prophylactic and treatment option for hypertrophic and keloid scars. The management of hypertrophic and keloid scars is difficult and international recommendations from 2014 are summarised in ***Figures 3.17 and 3.18***.[15]

Later scar treatment includes intralesional corticosteroid injections, typically using triamcinolone acetonide 10–40 mg/mL every 4–6 weeks until the scar has flattened. Revisional scar surgery may be appropriate. For example, for correcting alignment of scars.

Contractures

Scar contractures can cause severe functional, psychological and aesthetic problems (***Figure 3.19***). Contractures across joints may restrict the range of movement, leading to deformity, impairment and disability. Contractures may also result from the differential growth pattern between scar and surrounding tissues.

Surgical contracture release and reconstruction can be an effective treatment option. A key principle is the replacement of scar tissue with healthy tissue. A wide range of reconstructions are described (***Summary box 3.4***) and typically involve skin grafts or flaps (more information can be found in ***Part 6***). Local flaps such as Z-plasty (***Figure 3.20***) and its variants can be used to lengthen and transpose the scar. Many other local flaps have been described, including Y–V, V–Y and W-plasty. Free flaps may be required for resurfacing severe contractures. In general, flaps are preferable to skin grafts because of graft contracture. When skin grafts are used, full thickness is preferred to split thickness as they have a better texture and contract less during healing.

Antonio Scarpa, 1747–1832, Professor of Anatomy, Pavia, Italy.

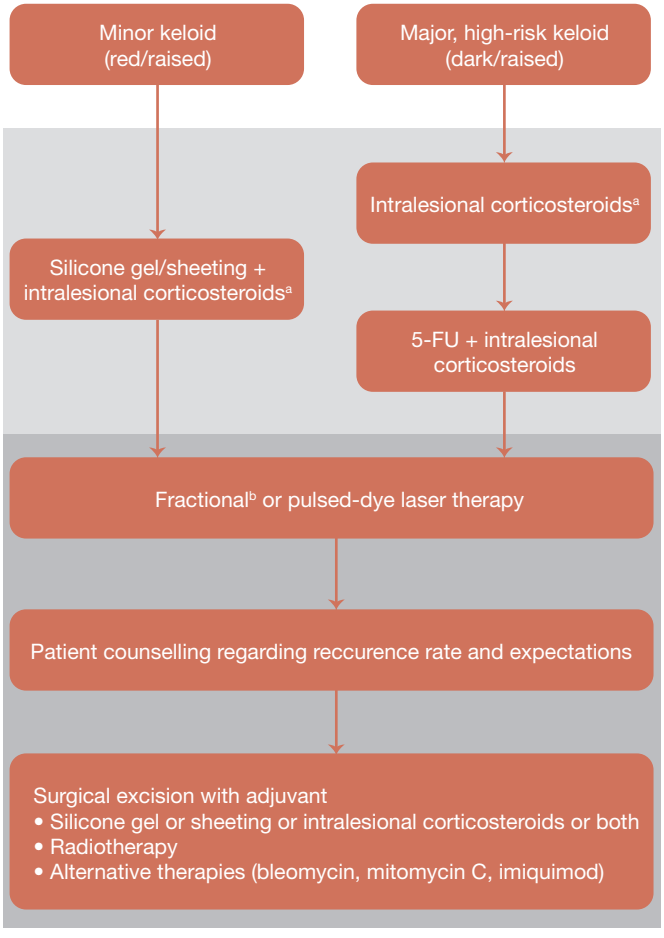

Figure 3.18 Management algorithm for keloids. Light grey indicates initial management strategies; dark grey indicates secondary management options. [a]Cryotherapy may be used in conjunction with intralesional corticosteroids, depending on physician experience and comfort with its application. [b]Ablative fractional lasers are the preferred initial laser therapy option for patients with minor keloids. 5-FU, 5-fluorouracil. CHAPTER 4

Tissue engineering and regenerative therapies

Learning objectives

To understand:

- The potential opportunities afforded by tissue engineering and regenerative therapy
- The nature of stem cells, including somatic and adult stem cells, embryonic stem cells and induced pluripotent stem cells
- The role and range of materials and scaffolds for tissue engineering
- The role and range of molecules and their delivery
- The main challenges, safety issues and future directions

INTRODUCTION

Tissue engineering and regenerative medicine are relatively new but rapidly expanding multidisciplinary fields relevant to surgery that have the potential to transform the treatment of a wide range of human diseases. The ability of tissues to undergo spontaneous repair and regeneration is highly variable and, in most cases, limited. This has driven the development of approaches that harness the biology at the site of tissue damage to mediate regeneration through the localised delivery of cells, materials and molecules. The continuing improvement in our understanding of how tissues are formed and how they heal underpins the continuous development of novel approaches. As these technologies improve, translate and build up clinical evidence of effectiveness, the prospect of actual tissue regeneration, not just repair, will establish clinical utility. In this chapter, we explore the development of the tissue engineering paradigm (*Figure 4.1*) and the constituent processes that have been used to enhance tissue healing by considering cells, materials and molecules and the interplay between them, alongside key exemplars. We further highlight the opportunities, challenges and likely future directions for the field.

OPPORTUNITIES

The potential impact of tissue engineering and regenerative therapies is so far-reaching that practising surgeons should be aware of the resulting opportunities to improve patient management. Several conditions that could benefit from this approach are of particular relevance to surgeons because they are closely involved in assessment and treatment (*Table 4.1*). Selected examples include the repair or replacement of injured or diseased cartilage, skin, pancreatic islets, bladder, intestine, heart tissue, arteries, larynx and bronchus. A longer term goal in tissue engineering is the replacement of diseased whole organs such as the liver and kidney, although the technical challenges here are enormous.

TABLE 4.1 Examples of tissues created by tissue engineering and conditions they may be used to treat.

Tissue	Conditions treated
Skin	Burns and skin defects after excision or trauma
Eye	Retinal and corneal disease
Cardiac muscle	Heart failure
Heart valves	Congenital and acquired valvular heart disease
Cartilage and bone	Degenerative and traumatic bone and joint disorders
Trachea and bronchus	Congenital and acquired stenosis and resection for malignancy
Bladder	Congenital bladder malformation and cystectomy
Anal/bladder sphincter	Incontinence
Pancreatic islets	Insulin-dependent diabetes
Large blood vessels	Atheromatous, aneurysmal and traumatic arterial disease
Oesophagus	Benign stenosis and resection for malignancy
Small intestine	Intestinal failure after surgical resection for Crohn's disease, cancer or ischaemia

Surgeons are integral to many of the multidisciplinary research teams currently undertaking translational research in this field and will play a vital role in the future delivery and

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

evaluation of resulting treatments. In addition to its direct therapeutic application, tissue engineering also has the potential to provide *in vitro* tissues that can be used to model human disease and to test therapeutic drugs for efficacy and toxicity. However, it is important to emphasise that, while the potential benefit of cell therapy and tissue engineering is undeniable, there are many technical, regulatory and safety issues to be addressed for it to have wide clinical impact.

Summary box 4.1

Tissue engineering and regenerative therapies

These have potential to provide:

- Treatment for a wide range of diseases
- Clinical applications – underpinned by translational research, delivery strategies and clinical evidence
- Models to test therapeutic efficacy and toxicity

KEY AREAS OF UNDERPINNING SCIENCE

Advances in tissue engineering and more broadly regenerative medicine are underpinned by developments in both the physical and biological sciences, building on the classical tissue engineering paradigm (***Figure 4.1***). An improved understanding of developmental biology and the cues that direct stem cell fate have been key to advancement of the field. A better understanding of the stem cell niche has enabled scientists to propose changes to molecular and mechanical properties that could bring about modified cell behaviour. This has been realised by advances in materials science, which have been critical in the development of structures (scaffolds), onto and into which cells can be grown and where delivery vehicles can be used to localise cells and molecules to a specific site within the body. Notwithstanding the potential offered by these therapies, it should be emphasised that the whole field is still at a relatively early stage of development. Although there are examples where tissue engineering and regenerative therapies have already been introduced into clinical practice, for example the repair of damaged cartilage, most potential regenerative therapies have not yet entered routine surgical practice as there are considerable barriers to be overcome before this translational step can be achieved. We have divided the chapter into sections relating to cells, materials and molecules, while recognising the interplay and composite therapeutic solutions that ultimately arise.

CELLS

Although both fully differentiated cells (somatic cells) and stem cells are being used and developed for tissue engineering and regenerative therapy, most of the focus is on the use of stem cells, particularly somatic stem cells (SSCs) and induced pluripotent stem cells (iPSCs). The major features of the different cell types are listed in ***Table 4.2***.

Somatic cells

Fully differentiated specialised cells (somatic cells) obtained from normal tissues have been used for tissue engineering and regenerative therapy with some degree of success. For example, skin has been engineered using cultured epithelial cells grown *in vitro* and used to treat patients with burn injuries. Chondrocytes have been isolated, expanded *in vitro* and implanted into areas of deficient cartilage in a procedure called autologous chondrocyte implantation. Bladder wall has

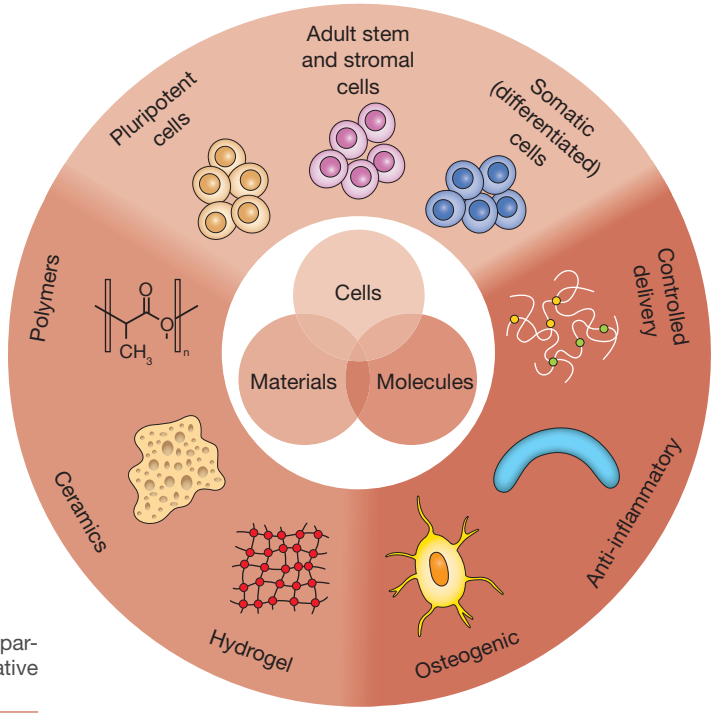

Figure 4.1 The tissue engineering paradigm in the context of regenerative therapies.

TABLE 4.2 Cells used in tissue engineering and regenerative therapy.

Cell type	Somatic cells	SSCs	hESCs	Fetal cells	iPSCs
Ease of availability	Limited	Good	Moderate	Moderate	Good
Expansion *in vitro*	Limited	Good	Excellent	Good	Excellent
Potency	No	Limited	Excellent	Limited	Excellent
Ethical concerns	No	No	Yes	Yes	Yes[a]
Risk of malignancy	None	Low	Moderate	Moderate	Moderate
Autologous	Yes	Yes	No	No	Yes
Anticipated future use	Limited	High	Limited	Limited	High

hESCs, human embryonic stem cells; iPSCs, induced pluripotent stem cells; SSCs, somatic stem cells. [a]Note that iPSCs avoid some of the ethical issues associated with hESCs.

also been engineered using a combination of smooth muscle cells and uroepithelial cells expanded *in vitro* and grown on a scaffold before reimplantation. Such tissues can be grown using cells obtained from the intended recipient by tissue biopsy (autologous cells) or using cells obtained from unrelated donors (allogeneic cells). The major advantage of the former source is that, after implantation, they are not rejected by the recipient's immune system; hence there is no requirement for immunosuppression (see ***Chapter 88***).

For other indications, the use of fully differentiated specialised cells is not practical in most situations because such cells are not readily available in sufficient numbers and they have only limited proliferative ability *in vitro*, which means that their numbers cannot be readily expanded to sufficient levels. To overcome these limitations, the major focus in the field of cell therapy has been on the use of stem cells.

Stem cells

Stem cells are undifferentiated or non-specialised cells that are able, through cell division, to renew themselves indefinitely (self-renewal). Crucially, they are also able, when provided with appropriate stimuli, to differentiate into one or more of the different types of specialised cell found in tissues and organs (potency). Because of their unique ability to undergo self-renewal when cultured *in vitro* and to be directed to differentiate into specialised cell types, they have enormous potential for use as cell-based therapies or, by way of their different characteristics, to otherwise contribute to regenerative medicine.

Stem cells can be classified in different ways, for example by using their characteristic level of potency such as pluripotent and multipotent (***Figure 4.2***) or with reference to the tissue from which they are derived, for example the early embryo

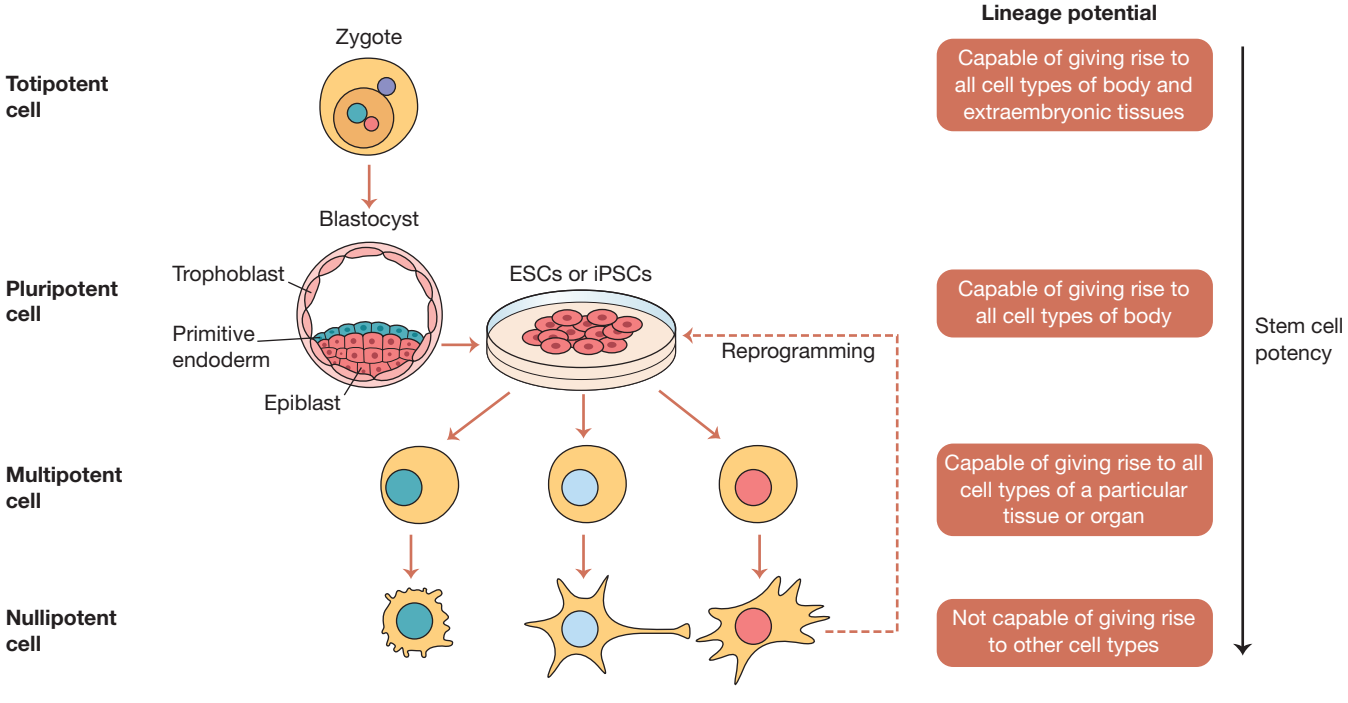

Figure 4.2 Hierarchy of cells according to potency, ranging from stem cells to specialised differentiated cells. ESC, embryonic stem cell; iPSC, induced pluripotent stem cell. (Adapted with permission from Tewary M, Shakiba N, Zandstra PW. Stem cell bioengineering: building from stem cell biology. *Nat Rev Genet 2018*; **19**: 595–614.)

(embryonic stem cells [ESCs]), later in development (SSCs) or whether they are derived by reprogramming adult specialised cells to a pluripotent state (iPSCs).

Adult tissue resident or somatic stem cells

Stem cells resident in the different tissues and organs are responsible for providing replacements for specialised cells that have reached the end of their functional lifespan either through natural attrition or because of damage and disease. In certain tissues and organs, notably the bone marrow and gut, stem cells regularly divide and differentiate into specialised cells to replace senescent or damaged cells in the blood and the gastrointestinal mucosa, respectively. Stem cells in other organs, such as the heart or central nervous system, are less able to effect repair or replacement. SSCs have the capacity to differentiate into a limited number of specialised cell types (multipotent); among the best characterised types are haematopoietic stem cells. In tissue engineering and regenerative medicine, mesenchymal stem or stromal cell (MSC) populations are widely described but have been more difficult to characterise, particularly in terms of stem cell attributes relating to clinical use.

Mesenchymal stem and stromal cells

Building on earlier observations in the 1960s[1] relating to bone marrow-derived cell populations, in the 1990s the term 'mesenchymal stem cell' (MSC) was used in relation to therapy, based on observations that some of these cells, under the right conditions, could differentiate into cell types relating to musculoskeletal, adipose and other tissues.[2] In 2005 the International Society for Cellular Therapy (now the International Society for Cell and Gene Therapy; ISCT) proposed that these cells be termed multipotent 'mesenchymal stromal cells' with the same abbreviation MSC, and that the term mesenchymal stem cell should be 'reserved for a subset of these (or other) cells that demonstrate stem cell activity by clearly stated criteria'.[3] They went on to describe minimum criteria in 2006[4]: adherence to plastic, expression of certain surface markers (CD105, CD73 and CD90) but a lack of expression of others (CD45, CD34, CD14 or CD11b, CD79α or CD19 and HLA-DR) and, finally, the ability to differentiate into osteoblasts, adipocytes and chondroblasts *in vitro*, often described by authors as trilineage differentiation.

The importance of nomenclature relates to the mechanism by which such cells might achieve a clinical effect. The earlier term mesenchymal 'stem' cell implies that cells directly contribute to repair and regeneration by differentiation, whereas using the term 'stromal' can encompass paracrine and secretory behaviour, in which cells are envisaged to work with other cells to influence the outcome of repair and regeneration (***Figure 4.3***). As a consequence, the term mesenchymal 'stem' cell has been highlighted as a cause of potential confusion, whereby patients might wrongly infer that the cell constitutes a 'stem cell therapy'.[5,6] In 2019, the ISCT gave continued support for the term mesenchymal stromal cell but recommended that it be: supplemented with the tissue source of the cell; intended unless rigorous evidence for stemness exits; associated with robust functional assays demonstrating properties.[7]

A further consideration is the manufacture and delivery of such cells. MSCs can be isolated from bone marrow (iliac crest aspiration) or from subcutaneous fat (liposuction/lipoaspiration). Cells can be delivered at the point of care, using bedside systems, or isolated *in vitro* on the basis of their adherence to plastic and subsequently further characterised. Therefore, they can be used shortly after extraction or after expansion of their numbers by *in vitro* culture. Furthermore, MSCs can be differentiated into the desired lineage *in vitro* by addition of suitable growth factors and chemicals.

The wide variety of cell type, source and manufacturing process represent important opportunities for treatment.

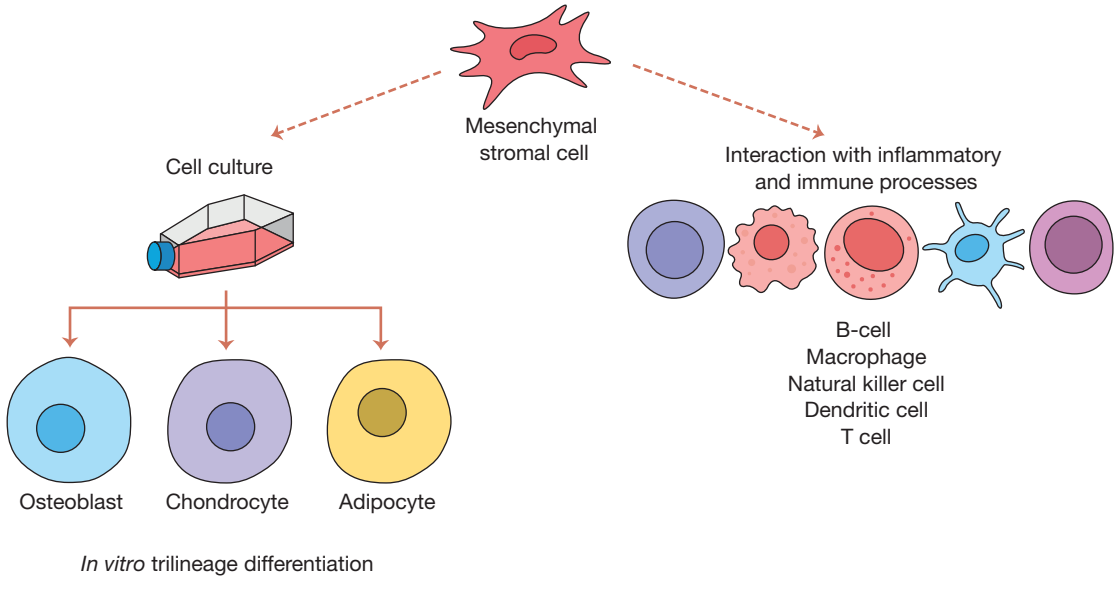

Figure 4.3 Proposed characteristics of mesenchymal stromal cells relevant to tissue engineering and regenerative medicine.

However, they also demonstrate considerable heterogeneity, the understanding of which will be greatly improved by molecular biology techniques and functional assay. In terms of agreed nomenclature, a report on consensus has described key parameters in the abbreviation DOSES: D – donor, O – origin tissue, S – separation method, E – exhibited characteristics, S – site of delivery.[8]

The relative ease of cell acquisition has meant that autologous MSCs have been used in clinical settings and they represent a great opportunity for new treatment development. Before widespread adoption, more translational research is required to understand and refine the therapeutic mechanism of action and conduct well-designed clinical trials to establish the evidence of effectiveness.

Embryonic stem cells

In the embryo, stem cells are able to give rise to all of the different cell types of the body at the gamete stage (totipotent) and nearly all cell types (pluripotent) when at the blastocyst stage (***Figure 4.1***). ESCs can be obtained from the inner cell mass of the early human blastocyst (days 4–5), using embryos that have been created through *in vitro* treatment of infertility and are surplus to those needed for reimplantation. The technique for isolating and growing human ESCs in culture was developed by James Thomson in 1998.[9]

ESCs have proliferative ability and possess key characteristics of self-renewal and pluripotency. However, their use in the clinic has major limitations, one of which is ethical. The surplus embryos used for derivation of ESCs would otherwise be discarded but, because they need to be destroyed to obtain ESCs, the approach has raised major ethical and political debate. The dominant view in many countries, including the UK, is that the potential therapeutic benefits of ESCs justify their use but there are very strict guidelines for their derivation; to date their clinical use has been limited. Cells from ESCs would be allogeneic and therefore be at risk of immunological rejection.

Induced pluripotent stem cells

The discovery in 2006 by Shinya Yamanaka,[10] building on the earlier work of John Gurdon,[11] that certain types of specialised adult cells could be reprogrammed using genetic manipulation to become embryonic-like iPSCs was a major breakthrough. Using retroviral or lentiviral transfection to introduce a combination of transcription factors (OCT3/4, SOX2 and either Kruppel-like factor and C-MYC [together designated the OSKM reprogramming factors] or NANOG and LIN28), it was shown that specialised somatic cells can be reprogrammed to become stem cells. Moreover, iPSCs proliferate *in vitro* as efficiently as ESCs and are pluripotent, thereby circumventing concerns about the use of human embryos. Importantly, the development of iPSCs also means that, at least in principle, an intended recipient of stem cell therapy can themselves provide a source of stem cells (e.g. from a skin biopsy or blood sample) that can then be directed to differentiate into the desired specialised cell type for therapy; because such cells would be autologous they would not provoke an immunological rejection response (***Figure 4.4***). Alternatively, iPSCs could be obtained from a number of volunteer donors selected on the basis of their HLA type and stored to create a national or international tissue bank of iPSCs. Lines of iPSCs could then be chosen from the bank to provide a fully or partially matched cell transplant for recipients, eliminating or reducing the need for immunosuppression to prevent immunological rejection.

One of the problems of reprogramming somatic cells to become iPSCs using retroviruses is that genomic integration of the virus may lead to activation of oncogenic genes, causing tumorigenesis. To reduce this risk, non-retroviral vectors have been used (such as adenovirus and Sendai virus vectors, which do not insert their own genes into the host cell genome) or plasmids, episomal vectors and synthetic RNA. There has also been much recent progress in identifying combinations of small molecules, growth factors and chemicals that mimic the effect of viral transfection with transcription factors and obviate the need for viral vectors altogether. The production process from sourcing cells (e.g. skin fibroblasts or peripheral blood mononuclear cells) to obtaining an adequate number of validated iPSCs may take several weeks.

In vitro differentiation of stem cells to specialised tissue cells

There is an enormous research effort aimed at better understanding the factors responsible for cell fate decisions and establishing effective and reproducible protocols that can be used to differentiate stem cells *in vitro* into the desired type of specialised cell. Typically, such protocols use culture in chemically defined media containing cocktails of small molecules that stimulate or inhibit key signalling pathways, along with cytokines, growth factors and chemicals. It is becoming increasingly clear that exposure to certain biomaterials and the physical attributes of a scaffold, including its surface characteristics, also promote stem cell differentiation along a particular lineage. Mechanical stress also influences cell fate decisions. After stem cells have been subjected to *in vitro* differentiation, it is essential that the purity of the differentiated cells and the absence of undifferentiated stem cells are confirmed to reduce the risk of tumour transmission. The cells must also be fully characterised and their function confirmed before they are used for therapeutic purposes.

Exemplars: cells as a therapy

The delivery of cells into damaged tissues has long been used to facilitate enhanced regeneration. The first modern example of successful cell therapy was bone marrow transplantation for the treatment of leukaemia, which was successfully performed in 1956. Since then, cells have been used for the regeneration

Sir John Bertrand Gurdon, b. 1933, British developmental biologist, winner of the Nobel Prize in Physiology or Medicine in 2012 with Shinya Yamanaka.

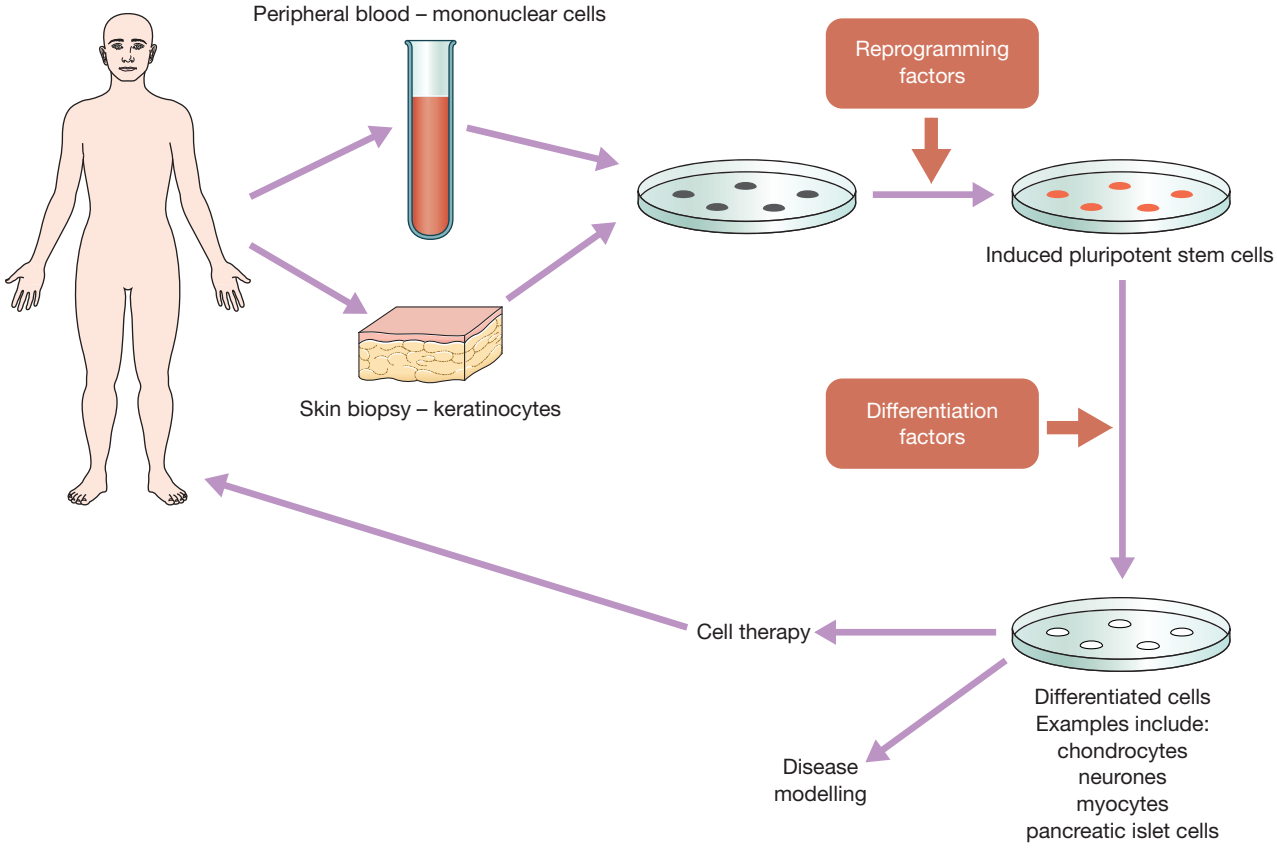

Figure 4.4 Schematic diagram showing the principles of induced pluripotent stem cell (iPSC) therapy. Mononuclear cells from peripheral blood or keratinocytes from a skin biopsy are cultured *in vitro* and then reprogrammed to become iPSCs by addition of reprogramming factors. The iPSCs are then expanded and selected differentiation factors added to promote differentiation of iPSCs into the desired specialised cell type for use as therapy.

of a range of different tissues. The following section details exemplars of the use of cells as therapeutic agents, for the regeneration of skin and cartilage (articular and auricular).

Skin

The tissue that was one of the first regenerated using human cells was skin. The pioneering work of Rheinwald and Green in this area led to the identification of optimal conditions for the growth and maintenance of keratinocytes harvested from skin in culture. The first tissue engineered skin consisted of a layer of keratinocytes grown on a collagenous membrane, which could be directly applied to a healing wound. In the original skin tissue engineering process, the keratinocytes were grown onto a membrane and were cultured in the same system as a layer of confluent but (unable to divide) fibroblasts. The fibroblasts are required in this culture because they provide a series of paracrine factors that allow for the keratinocytes to maintain their phenotype and also mature when lifted to the air–liquid interface. The fibroblasts had to be mitotically inhibited because they tend to proliferate at a greater rate than the keratinocytes and can consequently overtake the complex culture. As a consequence of the need for multiple steps and cell types, in addition to the air-lift required for stratification of the epidermal keratinocyte layer to occur, the process is relatively slow (requiring up to a month). This means that the burn wound to be resurfaced using this process needs to be closed and protected prior to application. This process has been refined over the years and has resulted in the development of a range of technologies, some of which are still on the market. Despite a reasonable level of integration, the skin itself lacks many of the features of normal human skin, for example coloration, and is not in widespread use in the clinic.

Articular cartilage regeneration

Microfracture or microdrilling (***Figure 4.5***) into subchondral bone at the base of a chondral defect creates a communication between the intra-articular and subchondral spaces, allowing blood, containing bone marrow stromal cells, to arrive at the defect. Used clinically for more than 30 years, the formation of the clot creates an environment that allows for the reformation of cartilage within the defect, which subsequently provides a level of mechanical function. Although widely used in the clinic with success, the cartilage formed is typically fibrocartilage, which is mechanically inferior to the native articular cartilage and lacks longer term durability.

James George Rheinwald, b. 1948, American research scientist.
Howard Green, 1925–2015, George Higginson Professor of Cell Biology, Harvard Medical School, Boston, MA, USA, pioneer in the science of skin regeneration.

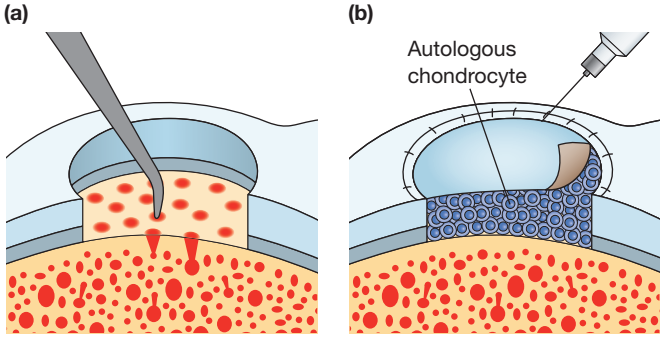

Figure 4.5 Examples of (a) endogenous cell targeting (microfracture) and (b) cells being used as a therapy (autologous chondrocyte implantation). (Adapted with permission from Makris E, Gomoll A, Malizos K *et al*. Repair and tissue engineering techniques for articular cartilage. *Nat Rev Rheumatol* 2015; **11**, 21–34.)

To overcome these limitations, research has focused on ways to create an environment in the chondral defect that is more conducive to the formation of articular or hyaline cartilage. Autologous chondrocyte implantation (ACI) is one such method (***Figure 4.5***). In the first step a small number of cells are harvested from healthy cartilage within a patient's joint, for example the knee. The cells are then expanded, to increase the cell number, in a laboratory (with good manufacturing practice [GMP] quality standards). In a second procedural step, cells are reintroduced into the defect, classically with a surgically positioned 'roof' or patch over the defect, prior to injection of the cells below. In 2017, following the evaluation of evidence, the UK's National Institute for Health and Care Excellence (NICE) recommended ACI for use in the National Health Service (NHS). The recommendation was for defined patients who have symptomatic articular cartilage defects of the knee, with a cost-effectiveness estimate thought likely to be less than £20 000 per quality-adjusted life year (QALY) gained.

MATERIALS

A large number of materials have been used in tissue engineering and regenerative medicine, either as delivery vehicles or as scaffolds; it is beyond the scope of this chapter to describe them extensively (see ***Further reading***). In simple terms, materials can be either natural or synthetic and further characterised by their mechanical properties, which will often need to take account of porosity. A further layer of complexity relates to specific molecules within and upon the material and the intended targeting or seeding with cells. In this section, we will focus on synthetic polymers, hydrogels and osteoinductive ceramics such as Bioglass®. These materials have been selected because of their broad relevance in tissue engineering and regenerative medicine.

Exemplars: materials in development

Synthetic and engineered polymers

Synthetic polymers are those made from chemical processing of natural components or from complex synthesis from precursors such as fossil fuels. There are a great many synthetic polymers that are used in the body, including polymethyl methacrylate (PMMA), which is used to make intraocular lenses and as a cement in joint replacement; Dacron™ (Terylene™), used in vascular grafts; and a range of resorbable materials, including poly(caprolactone) (PCL), poly(lactic acid) (PLA), poly(glycolic acid) (PGA) and copolymers thereof (PLGA). These resorbable polymers have been used in the body for some time as sutures and in other degradable structures. Moreover, they have become widely used in regenerative medicine for the production of scaffolds, on which cells can be seeded and grown prior to, during or after implantation into the body. Synthetic materials can be processed in a range of different ways in order to provide a structure optimised to the intended purpose. Porous monoliths can be produced by foaming processes, which can include but are not limited to infiltration and then expansion of supercritical carbon dioxide in order to create a foamed structure. The pore sizes of such structures may be tailored by modifying process conditions or material compositions (***Figure 4.6***).

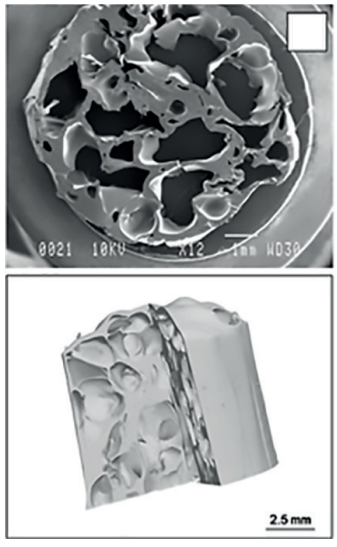

Figure 4.6 Electron micrograph of a poly(lactic acid) scaffold foamed using supercritical carbon dioxide (a) with pore structure assessed using micro-computed tomography (b). (Adapted with permission from Collins NJ, Leeke GA, Bridson RH *et al*. The influence of silica on pore diameter and distribution in PLA scaffolds produced using supercritical CO_2. *J Mater Sci: Mater Med* 2008; **19**: 1497–502.)

Such polymers can also be formed as spheres by using emulsion processing or they can be processed into a mat of fibres using a process known as electrospinning, whereby charged threads of polymer are drawn using an electric field and subsequently deposited onto a surface (***Figure 4.7***). Manufactured in this way, the materials tend to have a very high surface area and can exhibit structural features across the same length scales as the fibrous components of the extracellular matrix. As a consequence, electrospun patches have been designed for the repair of anatomical structures such as the rotator cuff and have even been used to explore how modifications in matrix geometry may result in pathology.

Bioceramics

A range of ceramics have been used for the delivery of compounds that can trigger the regeneration of mineralised tissues.

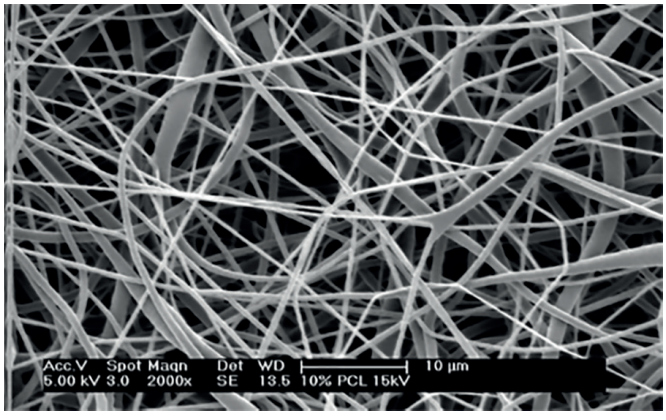

Figure 4.7 Electrospun poly(caprolactone) fibres intended for use in tendon reconstruction (courtesy of Dr Anita Ghag).

The most widely used such material is Bioglass®, a glassy material (a ceramic with no crystal structure) containing calcium, silicate and phosphate ions (Na_2O–CaO–P_2O_5–SiO_2). When placed into an aqueous environment, such as within body fluids, the surface of the ceramic material can break down, releasing the component ions into the surrounding liquid. This can result in the deposition of a bone-like mineral across the surface of the material itself, which can encourage the material to bond to surrounding hard and soft tissues. In addition, the eluted ions can trigger specific biological responses that include the recruitment and differentiation of mesenchymal cell populations. Bioglass® has been used in a range of medical products and has recently been widely applied in remineralising toothpaste formulations (as Novamin®). The incorporation of other ions, such as strontium and lithium, into the glassy matrix can drive specific biological processes, enhancing the process of bone formation. Bioglass® can be manufactured as a foamed structure and as a monolith. It is most frequently supplied in the form of granules and incorporated into polymer matrices to drive the process of bone integration.

Hydrogels

Hydrogels are an emerging and increasingly researched class of materials in regenerative medicine. They consist of hydrophilic polymers that are typically dispersed in an aqueous component to form a hydrocolloid. Interactions between the individual polymer chains can then be formed by modifying the temperature, adding ions or adding a chemical cross-linking agent. The resulting network retains water and forms a solid but highly hydrated structure (typically *c.* 99wt% water). The high water content of these materials means that nutrients, oxygen and metabolic by-products can diffuse through them. As a consequence, they have been widely used for the encapsulation of cells, typically allowing the maintenance of high levels of viability. Alginate, a seaweed-derived polysaccharide blend, for example, has been used to protect pancreatic islets from immunological attack. In recent years, this approach has been refined to allow for pancreatic islets to be shipped between medical centres (***Figure 4.8***). Other materials that form gels include chitosan, gellan, collagen and hyaluronic acid. In addition to these biologically derived materials, hydrogels may also be formed from synthetic polymers, including poly(ethylene glycol), and these can be chemically modified to provide specific biological stimuli to entrapped cells.

Additive layer manufacturing and hydrogels

As described above, hydrogels have been used for cell encapsulation. The potential to modify both the chemical and mechanical properties exhibited by these materials makes them perfect candidates for the growth of tissues outside the body, prior to eventual implantation into a defect site inside the body. As a consequence, hydrogel-based structures have provided scaffolding for many different engineered tissues, ranging from bone through to brain. However, a major issue

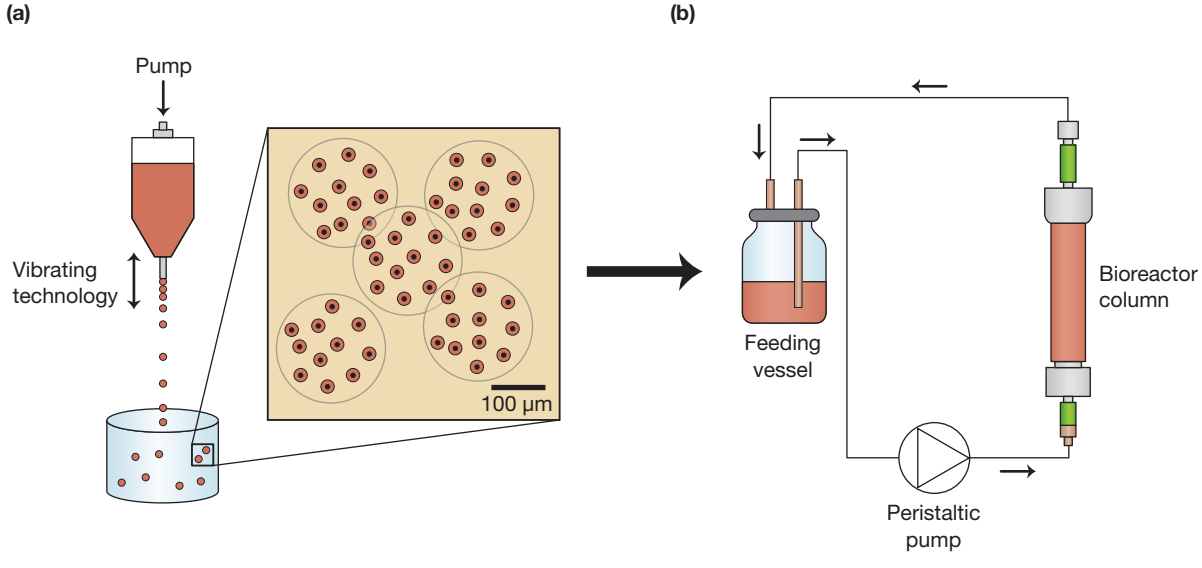

Figure 4.8 Schematic of **(a)** pancreatic β-cell encapsulation and **(b)** bioreactor cultivation. (Adapted with permission from Nikravesh N, Cox SC, Ellis MJ, Grover LM. Encapsulation and fluidization maintains the viability and glucose sensitivity of beta-cells. *ACS Biomater Sci Eng* 2017; 3(8): 1750–7.)

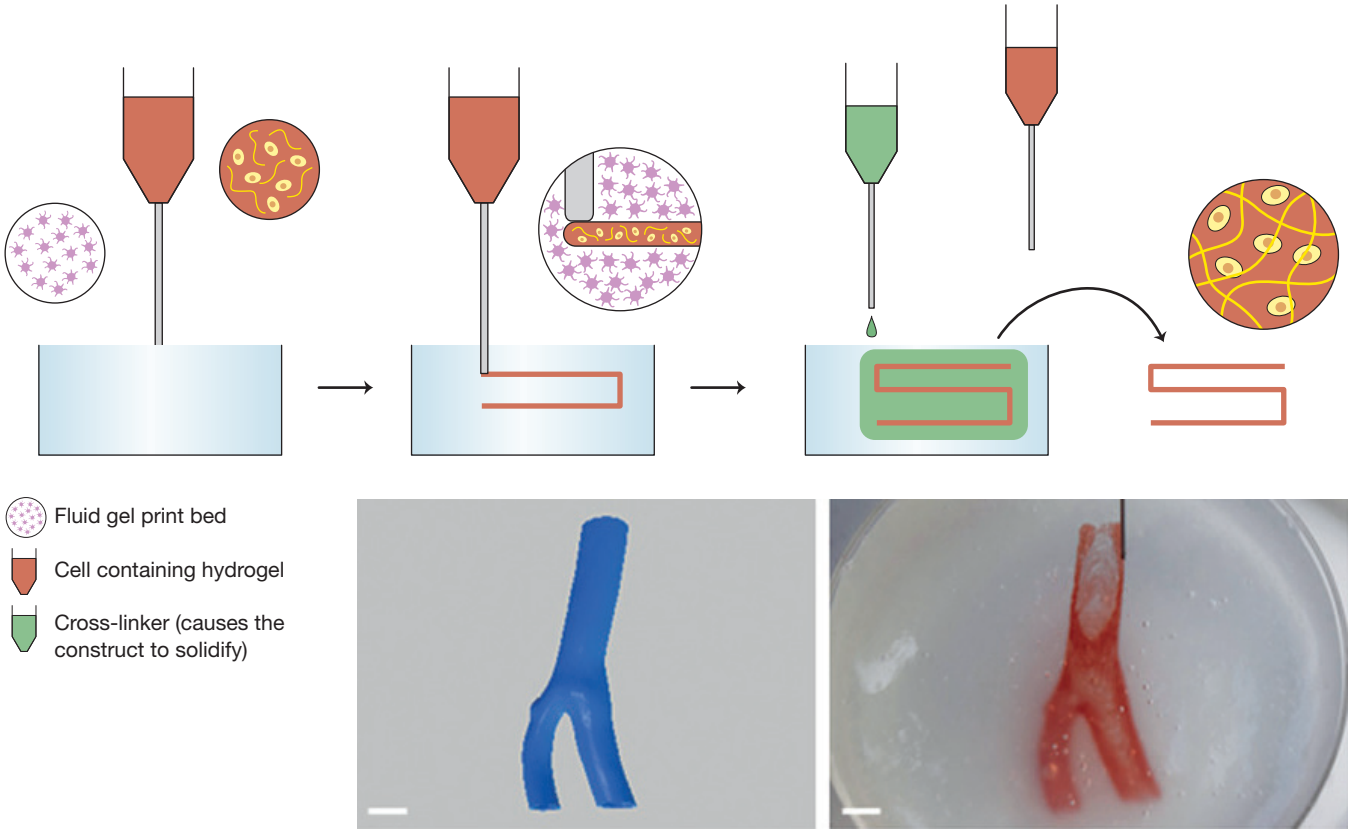

Figure 4.9 Schematic showing the formation of complex hydrogel structures using a suspended manufacturing process where a cell containing hydrogel is deposited into a supportive bed. This process allows for the production of hydrogels in complex geometries such as the carotid arteries shown here. (Adapted with permission from Senior JJ, Cooke ME, Grover LM, Smith AM. Fabrication of complex hydrogel structures using suspended layer additive manufacturing (SLAM). *Adv Funct Mater* 2019; **29**: 1904845.)

with hydrogels is that they are normally extremely weak during the gelation process, meaning that they will slump and lose their shape when cast. In order to get around this major issue, printed structures may be suspended in a secondary (often shear thinning) medium that provides both a level of support during the printing process and time for the hydrogel to develop sufficient mechanical integrity to support its own weight. Once this point has been reached, the structure can be removed from the supporting medium and washed prior to onward culturing. A wide range of substances have been used to provide support, including Pluronic® and agarose; however, the most widely used method currently is known as free-form reversible embedding of suspended hydrogels (FRESH), which uses gelatin. The FRESH method utilises a macerated gelatin-based support matrix. The particulate nature of the gelatin means that the printed hydrogel (which may or may not contain cells) can be deposited within the bed and will be supported while the mechanical properties exhibited by the as-deposited hydrogel become fully developed. The supporting matrix can then be melted (at 37°C) to leave the complex hydrogel structure. Other suspended printing methods have been developed that do not require the use of an animal-derived support medium (and that are therefore compatible with translation to the clinic) or the elevation of temperature to remove the supporting phase. One such method, suspended layer additive manufacturing (SLAM), uses a supportive matrix formed from hydrogel particulate systems that shear thin but exhibit rapid elastic recovery; this allows for the production of high-resolution prints that can be removed from the supporting bed by the application of a simple wash with water. This method enables the production of structures exhibiting complex morphology, such as the carotid artery (***Figure 4.9***), and can even be used to produce structures formed or modified from multiple material types, meaning that structures can be tailored with high resolution. With clinical relevance, SLAM has been used to manufacture osteochondral plugs containing both bony and cartilaginous regions. At present, these technologies are most likely to have an impact on disease modelling and drug candidate evaluation, but in the longer term they may emerge as key technologies facilitating tissue regeneration.

MOLECULES

Modification of the tissue environment during healing can be achieved by the delivery of molecules that are selected and able to specifically modify biological responses at the site of injury. In terms of tissue regeneration, these molecules can modulate the inflammatory environment, either by enhancement or by

inhibition of specific biological response pathways, such as angiogenesis. This approach has been used to optimise tissue regeneration across several applications, with specific examples, for the skin and the eye, described below.

Exemplars: molecules in action

Healing skin without scarring

All tissues in the body, when damaged, are subject to a conserved process by which cells are recruited to the wound to remove damaged tissue fragments and then deposit and subsequently remodel the tissue (see ***Chapter 3***). In the case of the skin, the initial damage results in bleeding into the wound followed by haemostasis and, when the platelets within the clot degranulate, the secretion of proinflammatory factors. The tumour necrosis factor alpha (TNFα), interleukin (IL) 1 and IL-6, platelet-derived growth factor (PDGF), fibroblast growth factor (FGF), insulin-like growth factor 1 (IGF-1) and vascular endothelial growth factor (VEGF) recruit monocytes and endothelial cells into the wound bed to begin the wound-healing process. These cells release further cytokines, such as transforming growth factor beta 1 (TGFβ1), that mediate the formation of new extracellular matrix (normally initially collagen III in skin). Over time, the collagen III is remodelled and replaced with collagen I, which is normally deposited in a basket weave pattern. This process very efficiently closes wounds and, when not too severe, healing can be with minimal scar formation. In the case of severe damage or infection, the inflammatory response can 'overshoot', resulting in the overproduction of cytokines such as TGFβ1, which drive the recruitment of excess myofibroblasts to the wound site. This leads to the deposition and subsequent overcontraction of collagen matrix, which can result in the classic appearance of a scar.

A number of interventions have targeted this process with the aim of preventing the formation of a scar on the skin. Of note was the identification and isolation of TGFβ3, which plays a role in regulating extracellular matrix formation. This molecule was shown to regulate wound healing by blocking the TGFβ1 and -2 receptors on the cell surface and by modulating the penetration of cells in a newly forming tissue. TGFβ3 was subsequently developed as a therapeutic agent for use within the skin, with the aim of preventing scar formation. As TGFβ3 is a large, protein-based drug it was challenging to manufacture and purify and so was expensive in comparison with small-molecule drugs. Although this molecule had significant potential as an antiscarring agent in phase I and II trials, ultimately it was not adopted. This is an exemplar of a translational approach, working from a proposed mechanism through to stepwise clinical trials to test effectiveness.

Molecular delivery to prevent ocular fibrosis

Another example of the function of a tissue being significantly impaired by fibrosis is the eye. When the cornea is damaged, as long as the wound is kept clean, re-epithelialisation of the surface can occur relatively quickly with full restoration of the corneal surface within 7 days or so. However, if there is an infection on the surface of the eye there can be a potent inflammatory response that results in the rapid and disordered deposition of collagenous tissue across the ocular surface. If the surface of the eye becomes cloudy as a consequence, the patient can become blind. Recent work to create a therapeutic agent to prevent ocular scarring has focused on the localised delivery of a TGFβ1 antagonist called decorin. Decorin is a proteoglycan with a high affinity for collagen I, which it decorates the surface of in normal extracellular matrix. When free in solution, decorin also has an affinity to seven different cytokine molecules, one of which is TGFβ1, and has been shown to modulate fibrosis. A decorin-containing eye drop is able to deliver a sustained dose of decorin to the surface of the cornea following damage and subsequent infection. The drop has been shown to be effective in preclinical models of ocular fibrosis, facilitating the restoration of a transparent ocular surface with a significant reduction in markers that are usually indicative of scar formation (***Figure 4.10***).

Challenges to the delivery of molecules

Despite the opportunities afforded by molecules in tissue regeneration, major challenges remain that relate to getting the therapeutic agent to the right part of the body at the right time. Small molecules tend to diffuse rapidly through excipient (delivery) materials and so are rapidly released into the tissue environment, meaning that a strategy for sustained delivery is a necessity if repeat administration of the drug molecule is to be avoided. A number of implantable materials exist that allow for the slow localised release of molecules at the desired site of application. The majority of these are dense, degradable polymers that can be implanted locally and allowed to degrade, thus enabling sustained release of the therapeutic agent. The issues are potentially even more significant for large biomolecules such as proteins, which tend to be very sensitive to local environmental changes, with associated reductions in bioactivity. They can also have extremely high activities at very low concentrations and can be extremely expensive. In addition, excipients for these therapeutic products must be chosen very carefully so that potency is maintained and storage time maximised.

SAFETY CONCERNS

The major safety concerns of cell-based therapy and tissue engineering are listed in ***Table 4.3***. One of the most serious concerns is that of tumour formation and malignant transformation. The risk of tumour formation varies according to the cell type used, the genetic modification strategy used to transform the stem cells, the site of transplantation and whether the cells are autologous or allogeneic. The direct risk of tumour formation by the transplanted cells relates specifically to ESCs and iPSCs and there appears to be little risk with SSCs. The ability of stem cells to form teratomas is one of the hallmarks

TABLE 4.3 Risks of cell-based therapy.

- Tumour formation
- Genetic and epigenetic abnormalities
- Transmission of infection
- Poor viability and loss of function
- Differentiation to undesired cell types
- Rejection (allogeneic cells)
- Side effects of immunosuppression (allogeneic cells)

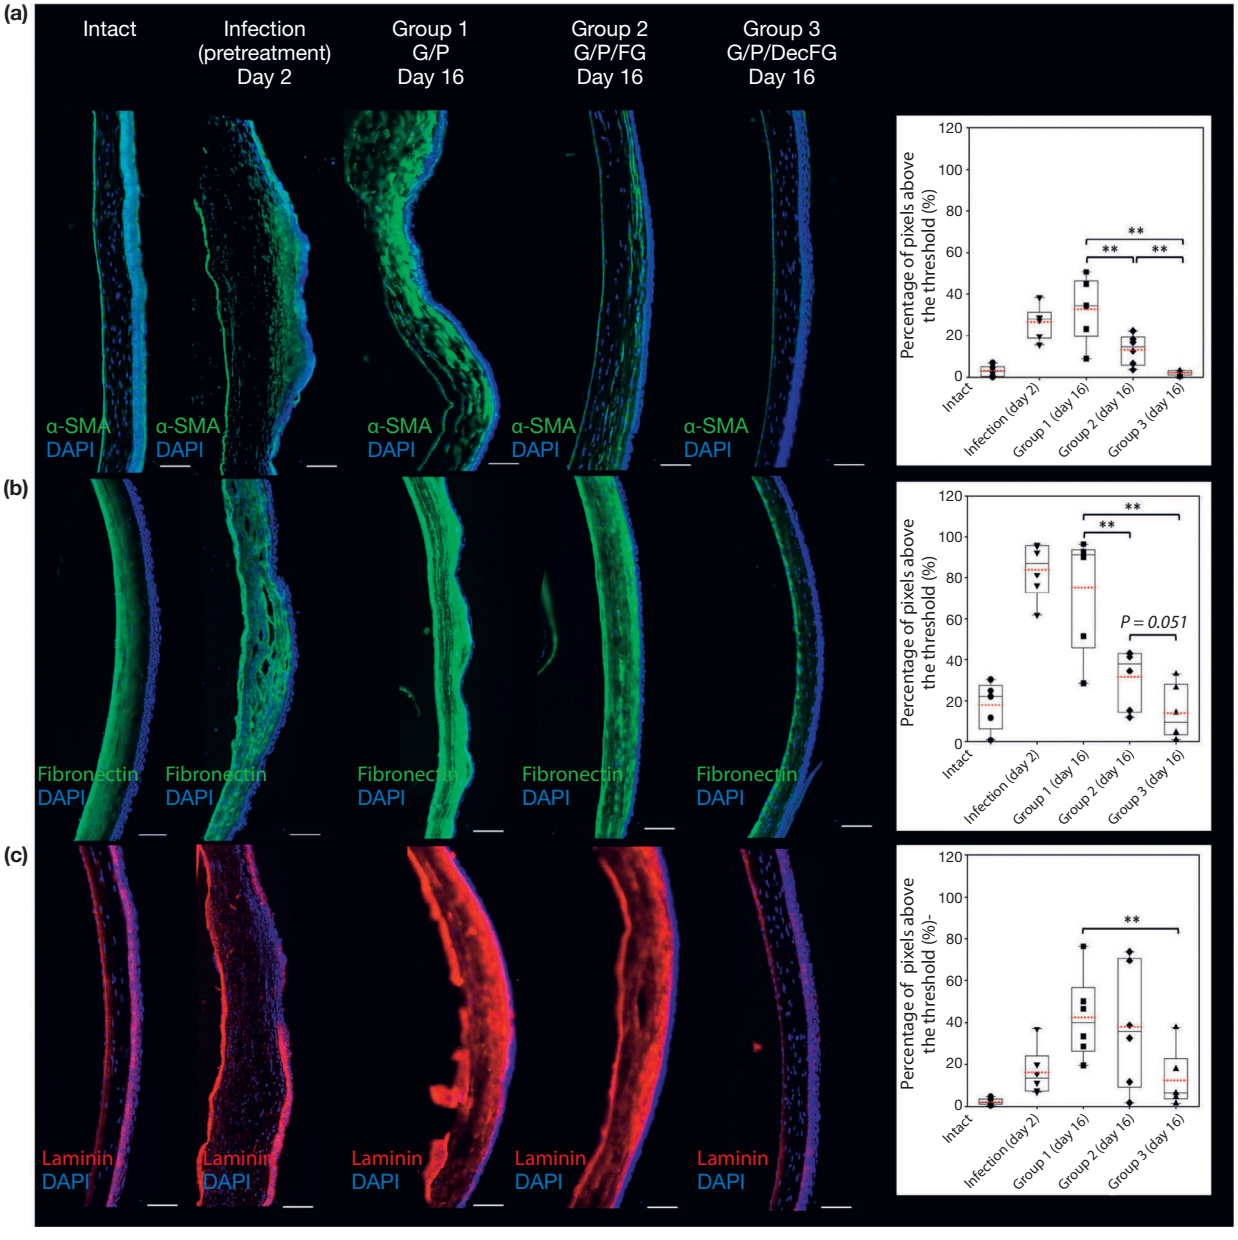

Figure 4.10 Stained sections through a mouse cornea before (left) and after (second column) injury and subsequent treatment with standard of care (gentamicin [G] and prednisolone [P]; group 1), standard of care plus a novel fluid gel carrier (FG) (group 2) and standard of care plus the carrier and decorin (Dec) (group 3). Sections are stained for markers of scarring: **(a)** α-smooth muscle actin (α-SMA), **(b)** fibronectin and **(c)** laminin. Importantly, the use of the slow-release decorin resulted in rapid restoration of the corneal structure with a significant reduction in scar markers. DAPI, 4′,6-diamidino-2-phenylindole (fluorescent stain that binds strongly to adenine-/thymine-rich regions in DNA). (Adapted with permission from Hill LJ, Moakes RJA, Vareechon C *et al*. Sustained release of decorin to the surface of the eye enables scarless corneal regeneration. *npj Regen Med* 2018; 3: 23.)

of pluripotency, and the risk of this happening following stem cell therapy may be reduced by ensuring that only cells that have been fully differentiated *in vitro*, and not those that are still pluripotent, are used for therapy. The risk of malignancy may also be reduced by the choice of *in vitro* strategy used to differentiate stem cells prior to use: the use of viral vectors that do not integrate into the genome or of non-viral approaches to differentiation reduces the risk of malignant transformation. There is also interest in developing techniques for directly reprogramming somatic cells to adopt the function of a different cell type without having to make them first revert back to the pluripotent state – so-called transdifferentiation.

Another major concern is that of transmitting infection. It is essential that if allogeneic stem cells are used they are screened to exclude infection and that cells and engineered tissues are prepared according to GMP guidelines to avoid bacterial infection during *in vitro* culture prior to use. Moreover, if allogeneic cells are used for tissue engineering and regenerative therapy, they may be susceptible to graft rejection and immunosuppressive therapy may be necessary.

FUTURE DIRECTIONS

Tissue engineering and regenerative strategies hold out great hope for effectively repairing or replacing tissues in a wide number of human diseases. The field is moving rapidly, underpinned by new developments in the relevant science in stem cells, materials and molecules. New emerging areas of technology include therapeutic signalling by way of extracellular vesicles (EVs) and gene editing of cells using CRISPR-Cas9, and gene therapies. All will require the use of a translational approach, whereby the hypothesised mechanism is developed and translated to the clinic, building up robust clinical evidence of efficacy, by way of well-designed and well-conducted clinical trials before widespread adoption.

It is likely that patient stratification will further refine therapy options. The ability to phenotype, genotype and profile patients at a molecular level will allow more detailed characterisation of patient subgroups and staging of disease. In addition to clinical studies and evidence, the rapid pace of therapy development will need to be accompanied by the development of new regulatory frameworks, for example in point-of-care manufacturing.

PART 1 | Basic principles

CHAPTER 5

Surgical infection

Learning objectives

To understand:
- The characteristics of the common surgical pathogens and their sensitivities
- The factors that determine whether a wound will become infected
- The classification of sources of infection and their severity
- The clinical presentation of surgical infections
- The indications for and choice of prophylactic antibiotics
- The spectrum of commonly used antibiotics in surgery and principles of therapy
- The misuse of antibiotic therapy with the risk of resistance to antibiotics (such as methicillin-resistant *Staphylococcus aureus* [MRSA]) and emergence of resistant strains (such as *Clostridium difficile* enteritis)

To learn:
- Koch's postulates
- The management of abscesses
- The Surviving Sepsis Campaign, sepsis bundle and Sepsis Six
- Surgical implications of the COVID-19 pandemic

To appreciate:
- The importance of aseptic and antiseptic techniques and delayed primary or secondary closure in contaminated wounds

To be aware of:
- The causes of reduced resistance to infection (host response)

To know:
- The definitions of infection, particularly at surgical sites
- What basic precautions to take to avoid surgically relevant hospital-acquired infections

HISTORY OF SURGICAL INFECTION

Background

Surgical infections have always been a major complication related to surgery and trauma and have been documented for 4000–5000 years. Egyptians popularised some concepts about infection, as they were able to prevent putrefaction using their skills in mummification. Their medical papyruses also describe the use of salves and antiseptics to prevent surgical site infections (SSIs). This 'prophylaxis' had also been known earlier by the Assyrians, although it is less well documented. It was described again independently by the Greeks.

The Hippocratic teachings described the use of antimicrobials, such as wine and vinegar, which were widely used to irrigate open, infected wounds before delayed primary or secondary wound closure. A belief common to all these civilisations, and indeed even later to the Romans, was that whenever pus was localised in an infected wound it needed to be drained.

Galen recognised that this localisation of infection (suppuration) in wounds inflicted in the gladiatorial arena often heralded recovery, particularly after drainage (*pus bonum et laudabile*). Theodoric of Cervia, Ambroise Paré and Guy de Chauliac observed that clean wounds, closed primarily, could heal without infection or suppuration.

Koch's postulates

An understanding of the causes of infection came in the nineteenth century. Microbes had been seen under the microscope, but Koch laid down the first definition of infective disease (Koch's postulates; see ***Summary box 5.1***).

The Austrian obstetrician Ignaz Semmelweis showed that puerperal sepsis could be reduced from an incidence of over

Hippocrates of Kos, Greek physician and surgeon, and by common consent 'the father of medicine', was born on the island of Kos, off Turkey, about 460 BCE and probably died in 375 BCE.
Galen, 130–200, Roman physician, commenced practice as Surgeon to the Gladiators at Pergamum (now Bergama in Turkey) and later became personal physician to the Emperor Marcus Aurelius. As a prolific writer in anatomy, medicine, pathology and philosophy, his work affected medical thinking for 15 centuries after his death. (Gladiator is Latin for 'swordsman'.)
Theodoric of Cervia, 1210–1298, Bishop of Cervia, published a book on surgery ca. 1267.
Ambroise Paré, 1510–1590, French military surgeon, also worked at the Hotel Dieu, Paris, France.
Guy de Chauliac, 1298–1368, physician and chaplain to Pope Clement VI at Avignon, France, and the author of *Chirurgia Magna*, which was published about 1363.
Robert Koch, 1843–1910, Professor of Hygiene and Bacteriology, Berlin, Germany, stated his 'Postulates' in 1882.
Ignaz Semmelweis, 1818–1865, Professor of Obstetrics, Budapest, Hungary.

Summary box 5.1

Koch's postulates proving whether a given organism is the cause of a given disease

- It must be found in every case
- It should be possible to isolate it from the host and grow it in culture
- It should reproduce the disease when injected into another healthy host
- It should be recovered from an experimentally infected host

10% to under 2% by the simple act of handwashing between cases, particularly between postmortem examinations and the delivery suite.

Louis Pasteur recognised through his germ theory that microorganisms were responsible for infecting humans and causing disease. Joseph Lister applied this knowledge to the reduction of colonising organisms in compound fractures by using antiseptics. The principles of antiseptic surgery were soon enhanced with aseptic surgery at the turn of the twentieth century. As well as killing the bacteria on the skin before surgical incision (antiseptic technique), the conditions under which the operation was performed were kept free of bacteria (aseptic technique). This technique is still employed in modern operating theatres (***Figure 5.1***).

Discovery of antibiotics

The concept of a 'magic bullet' (*Zauberkugel*) that could kill microbes but not their host became a reality with the discovery of sulphonamide chemotherapy in the mid-twentieth century. The discovery of the antibiotic penicillin is attributed to Alexander Fleming in 1928, but it was not isolated for clinical use until 1941, by Florey and Chain. The first patient to receive penicillin was Police Constable Alexander in Oxford. Since then there has been a proliferation of antibiotics with broad-spectrum activity and antibiotics today remain the mainstay of antimicrobial therapy.

Misuse of antibiotic therapy with the risk of resistance

Many staphylococci today have become resistant to penicillin. Often bacteria develop resistance through the acquisition of β-lactamases, which break up the β-lactam ring present in the molecular structure of many antibiotics. The acquisition of extended-spectrum β-lactamases (ESBLs) is an increasing concern in some Gram-negative organisms that cause urinary tract infections because it is difficult to find an antibiotic effective against them. In addition, there is increasing concern about the rising resistance of many other bacteria to antibiotics, in particular the emergence of methicillin-resistant *Staphylococcus aureus* (MRSA), which is very relevant in general surgical practice.

The introduction of antibiotics for prophylaxis and for treatment, together with advances in anaesthesia and critical care medicine, has made possible surgery that would not previously have been considered. Faecal peritonitis is no longer inevitably fatal, and incisions made in the presence of such contamination can heal primarily without infection in over 90% of patients with appropriate antibiotic therapy. Despite

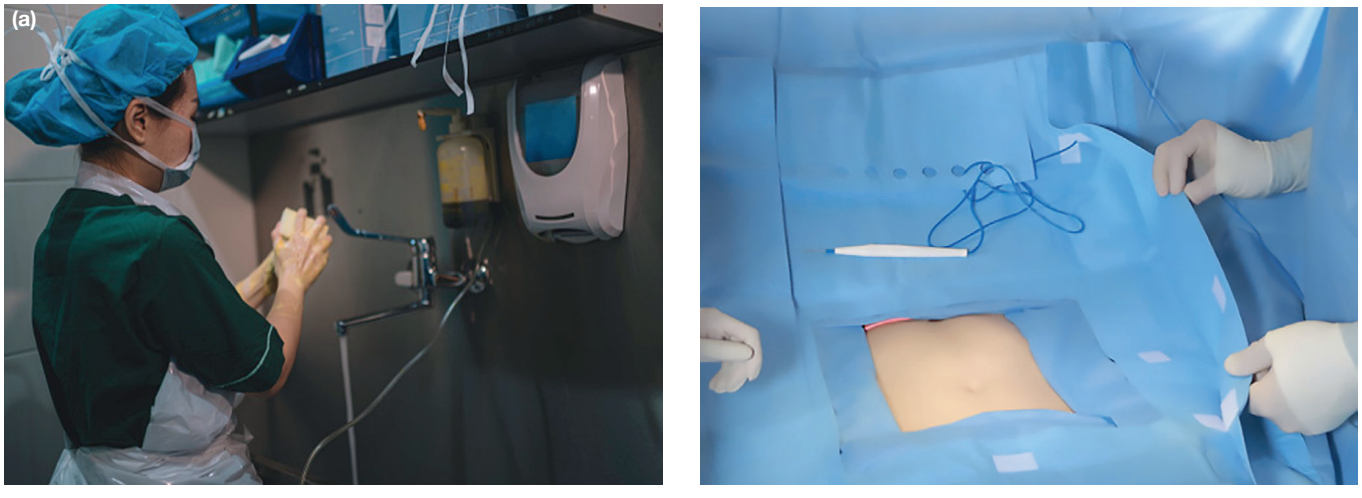

Figure 5.1 Aseptic techniques of scrubbing and draping in a modern operating theatre.

Louis Pasteur, 1822–1895, French chemist, bacteriologist and immunologist, Professor of Chemistry at the Sorbonne, Paris, France.
Lord Joseph Lister, 1827–1912, Professor of Surgery, Glasgow, Scotland (1860–1869), Edinburgh, Scotland (1869–1877) and King's College Hospital, London, England (1877–1892).
Sir Alexander Fleming, 1881–1955, Professor of Bacteriology, St Mary's Hospital, London, England, discovered *Penicillium notatum* in 1928.
Howard Walter Florey (Lord Florey of Adelaide), 1898–1968, Professor of Pathology, the University of Oxford, Oxford, England.
Sir Ernst Boris Chain, Professor of Biochemistry, Imperial College, London, England. Fleming, Florey and Chain shared the 1945 Nobel Prize in Physiology or Medicine for their work on penicillin.
Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

this, it is common practice in many countries to delay wound closure in patients in whom the wound is known to be contaminated or dirty. Waiting for the wound to granulate and then performing a delayed primary or secondary closure may be considered a better option in such cases (***Summary box 5.2***).

Summary box 5.2

Advances in the control of infection in surgery

- Aseptic operating theatre techniques have enhanced the use of antiseptics
- Antibiotics have reduced postoperative infection rates after elective and emergency surgery
- Delayed primary, or secondary, closure remains useful in heavily contaminated wounds

SSI in patients who have contaminated wounds, who are immunosuppressed or who are undergoing prosthetic surgery is now the exception rather than the rule since the introduction of prophylactic antibiotics. The evidence for this is of the highest level. The use of prophylactic antibiotics in clean, non-prosthetic surgery is of less value as infection rates are low and the indiscriminate use of antibiotics simply encourages the emergence of resistant strains of bacteria.

MICROBIOLOGY OF SURGICAL INFECTION

Common bacteria involved in surgical infections

Streptococci

Streptococci form chains and are Gram positive on staining (***Figure 5.2a***). The most important is the β-haemolytic *Streptococcus*, which resides in the pharynx of 5–10% of the population. In the Lancefield A–G carbohydrate antigens classification, it is the group A *Streptococcus*, also called *Streptococcus pyogenes*, that is the most pathogenic. It has the ability to spread, causing cellulitis, and to cause tissue destruction through the release of enzymes such as streptolysin, streptokinase and streptodornase.

Streptococcus faecalis is an enterococcus in Lancefield group D. It is often found in synergy with other organisms, as are the γ-haemolytic *Streptococcus* and *Peptostreptococcus*, which is an anaerobe.

Both *Streptococcus pyogenes* and *Streptococcus faecalis* may be involved in wound infection after bowel surgery, but the α-haemolytic *Streptococcus viridans* is not associated with wound infections.

All the streptococci remain sensitive to penicillin and erythromycin. The cephalosporins are a suitable alternative in patients who are allergic to penicillin.

Staphylococci

Staphylococci form clumps and are Gram positive (***Figure 5.2b***). *Staphylococcus aureus* is the most important pathogen in this group and is found in the nasopharynx of up to 15% of the population. It can cause suppuration in wounds and around implanted prostheses. Some strains are resistant to many common antibiotics (especially MRSA) and so are difficult to treat. MRSA can be found in the nose of asymptomatic carriers among both patients and hospital workers, a potential source of infection after surgery. In parts of northern Europe, the prevalence of MRSA infections has been kept at very low levels using 'search and destroy' methods, which use screening techniques to look for MRSA in patients before they come in to hospital for elective surgery so that any carriers can be treated before their admission for surgery. Local policies on the management of MRSA depend on the prevalence of MRSA, the type of hospital, the clinical specialty and the availability of facilities. Widespread swabbing, ward closures, isolation of patients and disinfection of wards by deep cleaning must all be carefully considered.

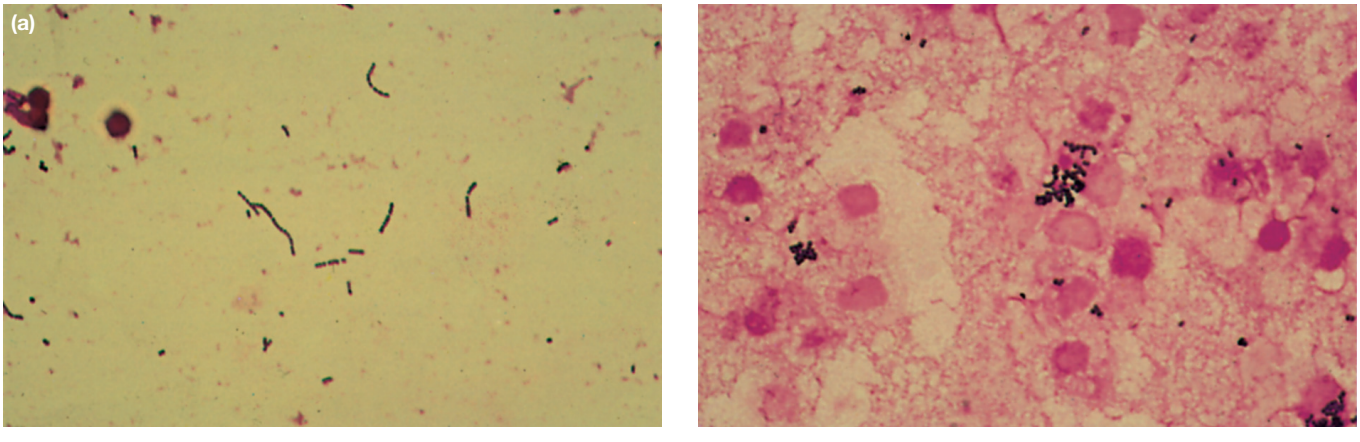

Figure 5.2 **(a)** Streptococci. **(b)** Staphylococcal pus.

Rebecca Graighill Lancefield, 1895–1981, American bacteriologist, classified streptococci in 1933.

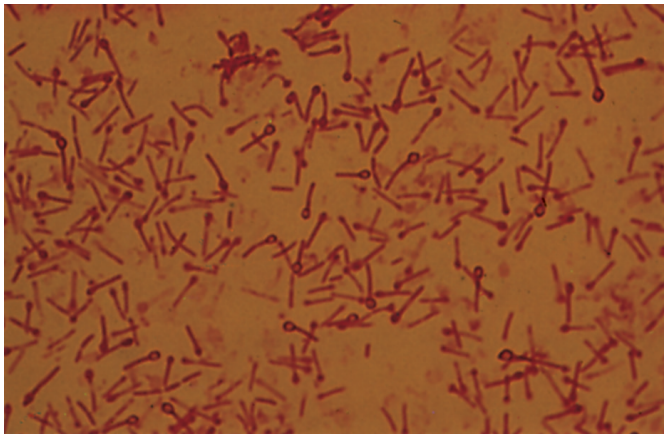

Figure 5.3 *Clostridium tetani* (drumstick spores).

Staphylococcal infections are usually suppurative and localised. Most hospital *Staphylococcus aureus* strains are now β-lactamase producers and so are resistant to penicillin, but many strains remain sensitive to flucloxacillin, vancomycin, aminoglycosides and some cephalosporins. Nowadays, several novel and innovative antibiotics have become available that have high activity against resistant strains. Some have the advantage of good oral activity (linezolid), some have a wide spectrum (teicoplanin), some have good activity in bacteraemia (daptomycin) but all are relatively expensive, and some have side effects involving marrow, hepatic and renal toxicity. Their use is justified but needs to be controlled by tight local policies and guidelines that involve clinical microbiologists.

Staphylococcus epidermidis (previously *Staphylococcus albus*), also known as coagulase-negative *Staphylococcus*, was regarded as a non-pathogenic commensal organism commonly found on the skin, but is now recognised as a major threat in vascular and orthopaedic prosthetic surgery and in indwelling vascular cannulae/catheters. The bacteria form biofilms that adhere to prosthetic surfaces and limit the effectiveness of antibiotics.

Clostridia

Clostridial organisms are Gram-positive, obligate anaerobes that produce resistant spores (***Figure 5.3***). *Clostridium perfringens* is the cause of gas gangrene, and *Clostridium tetani* causes tetanus.

Clostridium difficile (*C. diff.*) is the cause of pseudomembranous colitis, in which destruction of the normal colonic bacterial flora by antibiotic therapy allows an overgrowth of the normal gut commensal *C. diff.* to pathological levels. Any antibiotic may cause this phenomenon, although the quinolones such as ciprofloxacin seem to be the highest risk, especially in elderly or immunocompromised patients. In its most severe form, the colitis may lead to perforation and the need for emergency colectomy with an associated high mortality. Treatment involves resuscitation and antibiotic therapy. The fibrinous exudate is typical and differentiates the colitis from other inflammatory diseases.

Rapid testing for *C. diff.* is now available in the form of testing either *C. diff.* glutamate dehydrogenase (GDH) antigen or *C. diff.* toxin A/B. The *Clostridium difficile* GDH Ag Rapid test qualitatively detects for the presence of *C. diff.* GDH antigen in faeces. On the other hand, the *Clostridium difficile* Toxin A/B rapid test qualitatively detects for the presence of *C. diff.* toxins A and B in faeces. These rapid tests apply lateral flow immunochromatography and are for professional *in vitro* diagnostic use. Results are usually returned from this rapid testing in less than 30 minutes. Empirical treatment with metronidazole or vancomycin is recommended while awaiting results.

Aerobic Gram-negative bacilli

These bacilli are normal inhabitants of the large bowel. *Escherichia coli* and *Klebsiella* spp. are lactose fermenting; *Proteus* is non-lactose fermenting. Most organisms in this group act in synergy with *Bacteroides* to cause SSIs after bowel operations (in particular, appendicitis, diverticulitis and peritonitis). *Escherichia coli* is a major cause of urinary tract infection, although most aerobic Gram-negative bacilli can be involved, particularly in relation to urinary catheterisation. There is increasing concern about the development of ESBLs in many of this group of bacteria, which confer resistance to many antibiotics, particularly cephalosporins.

Pseudomonas spp. tend to colonise burns and tracheostomy wounds, as well as the urinary tract. Once *Pseudomonas* has colonised wards and intensive care units (ICUs), it may be difficult to eradicate. Surveillance of cross-infection is important in outbreaks. Hospital strains become resistant to β-lactamase as resistance can be transferred by plasmids. Wound infections need antibiotic therapy only when there is progressive or spreading infection with systemic signs. The aminoglycosides and the quinolones are effective, but some cephalosporins and penicillin may not be. Many of the carbapenems (e.g. meropenem) are useful in severe infections.

Bacteroides

Bacteroides are non-spore-bearing, strict anaerobes that colonise the large bowel, vagina and oropharynx. *Bacteroides fragilis* is the principal organism that acts in synergy with aerobic Gram-negative bacilli to cause SSIs, including intra-abdominal abscesses after colorectal or gynaecological surgery. They are sensitive to the imidazoles (e.g. metronidazole) and some cephalosporins (e.g. cefotaxime).

Sources of infection

The infection of a wound can be defined as the invasion of organisms into tissues following a breakdown of local and systemic host defences, leading to cellulitis, lymphangitis, abscess formation or bacteraemia. The infection of most surgical wounds is referred to as superficial surgical site infection (SSSI). The other categories include deep SSI (infection in the deeper musculofascial layers) and organ space infection (such

Theodor Escherich, 1857–1911, Professor of Paediatrics, Vienna, Austria, discovered the Bacterium coli commune in 1886.
Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology successively at Prague, Czechoslovakia, Zurich, Switzerland and The Rush Medical College, Chicago, IL, USA.

as an abdominal abscess after an anastomotic leak or pelvic abscess after a perforated appendicitis).

Pathogens resist host defences by releasing toxins, which favour their spread, and this is enhanced in anaerobic or frankly necrotic wound tissue. *Clostridium perfringens*, which is responsible for gas gangrene, releases proteases such as hyaluronidase, lecithinase and haemolysin, which allow it to spread through the tissues. Resistance to antibiotics can be acquired by previously sensitive bacteria by transfer through plasmids.

The human body harbours approximately 10^{14} organisms. They can be released into tissues before, during or after surgery, contamination being most severe when a hollow viscus perforates (e.g. faecal peritonitis following a diverticular perforation). Any infection that follows surgery may be termed endogenous or exogenous, depending on the source of the bacterial contamination. Endogenous organisms are present on or in the patient at the time of surgery, whereas exogenous organisms come from outside the patient. In modern hospital practice, endogenous organisms colonising the patient are by far the most common source of infection (***Summary box 5.3***).

Summary box 5.3

Classification of sources of infection

- **Endogenous**: present in or on the host, e.g. SSSI following contamination of the wound from a perforated appendix
- **Exogenous**: acquired from a source outside the body, such as the operating theatre (inadequate air filtration, poor antisepsis) or the ward (e.g. poor handwashing compliance). The cause of hospital-acquired infection (HAI)

Microorganisms are normally prevented from causing infection in tissues by intact epithelial surfaces, most notably the skin. These surfaces are broken down by trauma or surgery. In addition to these mechanical barriers, there are other protective mechanisms, which can be divided into:

- **chemical**: low gastric pH;
- **humoral**: antibodies, complement and opsonins;
- **cellular**: phagocytic cells, macrophages, polymorphonuclear cells and killer lymphocytes.

All of these natural mechanisms may be compromised by surgical intervention and treatment.

The chance of developing an SSI after surgery is also determined by the pathogenicity of the organisms present and by the size of the bacterial inoculum. The more virulent the organism or the larger the extent of bacterial contamination, the more likely is wound infection to occur. Host factors are also important, so a less virulent organism or a lower level of wound contamination may still result in a wound infection if the host response is impaired (***Summary box 5.4***). Devitalised tissue, excessive dead space or haematoma, which are all the results of poor surgical technique, increase the chances of infection. The same applies to foreign materials of any kind, including sutures and drains. These principles are important to an understanding of how best to prevent infection in surgical practice (***Summary box 5.5***).

Summary box 5.4

Factors that determine whether a wound will become infected

- Host response
- Virulence and inoculum of infective agent
- Vascularity and health of tissue being invaded (including local ischaemia as well as systemic shock)
- Presence of dead or foreign tissue
- Presence of antibiotics during the 'decisive period'

Summary box 5.5

Risk factors for increased risk of wound infection

- Malnutrition (obesity, weight loss)
- Metabolic disease (diabetes, uraemia, jaundice)
- Immunosuppression (cancer, acquired immunodeficiency syndrome [AIDS], steroids, chemotherapy and radiotherapy)
- Colonisation and translocation in the gastrointestinal tract
- Poor perfusion (systemic shock or local ischaemia)
- Foreign body material
- Poor surgical technique (devitalised tissue, dead space, haematoma)

The decisive period

There is up to a 4-hour interval before bacterial growth becomes established enough to cause an infection after a breach in the tissues, whether caused by trauma or by surgery. This interval is called the 'decisive period' and strategies aimed at preventing infection from taking a hold become ineffective after this time period. It is therefore logical that prophylactic antibiotics should be given to cover this period and that they could be decisive in preventing an infection from developing before bacterial growth takes a hold. The tissue levels of antibiotics during the period when bacterial contamination is likely to occur should be above the minimum inhibitory concentration (MIC90) for the expected pathogens.

Reduced resistance to infection

Reduced resistance to infection has several causes, particularly those that impair the inflammatory response. Host response is weakened by malnutrition associated with a low or high body mass index. Metabolic diseases such as diabetes mellitus, uraemia and jaundice, disseminated malignancy and acquired immunodeficiency syndrome (AIDS) are other contributors to infection and a poor healing response, as are iatrogenic causes including the immunosuppression caused by radiotherapy, chemotherapy and drugs such as steroids and methotrexate (***Figures 5.4 and 5.5***).

When enteral feeding is suspended during the perioperative period, and particularly with underlying disease such as cancer, immunosuppression, shock or sepsis, bacteria (particularly aerobic Gram-negative bacilli) tend to colonise the normally sterile upper gastrointestinal tract. They may then translocate

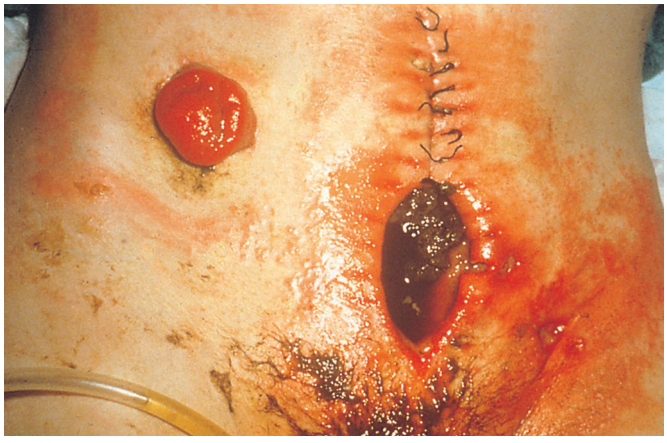

Figure 5.4 Major wound infection and delayed healing presenting as a faecal fistula in a patient with Crohn's disease on steroid treatment.

Figure 5.5 Delayed healing relating to infection in a patient on high-dose steroids.

to the mesenteric nodes and cause the release of endotoxins (lipopolysaccharide in bacterial cell walls), which can be one cause of a harmful systemic inflammatory response through the excessive release of proinflammatory cytokines and activation of macrophages (*Figure 5.6*). In the circumstances of reduced host resistance to infection, microorganisms that are not normally pathogenic may start to behave as pathogens. This is known as opportunistic infection. Opportunistic infection with fungi is an example, particularly when prolonged and changing antibiotic regimes have been used.

PRESENTATION OF SURGICAL INFECTION

Major and minor surgical site infection (SSI)

Infection acquired from the environment or the staff following surgery or admission to hospital is termed hospital-acquired infection (HAI). There are four main groups: respiratory infections (including ventilator-associated pneumonia), urinary tract infections (mostly related to urinary catheters),

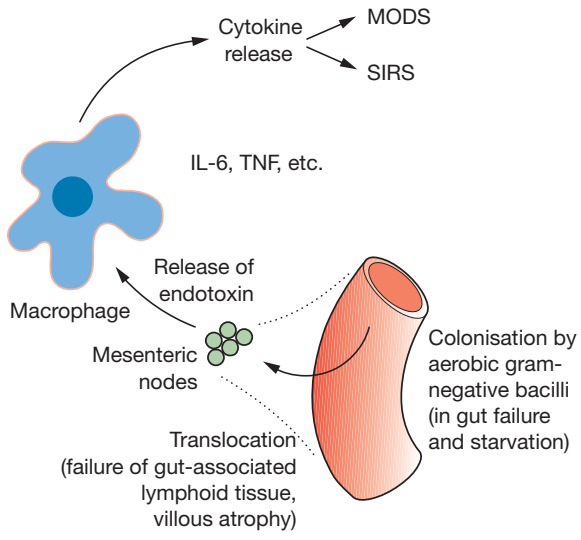

Figure 5.6 Gut failure, colonisation and translocation related to the development of systemic inflammatory response syndrome (SIRS) and multiple organ dysfunction syndrome (MODS). IL, interleukin; TNF, tumour necrosis factor.

bacteraemia (mostly related to indwelling vascular catheters) and SSIs.

A major SSI is defined as a wound that either discharges significant quantities of pus spontaneously or needs a secondary procedure to drain it (*Figure 5.4*). The patient may have systemic signs such as tachycardia, pyrexia and a raised white cell count (*Summary box 5.6*).

Summary box 5.6

Major wound infections

- Significant quantity of pus
- Delayed return home
- Patients are systemically ill

Minor wound infections may discharge pus or infected serous fluid but are not associated with excessive discomfort, systemic signs or delay in return home (*Figure 5.7*).

Figure 5.7 Minor wound infection that settled spontaneously without antibiotics.

Localised infection

Abscess

An abscess presents all the clinical features of acute inflammation originally described by Celsus: *calor* (heat), *rubor* (redness), *dolor* (pain) and *tumor* (swelling). To these can be added *functio laesa* (loss of function: if it hurts, the infected part is not used). Abscesses usually follow a puncture wound of some kind, which may have been forgotten, as well as surgery, but can be metastatic in all tissues following bacteraemia.

Pyogenic organisms, predominantly *Staphylococcus aureus*, cause tissue necrosis and suppuration. Pus is composed of dead and dying white blood cells, predominantly neutrophils, that have succumbed to bacterial toxins. An abscess is surrounded by an acute inflammatory response composed of a fibrinous exudate, oedema and the cells of acute inflammation. Granulation tissue (macrophages, fibroblasts and new blood vessel proliferation) forms later around the suppurative process and leads to collagen deposition. If it is not drained or resorbed completely, a chronic abscess may result. If it is partly sterilised with empirical antibiotics, an antibioma may form.

Abscesses contain hyperosmolar material that draws in fluid. This increases the pressure and causes pain. If they spread, they usually track along planes of least resistance and point towards the skin. Wound abscesses may discharge spontaneously by tracking to a surface but may need drainage through a surgical incision. Most abscesses relating to surgical wounds take 7–10 days to form after surgery. As many as 75% of SSIs present after the patient has left hospital and may thus be overlooked by the surgical team.

Abscess cavities need cleaning out after incision and drainage and are traditionally encouraged to heal by secondary intention. When the cavity is left open to drain freely, there is no need for antibiotic therapy as well. Antibiotics should be used if the abscess cavity is closed after drainage, but the cavity should not be closed if there is any risk of retained loculi or foreign material. Thus a perianal abscess can be incised and drained, the walls curetted and the skin closed with good results using appropriate antibiotic therapy, but a pilonidal abscess has a higher recurrence risk after such treatment because a nidus of hair may remain in the subcutaneous tissue adjacent to the abscess. Some small breast abscesses can be managed by simple needle aspiration of the pus and antibiotic therapy (***Summary box 5.7***).

Persistent chronic abscesses may lead to sinus or fistula formation. In a chronic abscess, lymphocytes and plasma cells are seen. There is tissue sequestration and later calcification may occur. Certain organisms are associated with chronicity and with sinus and fistula formation. Common ones are *Mycobacterium* and *Actinomyces*. They should not be forgotten when these complications occur and persist.

Perianastomotic contamination may be the cause of an abscess but, in the abdomen, abscesses are more usually the result of anastomotic leakage. An abscess in a deep cavity such as the pleura or peritoneum may be difficult to diagnose or locate even when there is strong clinical suspicion that it is present (***Figure 5.8***). Plain or contrast radiographs may not be helpful, but ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI) and isotope-labelled white cell scans are all useful and may allow image-guided aspiration and drainage of intra-abdominal abscesses without the need for surgical intervention.

Summary box 5.7

Abscesses

- Abscesses need drainage
- Modern imaging techniques may allow guided needle aspiration, e.g. ultrasound-guided drainage of breast abscesses
- Antibiotics are indicated if the abscess cavity is not left open to drain freely
- An open abscess cavity heals by secondary intention

Cellulitis and lymphangitis

Cellulitis is a non-suppurative, invasive infection of tissues, which is usually related to the point of injury. There is poor localisation in addition to the cardinal signs of spreading inflammation. Such infections presenting in surgical practice are typically caused by organisms such as β-haemolytic streptococci (***Figure 5.9***), staphylococci (***Figure 5.10***) and *Clostridium perfringens*. Tissue destruction, gangrene and ulceration may follow, which are caused by release of proteases.

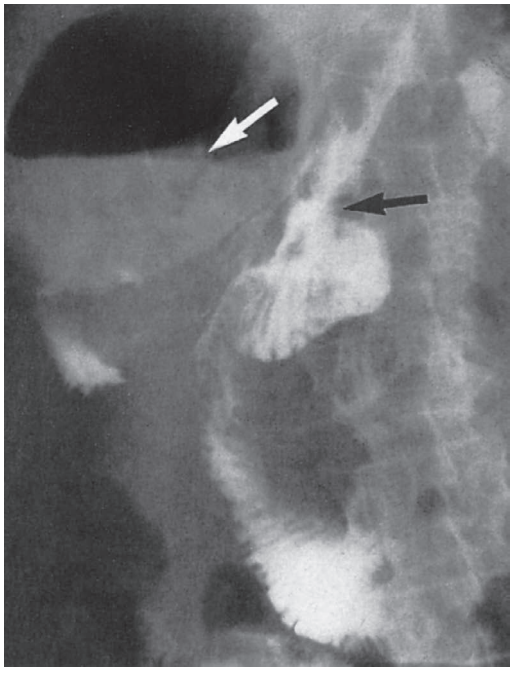

Figure 5.8 Plain radiograph showing a subphrenic abscess with a gas/fluid level (white arrow). Gastrografin is seen leaking from the oesophagojejunal anastomosis (after gastrectomy) towards the abscess (black arrow).

Aulus Aurelius Cornelius Celsus, 25 BCE–50 CE, Roman surgeon and the author of *De Re Medico Libri Octo*.

Figure 5.9 Streptococcal cellulitis of the leg following a minor puncture wound.

Figure 5.10 Staphylococcal cellulitis of the face and orbit following severe infection of an epidermoid cyst of the scalp.

Systemic signs (the old-fashioned term is toxaemia) are common, with chills, fever and rigors. These events follow the release of toxins into the circulation, which stimulate a cytokine-mediated systemic inflammatory response even though blood cultures may be negative.

Lymphangitis is part of a similar process and presents as painful red streaks in affected lymphatics draining the source of infection. Lymphangitis is often accompanied by painful lymph node groups in the related drainage area, e.g. cervical, axillary or inguinal (***Summary box 5.8***).

Summary box 5.8

Cellulitis and lymphangitis

- Non-suppurative, poorly localised
- Commonly caused by streptococci, staphylococci or clostridia
- Blood cultures are often negative

Specific local wound infections

Gas gangrene

Gas gangrene is caused by *Clostridium perfringens*. These Gram-positive, anaerobic, spore-bearing bacilli are widely found in nature, particularly in soil and faeces. Patients who are immunocompromised, diabetic or have malignant disease are at greater risk, particularly if they have wounds containing necrotic or foreign material, resulting in anaerobic conditions. Military wounds provide an ideal environment as the kinetic energy of high-velocity missiles or shrapnel causes extensive tissue damage. The cavitation which follows passage of a missile through the tissues causes a 'sucking' entry wound, leaving clothing and environmental soiling in the wound in addition to devascularised tissue. Gas gangrene wound infections are associated with severe local wound pain and crepitus (gas in the tissues, which may also be visible on plain radiographs). The wound produces a thin, brown, sweet-smelling exudate, in which Gram staining will reveal bacteria. Oedema and spreading gangrene follow the release of collagenase, hyaluronidase, other proteases and alpha toxin. Early systemic complications with circulatory collapse and organ failure follow if prompt action is not taken (***Summary box 5.9***).

Antibiotic prophylaxis should always be considered in patients at risk, especially when amputations are performed for peripheral vascular disease with open necrotic ulceration. Once gas gangrene infection is established, large doses of intravenous penicillin and aggressive debridement of affected tissues are required.

Summary box 5.9

Gas gangrene

- Caused by *Clostridium perfringens*
- Gas and smell are characteristic
- Immunocompromised patients are most at risk
- Antibiotic prophylaxis is essential when performing amputations to remove dead tissue

Clostridium tetani

This is another anaerobic, terminal spore-bearing, Gram-positive bacterium, which can cause tetanus following implantation into tissues or a wound. The spores are widespread in soil and manure. The signs and symptoms of tetanus are mediated by the release of the exotoxin tetanospasmin; these include spasms in the distribution of the short motor nerves of the face followed by the development of severe generalised motor spasms including opisthotonus, respiratory arrest and death. Prophylaxis with tetanus toxoid is the best preventative treatment but, in an established infection, minor debridement of the wound may need to be performed and antibiotic treatment with benzylpenicillin provided in addition. Relaxants may also be required and the patient will require ventilation in severe forms, which are associated with a high mortality.

Synergistic spreading gangrene (synonym: subdermal gangrene, necrotising fasciitis)

This is a rare but serious bacterial infection that affects and spreads via the deep fascia; hence, it is termed fasciitis. A mixed pattern of organisms is responsible for this serious condition: coliforms, staphylococci, *Bacteroides* spp., anaerobic streptococci and peptostreptococci have all been implicated, acting in synergy. Often, aerobic bacteria destroy the living tissue, allowing anaerobic bacteria to thrive. Severe wound pain, signs of spreading inflammation with crepitus and odour are all signs of the infection spreading. Untreated, it will lead to widespread local gangrene and systemic multisystem organ failure. Abdominal wall infections are known as Meleney's synergistic gangrene and scrotal infections as Fournier's gangrene (***Figure 5.11***). Patients are almost always immunocompromised, with conditions such as diabetes mellitus. The wound initiating the infection may have been minor, but severely contaminated wounds are more likely to be the cause.

The subdermal spread of gangrene is always much more extensive than appears from initial examination. The finger test can be used in the diagnosis of patients who present with suspected necrotising fasciitis. The area of suspected involvement is first infiltrated with local anaesthesia. A 2-cm incision is made in the skin down to the deep fascia. Lack of bleeding is a sign of necrotising fasciitis. On some occasions, a dishwater-coloured fluid is noticed seeping from the wound.

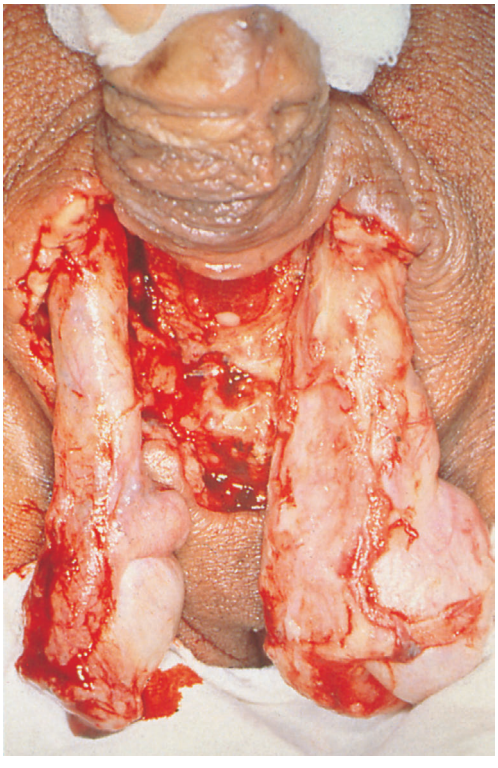

Figure 5.11 A classic presentation of Fournier's gangrene of the scrotum with 'shameful exposure of the testes' following excision of the gangrenous skin.

A gentle, probing manoeuvre with the index finger covered by a sterile glove is then performed at the level of the deep fascia. If the tissues dissect with minimal resistance, the finger test is positive. Tissue biopsies are then sent for frozen section analysis. The characteristic histological findings are obliterative vasculitis of the subcutaneous vessels, acute inflammation and subcutaneous tissue necrosis. If either the finger test or rapid frozen section analysis is positive, or if the patient has progressive clinical findings consistent with necrotising fasciitis, immediate operative treatment must be initiated.

Broad-spectrum antibiotic therapy must be combined with aggressive circulatory support. Locally, there should be wide excision of necrotic tissue and laying open of affected areas. The debridement may need to be extensive, and patients who survive may need large areas of skin grafting later.

Systemic infection

Bacteraemia

Bacteraemia is unusual following superficial SSIs, which tend to drain through the wound, but common after deep space SSIs, such as following an intestinal anastomotic breakdown. It is usually transient and can follow procedures undertaken through infected tissues (particularly instrumentation in infected bile or urine). It may also occur through bacterial infection of indwelling intravenous cannulae, which should be replaced regularly to avoid colonisation. Bacteraemia is important when a prosthesis has been implanted, as infection of the prosthesis can occur through haematogenous spread. Aerobic Gram-negative bacilli are often responsible, but *Staphylococcus aureus* and fungi may be involved (***Summary box 5.10***).

Summary box 5.10

Bacteraemia

- Common after anastomotic breakdown
- Dangerous if the patient has a prosthesis, which can become infected
- May be associated with systemic organ failure

Systemic inflammatory response syndrome

Systemic inflammatory response syndrome (SIRS) is a systemic manifestation of sepsis (***Table 5.1***), although the syndrome may also be caused by multiple trauma, burns or pancreatitis without infection. Serious infection, such as secondary peritonitis, may lead to SIRS through the release of lipopolysaccharide endotoxin from the walls of dying Gram-negative bacilli (mainly *Escherichia coli*) or other bacteria or fungi. This and other toxins stimulate the release of cytokines from macrophages (***Figure 5.6***). SIRS should not be confused with bacteraemia, although the two may coexist.

Frank Lamont Meleney, 1889–1963, Professor of Clinical Surgery, Columbia University, New York, NY, USA.
Jean Alfred Fournier, 1832–1915, syphilologist, the founder of the Venereal and Dermatological Clinic, Hôpital Saint-Louis, Paris, France.

TABLE 5.1 Definitions of systemic inflammatory response syndrome (SIRS) and sepsis

SIRS is ***Presence of two out of three of the following:*** • Hyperthermia (>38°C) or hypothermia (<36°C) • Tachycardia (>90/min, no β-blockers) or tachypnoea (>20/min) • White cell count >12 × 10^9/litre or <4 × 10^9/litre
Sepsis is SIRS with a documented source of infection
Severe sepsis or sepsis syndrome is sepsis with evidence of failure of one or more organs: respiratory (acute respiratory distress syndrome), cardiovascular (septic shock follows compromise of cardiac function and fall in peripheral vascular resistance), renal (usually acute tubular necrosis), hepatic, blood coagulation systems or central nervous system

Septic manifestations and multiple organ dysfunction syndrome (MODS) in SIRS are mediated by the release of pro-inflammatory cytokines such as interleukin-1 (IL-1) and tumour necrosis factor alpha (TNFα). These cytokines normally stimulate neutrophil adhesion to endothelial surfaces adjacent to the source of infection and cause them to migrate through the blood vessel wall by chemotaxis, where they can attack the bacterial invasion. A respiratory burst occurs within such activated neutrophils, releasing lysosomal enzymes, oxidants and free radicals, which are involved in killing the invading bacteria but which may also damage adjacent cells. Coagulation, complement and fibrinolytic pathways are also stimulated as part of the normal inflammatory response. This response is usually beneficial to the host and is an important aspect of normal tissue repair and wound healing. On occasions, this response may become harmful to the host if it occurs in excess, when it is known as the systemic inflammatory response syndrome or SIRS. There are high circulating levels of cytokines and activated neutrophils that stimulate fever, tachycardia and tachypnoea. The activated neutrophils adhere to vascular endothelium in key organs remote from the source of infection and damage it, leading to increased vascular permeability, which in turn leads to cellular damage within the organs, which become dysfunctional and give rise to the clinical picture of multiple organ dysfunction syndrome or MODS. In its most severe form, MODS may progress into multiple system organ failure (MSOF). Respiratory, cardiac, intestinal, renal and liver failure ensue in combination with circulatory failure and shock. In this state, the body's resistance to infection is reduced and a vicious cycle develops where the more organs that fail, the more likely it becomes that death will follow despite all that a modern ICU can do for organ support (*Summary box 5.11*).

Summary box 5.11

Definitions of infected states

- SSI is an infected wound or deep organ space
- SIRS is the body's systemic response to severe infection
- MODS is the effect that SIRS produces systemically
- MSOF is the end stage of uncontrolled MODS

Surviving Sepsis Campaign/sepsis bundle/ Sepsis Six

The European Society of Intensive Care Medicine (ESICM) alongside the Society of Critical Care Medicine (SCCM) spearheaded the Surviving Sepsis Campaign (SSC) in 2002 with several aims, including the development of guidelines for the diagnosis, treatment and post-ICU care of sepsis and a reduction in mortality from sepsis. The Surviving Sepsis Campaign continually develops and updates resources and implementation tools to further its mission of reducing sepsis and septic shock.

The **sepsis bundle**, also known as the resuscitation bundle, is a combination of evidence-based objectives that must be completed within 6 hours for patients presenting with severe sepsis, septic shock and/or lactate >4 mmol/L.

The **Sepsis Six** is the name given to a bundle of medical therapies designed to reduce mortality in patients with sepsis. Drawn from international guidelines that emerged from the Surviving Sepsis Campaign, the Sepsis Six was developed by the UK's Sepsis Trust. The components of the Sepsis Six are:

- **give three to patients:** (1) intravenous fluid challenge, (2) intravenous antibiotics, (3) oxygen and monitor urine output;
- **take three from patients:** (4) blood cultures, (5) full blood count, (6) lactate.

Viral infections relevant to surgery

Hepatitis

Both hepatitis B and hepatitis C carry risks in surgery as they are blood-borne pathogens that can be transmitted both from the patient to the surgeon and vice versa. The usual mode of transmission is blood-to-blood contact through a needle-stick injury or a cut. Many cases of hepatitis B are asymptomatic and a surgeon may carry the virus without being aware of it. As there is an effective vaccine against hepatitis B, surgeons should know their immune status to hepatitis B and be vaccinated against it. Hepatitis C infection often becomes chronic with the risk of significant liver damage but is potentially curable with interferon-alpha and ribavirin treatment, so surgeons who are exposed to an infection risk should seek medical advice and antibody measurement.

Human immunodeficiency virus

The type I human immunodeficiency virus (HIV) is one of the viruses of surgical importance because it can be transmitted by body fluids, particularly blood. It is a retrovirus that has become increasingly prevalent through sexual transmission (both homo- and heterosexual), intravenous drug addiction and in infected blood products used to treat patients with haemophilia in particular. The risk in surgery is mostly through needle-stick injury during operations.

The risk of opportunistic infections (such as *Pneumocystis carinii* pneumonia, tuberculosis and cytomegalovirus) and neoplasms (such as Kaposi's sarcoma and lymphoma) is thereby increased.

Moritz Kaposi, 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.

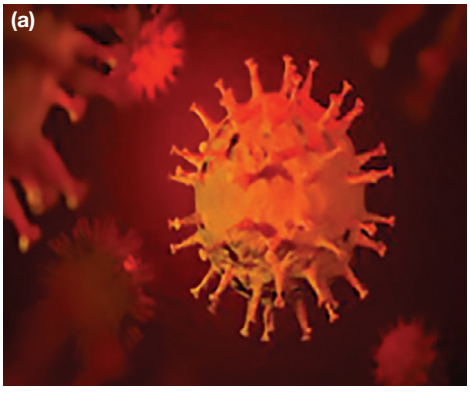

Figure 5.12 **(a)** Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2). **(b)** Chest radiograph showing coronavirus disease 2019 (COVID-19) pneumonia changes.

In the early weeks after HIV infection, there may be a flu-like illness and, during the phase of seroconversion, patients present the greatest risk of HIV transmission. It is during these early phases that drug treatment, highly active antiretroviral therapy (HAART), is most effective through the ability of these drugs to inhibit reverse transcriptase and protease synthesis, which are the principal mechanisms through which HIV can progress. These drugs suppress the virus but do not clear it completely from the body and treated patients can still transmit the virus to others. Within 2 years, untreated HIV can progress to acquired immunodeficiency syndrome (AIDS) in 25–35% of patients.

Universal precautions

Patients may present to surgeons for operative treatment if they have a surgical disease and they are known to be infected or 'at risk', or because they need surgical intervention related to their illness for vascular access or a biopsy when they are known to have hepatitis, HIV infection or AIDS. Particular care should be taken when there is a risk of splashing/aerosol formation, particularly with power tools. Universal precautions have been drawn up by CDC in the USA and largely adopted by the NHS in the UK. In summary, these are:

- use of a full face mask ideally, or protective spectacles;
- use of fully waterproof, disposable gowns and drapes, particularly during seroconversion;
- boots to be worn, not clogs, to avoid injury from dropped sharps;
- double gloving needed (a larger size on the inside is more comfortable);
- allow only essential personnel in theatre;
- avoid unnecessary movement in theatre;
- respect is required for sharps, with passage in a kidney dish;
- slow meticulous operative technique is needed with minimised bleeding.

After contamination

Needle-stick injuries are commonest on the non-dominant index finger during operative surgery. Hollow needle injury carries the greatest risk of viral transmission. The injured part should be washed under running water and the incident reported. Local policies dictate whether postexposure antiretroviral treatment should be given. Occupational health advice is required after high-risk exposure, together with the need for hepatitis/HIV testing and the option for continuation in a non-operative specialty.

COVID-19 pandemic

The global pandemic of coronavirus disease 2019 (COVID-19) was announced by the World Health Organization on 11 March 2020. As of 16 August 2021, more than 207 million cases and more than 4.36 million deaths had been reported in 210 countries.* The rapid spread of the outbreak has had short-term implications for global healthcare systems, including the field of surgery. Many hospitals were forced to stop or postpone elective surgical interventions during the first wave in early to mid-2020. However, emergency surgery and time-sensitive surgery, i.e. cancer surgery, continued with relevant precautions, including the use of personal protective equipment.

COVID-19 is a contagious respiratory and vascular disease. The aetiology is severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) (***Figure 5.12a***), which is a specific type of coronavirus. Common symptoms include fever, cough, fatigue, shortness of breath or breathing difficulties as well as loss of smell and taste. The incubation period may range from 1 to 14 days. While most people have mild symptoms, some people develop acute respiratory distress syndrome (ARDS), possibly precipitated by a cytokine storm; multiorgan failure; septic shock; and hypercoagulable states. Longer term damage to organs (in particular, the lungs and heart) has been observed.

Complications in postoperative surgical patients infected with COVID-19 in either an elective or emergency setting may include pneumonia (***Figure 5.12b***), ARDS, multiorgan failure, septic shock and death. Measures to control COVID-19-related morbidity and mortality have thus been implemented by many countries, including a mandatory preoperative cocooning of elective surgical patients 10–14 days prior to surgery and preoperative COVID-19 swab testing 2–3 days prior to elective surgery. Like many other viral infections, there is no definite pharmacological cure for this infection, although there has been some evidence for supportive care, e.g. with hydroxychloroquine and dexamethasone. Multiple vaccines were made available at the end of 2020 and, currently, the majority of countries have most of their population vaccinated.

*Data from: COVID-19 dashboard by the Center for Systems Science and Engineering (CSSE) at Johns Hopkins University (accessed 16 August 2021).

PREVENTION OF SURGICAL INFECTION

Preoperative preparation

A short preoperative hospital stay lowers the risk of acquiring MRSA, multidrug-resistant coagulase-negative staphylococci and other antibiotic-resistant organisms from the hospital environment. Medical and nursing staff should always wash their hands after any patient contact. Hand gels containing at least 70% alcohol can act as a substitute for handwashing, but do not destroy the spores of *C. diff.*, which may cause pseudomembranous colitis, especially in immunocompromised patients or those whose gut flora is suppressed by antibiotic therapy. Although the need for clean hospitals, emphasised by the media, is logical, the 'clean your hands campaign', particularly in the COVID-19 era, is beginning to result in falls in the incidence of HAIs. Staff with open, infected skin lesions should not enter the operating theatres. Ideally, neither should affected patients, especially if they are having a prosthesis implanted. Antiseptic baths (usually chlorhexidine) are popular in Europe, but there is no hard evidence for their value in reducing wound infections. Preoperative skin shaving should be undertaken in the operating theatre immediately before surgery as the SSI rate after clean wound surgery may be doubled if shaving is performed the night before because minor skin injury enhances superficial bacterial colonisation.

Scrubbing and skin preparation

When washing the hands prior to surgery, dilute alcohol-based antiseptic hand soaps such as chlorhexidine or povidone–iodine should be used, and the scrub should include the nails (***Figure 5.1***).

One application of a more concentrated alcohol-based antiseptic is adequate for skin preparation of the operative site. This leads to a >95% reduction in bacterial count but caution should be taken not to leave a pool of alcohol-based fluid on the skin as it could ignite with diathermy and burn the patient (***Figure 5.1***).

Theatre technique and discipline also contribute to low infection rates. Numbers of staff in the theatre and movement in and out of theatre should be kept to a minimum. Careful and regular surveillance is needed to ensure the quality of instrument sterilisation, aseptic technique and theatre ventilation. Laminar flow systems direct clean, filtered air over the operating field, with any air potentially contaminated as it passes over the incision then directed away from the patient. Operator skill in gentle manipulation and dissection of tissues is much more difficult to audit, but dead spaces and haematomas should be avoided. There is no evidence that drains, incision drapes or wound guards help to reduce wound infection. There is a high level of evidence that both the perioperative avoidance of hypothermia and the use of supplemental oxygen during recovery significantly reduce the rate of SSIs.

Prophylactic antibiotics

Prophylactic antibiotics are used when there is a risk of wound contamination with bacteria during surgery. The theoretical degree of contamination, proposed by the National Research Council (USA) over 40 years ago, relates well to infection rates (***Table 5.2***). The value of antibiotic prophylaxis is low in non-prosthetic clean surgery, with most trials showing no clear benefit because infection rates without antibiotics are so low. The exception to this is where a prosthetic implant is used, as the results of infection are so catastrophic that even a small risk of infection is unacceptable. There is undisputed evidence that prophylactic antibiotics are effective in reducing the risk of infection in clean-contaminated and contaminated operations. When wounds are heavily contaminated or when an incision is made into an abscess, a 5-day course of therapeutic antibiotics may be justified on the assumption that the wound is inevitably infected and so treatment is needed rather than prophylaxis.

TABLE 5.2 Surgical site infection rates relating to wound contamination with and without using antibiotic prophylaxis

Type of surgery	Infection rate with prophylaxis (%)	Infection rate without prophylaxis (%)
Clean (no viscus opened)	1–2	1–2
Clean-contaminated (viscus opened, minimal spillage)	3	6–9
Contaminated (open viscus with spillage or inflammatory disease)	6	13–20
Dirty (pus or perforation, or incision through an abscess)	7	40

If antibiotics are given to prevent infection after surgery or instrumentation, they should be used before bacterial growth becomes established (i.e. within the decisive period). Ideally, maximal blood and tissue levels should be present at the time at which the first incision is made and before contamination occurs. Tissue levels of the antibiotic should remain high throughout the operation and antibiotics with a short tissue half-life should be avoided. Intravenous administration at induction of anaesthesia is therefore optimal, as unexpected delays in the timing of surgery may occur before then and antibiotic tissue levels may fall off before the surgery starts. In long operations or when there is excessive blood loss, or when unexpected contamination occurs, antibiotics may be repeated at 4-hourly intervals during the surgery because tissue antibiotic levels often fall faster than serum levels. There is no evidence that further doses of antibiotics after surgery are of any value in prophylaxis against infection and the practice can only encourage the development of antibiotic resistance. The choice of an antibiotic depends on the expected spectrum of organisms likely to be encountered, which will depend on the site and type of surgery and whether the patient has any antibiotic allergies. Hospitals in the UK and across Europe now have standardised antibiotic prophylaxis policies that take account of the above factors and are only deviated from with microbiological advice.

Patients with known valvular disease of the heart (or with any implanted vascular or orthopaedic prosthesis) should have prophylactic antibiotics during dental, urological or open

viscus surgery to prevent bacterial colonisation of the valve or prosthesis during the transient bacteraemia which can occur during such surgery (*Summary box 5.12*).

Summary box 5.12

Antibiotic prophylaxis

- Not required in clean surgery unless a prosthesis is implanted
- Use antibiotics that are effective against expected pathogens within local hospital guidelines
- Plan for single-shot intravenous administration at induction of anaesthesia
- Repeat only during long operations or if there is excessive blood loss
- Patients with heart valve disease or a prosthesis should be protected from bacteraemia caused by dental work, urethral instrumentation or visceral surgery

Postoperative wound infections

The majority of wound infections arise from endogenous sources within the patient, but exogenous SSIs may also occur from bacteria present in the ward or on staff and so can be related to poor hospital standards. Strict attention to ward cleanliness, gloving before touching patient wounds and handwashing between all patient contacts are important preventive measures. An outbreak of wound infections on the ward with bacteria having the same antibiotic sensitivity profile implies an exogenous source of infection, which needs to be investigated by swabbing all staff and work surfaces. It may need temporary ward closure and a deep clean to eradicate the infection source.

Now that patients are discharged more quickly after surgery and many procedures are performed as day cases, many SSIs are missed by the surgical team unless they undertake a prolonged and carefully audited follow-up with primary care doctors. Suppurative wound infections take 7–10 days to develop, and even cellulitis around wounds caused by invasive organisms (such as β-haemolytic *Streptococcus*) takes 3–4 days to develop. Major surgical infections with systemic signs (*Figure 5.13*), evidence of spreading infection, cellulitis or bacteraemia need treatment with appropriate antibiotics. The choice may need to be empirical initially but is best based on culture and sensitivities of isolates harvested at surgery or from culture of wound fluids or wound swabs. Although the identification of organisms in surgical infections is necessary for audit and wound surveillance purposes, it is usually 2–3 days before sensitivities are known (*Figures 5.14 and 5.15*). It is illogical to withhold antibiotics until results are available but, if clinical response is poor by the time sensitivities are known, then antibiotics can be changed. Such changes are unusual if the empirical choice of antibiotics is sensible; change of antibiotics promotes resistance and risks complications, such as *C. diff.* enteritis.

If an infected wound is under tension, or there is clear evidence of suppuration, sutures or clips need to be removed, with curettage if necessary, to allow pus to drain adequately. In severely contaminated wounds, such as an incision made for drainage of an abscess, it is logical to leave the skin open. Delayed primary or secondary closure can be undertaken when the wound is clean and granulating (*Figures 5.16 and 5.17*). Some heavily infected wounds may be left to heal by secondary intention, with no attempt at closure, particularly where there is a loss of skin cover and healthy granulation tissue develops

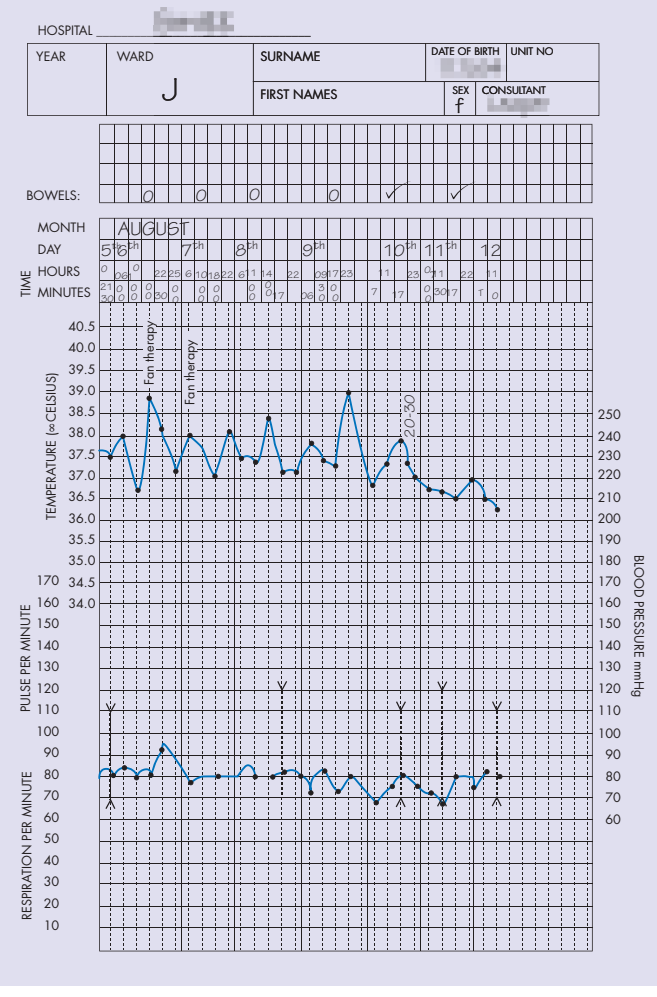

Figure 5.13 Classic swinging pyrexia related to a perianastomotic wound abscess that settled spontaneously on antibiotic therapy.

Figure 5.14 Mixed streptococcal infection of a skin graft with very poor 'take'.

Figure 5.15 After 5–6 days of antibiotics, the infection shown in ***Figure 5.14*** is under control, and the skin grafts are clearly viable.

Figure 5.16 (a, b) Delayed primary closure of a fasciotomy wound after 3–5 days.

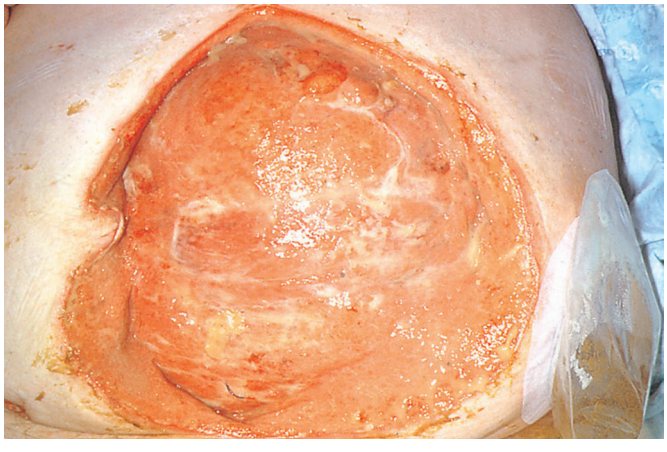

Figure 5.17 Skin layers left open to granulate after laparotomy for faecal peritonitis, ready for skin grafting.

(***Figure 5.18***). While the end result may be excessive scarring, that can always be revised with plastic surgery under clean surgical conditions at a later stage (***Summary box 5.13***).

Summary box 5.13

Surgical incisions through infected or contaminated tissues

- When possible, tissue or pus for culture should be taken before antibiotic cover is started
- The choice of antibiotics is empirical until sensitivities are available
- Heavily contaminated wounds are best managed by delayed primary or secondary closure

When taking pus from infected wounds, specimens should be sent fresh for microbiological culture. Swabs should be placed in transport medium, but the larger the volume of pus sent, the more likely is the accurate identification of the organism involved. Providing the microbiologist with as much information as possible and discussing the results with them gives the best chance of the most appropriate antibiotic treatment. If bacteraemia is suspected, but results are negative, then repeat specimens for blood culture and an immediate Gram stain.

Topical antiseptics should only be used on heavily contaminated wounds for a short period to clear infection as they inhibit epithelial ingrowth and so impair wound healing.

ANTIMICROBIAL TREATMENT OF SURGICAL INFECTION

Principles

Antimicrobials may be used to prevent or treat established surgical infection.

The use of antibiotics for the treatment of established surgical infection ideally requires recognition and determination of the sensitivities of the causative organisms. Antibiotic therapy

Figure 5.18 Infected animal bite/wound of the upper thigh, treated by open therapy following virulent staphylococcal infection.

should not be held back if it is indicated, the choice being empirical and later modified depending on microbiological findings on culture and sensitivity. Once antibiotics have been administered, it may not be possible to grow bacteria from the wound and so the opportunity to ascertain the most appropriate antibiotic sensitivities is lost if a patient's condition does not improve on empirical antibiotic therapy. Antibiotics alone are rarely sufficient to treat SSIs, which may also need open drainage and debridement (*Summary box 5.14*).

Summary box 5.14

Principles for the use of antibiotic therapy

- Antibiotics do not replace surgical drainage of infection
- Only spreading infections or signs of systemic infection justify the use of antibiotics
- Whenever possible, the organism and sensitivity should be determined

There are two approaches to antibiotic treatment:

A **narrow-spectrum antibiotic** may be used to treat a known sensitive infection; for example, MRSA (which may be isolated from pus) is usually sensitive to vancomycin or teicoplanin, but not flucloxacillin.

Combinations of broad-spectrum antibiotics can be used when the organism is not known or when it is suspected that several bacteria, acting in synergy, may be responsible for the infection. For example, during and following emergency surgery requiring the opening of perforated or ischaemic bowel, any of the gut organisms may be responsible for subsequent peritoneal or bacteraemic infection. In this case, a broad-spectrum antibiotic such as teicoplanin or meropenem, which are effective against a wide range of aerobic bacteria, is combined with metronidazole, which is effective against anaerobic bacteria. Alternatively, triple therapy is used with amoxicillin, gentamicin and metronidazole. The use of such broad-spectrum antibiotic strategies should be guided by specialist microbiological advice. If clinical response is poor after 3–4 days, there should be a re-evaluation with a review of available culture and sensitivity results and further investigations requested to exclude the development or persistence of infection such as a collection of pus.

In surgical units in which resistant *Pseudomonas* or other Gram-negative species (such as *Klebsiella*) have become 'resident opportunists', it may be necessary to rotate anti-pseudomonal and anti-Gram-negative antibiotic therapy (*Summary box 5.15*).

Summary box 5.15

Treatment of commensals that have become opportunist pathogens

- They are likely to have multiple antibiotic resistance
- It may be necessary to rotate antibiotics

Antibiotics used in treatment and prophylaxis of surgical infection

Antimicrobials may be produced by living organisms (antibiotics) or by synthetic methods. Some are bactericidal, e.g. penicillins and aminoglycosides, and others are bacteriostatic, e.g. tetracycline and erythromycin. In general, penicillins act upon the bacterial cell wall and are most effective against bacteria that are multiplying and synthesising new cell wall materials. The aminoglycosides act at the ribosomal level, preventing or distorting the production of proteins required to maintain the integrity of the enzymes in the bacterial cell. Hospital and formulary guidelines should be consulted for doses and monitoring of antibiotic therapy.

Penicillin

Benzylpenicillin has proved most effective against Gram-positive pathogens, including most streptococci, the clostridia and some of the staphylococci that do not produce β-lactamase. It is still effective against *Actinomyces,* which is a rare cause of chronic wound infection. It may be used specifically to treat spreading streptococcal infections. Penicillin is valuable even if other antibiotics are required as part of multiple therapy for a mixed infection. Some serious infections, e.g. gas gangrene, require high-dose intravenous benzylpenicillin.

Flucloxacillin

Flucloxacillin is resistant to β-lactamases, and is therefore of use in treating infections with penicillinase-producing staphylococci that are resistant to benzylpenicillin, but it has poor activity against other pathogens. It has good tissue penetration and therefore is useful in treating soft-tissue infections and osteomyelitis.

Ampicillin, amoxicillin and co-amoxiclav

Ampicillin and amoxicillin are β-lactam penicillins and can be taken orally or may be given parenterally. Both are effective against Enterobacteriaceae, *Enterococcus faecalis* and the majority of group D streptococci, but not species of *Klebsiella* or *Pseudomonas.* Clavulanic acid has no antibacterial activity itself, but it does inactivate β-lactamases, so can be used in conjunction with amoxicillin. The combination is known as co-amoxiclav and is useful against β-lactamase-producing bacteria that are resistant to amoxicillin on its own. These include resistant strains of *Staphylococcus aureus, Escherichia coli, Haemophilus influenzae, Bacteroides* and *Klebsiella.*

Piperacillin and ticarcillin

These are ureidopenicillins with a broad spectrum of activity against a broad range of Gram-positive, Gram-negative and anaerobic bacteria. Both are used in combination with β-lactamase inhibitors (tazobactam with piperacillin and clavulanic acid with ticarcillin). They are not active against MRSA but are used in the treatment of septicaemia, hospital-acquired pneumonia and complex urinary tract infections, where they are active against *Pseudomonas* and *Proteus* spp. and have a synergistic effect when used with aminoglycosides such as gentamicin.

Cephalosporins

There are several β-lactamase-susceptible cephalosporins that are of value in surgical practice: cefuroxime, cefotaxime and ceftazidime are widely used. The first two are most effective in intra-abdominal skin and soft-tissue infections, being active against *Staphylococcus aureus* and most Enterobacteriaceae. As a group, the enterococci (*Streptococcus faecalis*) are not sensitive to the cephalosporins. Ceftazidime, although active against the Gram-negative organisms and *Staphylococcus aureus*, is also effective against *Pseudomonas aeruginosa*. These cephalosporins may be combined with an aminoglycoside, such as gentamicin, if Gram-negative cover is needed, and an imidazole, such as metronidazole, if anaerobic cover is needed.

Aminoglycosides

Gentamicin and tobramycin have similar activity and are effective against Gram-negative Enterobacteriaceae. Gentamicin is effective against many strains of *Pseudomonas*, although resistance has been recognised. All aminoglycosides are inactive against anaerobes and streptococci. Serum levels immediately before and 1 hour after intramuscular injection must be taken and repeated at 48 hours after the start of therapy, and dosage should be modified to satisfy peak and trough levels. Ototoxicity and nephrotoxicity may follow sustained high toxic levels and therefore single, large doses may be safer.

Vancomycin and teicoplanin

These glycopeptide antibiotics are most active against Gram-positive aerobic and anaerobic bacteria and have proved to be effective against MRSA, so are often used as prophylactic antibiotics when there is a high risk of MRSA. They are ototoxic and nephrotoxic, so serum levels should be monitored. They are effective against *C. diff.* in cases of pseudomembranous colitis.

Carbapenems

Meropenem, ertapenem and imipenem are members of the carbapenems. They are stable to β-lactamase, have useful broad-spectrum anaerobic as well as Gram-positive activity and are effective for the treatment of resistant organisms, such as ESBL-resistant urinary tract infections or serious mixed-spectrum abdominal infections (peritonitis).

Metronidazole

Metronidazole is the most widely used member of the imidazole group and is active against all anaerobic bacteria. It is particularly safe and may be administered orally, rectally or intravenously. Infections caused by anaerobic cocci and strains of *Bacteroides* and *Clostridia* can be treated, or prevented, by its use. Metronidazole is useful for the prophylaxis and treatment of anaerobic infections after abdominal, colorectal and pelvic surgery and in the treatment of *C. diff.* pseudomembranous colitis.

Ciprofloxacin

Quinolones, such as ciprofloxacin, have a broad spectrum of activity against both Gram-positive and Gram-negative bacteria but are particularly useful against *Pseudomonas* infections. Many UK and European hospitals have restricted their use as a preventive measure against the development of *C. diff.* enterocolitis.

PART 1 | Basic principles

CHAPTER 6

Tropical infections and infestations

Learning objectives

To be able to list:
- The common surgical infections and infestations that occur in the tropics

To appreciate:
- That many patients do not seek medical help until late in the course of the disease because of socioeconomic reasons

To be able to describe:
- The emergency presentations of the various conditions, as patients may not seek treatment until they are very ill

To be able to:
- Diagnose and treat these conditions, particularly as emergencies. The ease of global travel has connected areas where tropical infections are common to areas where they are not. Patients with such an infection who are recently returned from the tropics will mostly present as emergencies

To realise:
- That the ideal management involves a multidisciplinary approach between the surgeon, physician, radiologist, pathologist and microbiologist. In case of doubt, in a difficult situation, there should be no hesitation in seeking help from a specialist centre

INTRODUCTION

Most surgical conditions in the tropics (regions of the Earth surrounding the equator) are associated with parasitic infestations and infections related to poor hygienic conditions. With the ease of international travel, diseases that are common in the tropics may present in areas of the world where they are not commonly seen, especially as emergencies.

This chapter deals with the conditions that a surgeon might occasionally see when working in an area where such diseases are uncommon. Typically the patient would be a visitor from a tropical climate or a local resident who has visited the tropics either on holiday or to work. The life cycles of the parasites will not be described. The principles of surgical treatment are dealt with in the appropriate sections although, for operative details, referral to a relevant textbook is advised.

AMOEBIASIS

Introduction

Amoebiasis is caused by *Entamoeba histolytica*. The disease is common in the Indian subcontinent, Africa and parts of Central and South America, where almost half the population is infected. The majority remain asymptomatic carriers. The mode of infection is via the faecal–oral route and the disease occurs as a result of substandard hygiene and sanitation; therefore, the population from the poorer socioeconomic strata are more vulnerable. The prevalence of *E. histolytica* in stool samples in high-endemic zones such as South East Asia averages 10%; the incidence of amoebic liver abscesses in such populations, however, can be as high as 21 per 100 000 population.

Pathogenesis

The organism enters the gut through food or water contaminated with the cyst. In the small bowel, the cysts hatch and a large number of trophozoites are released and carried to the colon, where flask-shaped ulcers form in the submucosa. The trophozoites multiply, ultimately forming cysts, which either enter the portal circulation or are passed in the faeces as an infective form that infects other humans as a result of insanitary conditions.

Having entered the portal circulation, the trophozoites are filtered and trapped in the interlobular veins of the liver. They multiply in the portal triads, causing focal infarction of hepatocytes and liquefactive necrosis as a result of proteolytic enzymes produced by the trophozoites. The areas of necrosis eventually coalesce to form the abscess cavity. The term 'amoebic hepatitis' is used to describe the microscopic picture in the absence of macroscopic abscess, a differentiation only in theory because the medical treatment is the same.

The right lobe is involved in 80% of cases, the left in 10% and the remainder are multiple. One possible explanation for the more common involvement of the right lobe of the liver is that blood from the superior mesenteric vein runs on a straighter course through the portal vein into the larger lobe. The abscesses are most common high in the diaphragmatic surface of the right lobe. This may cause pulmonary symptoms

and chest complications. The abscess cavity contains chocolate-coloured, odourless, 'anchovy sauce'-like fluid that is a mixture of necrotic liver tissue and blood. There may be secondary infection of the abscess, which causes the pus to smell. While pus in the abscess is sterile unless secondarily infected, trophozoites may be found in the abscess wall in a minority of cases. Untreated abscesses are likely to rupture.

Chronic infection of the large bowel may result in a granulomatous lesion along the large bowel, most commonly seen in the caecum, called an amoeboma.

Summary box 6.1

Amoebiasis: pathology

- *E. histolytica* is the most common pathogenic amoeba in humans
- The vast majority of carriers are asymptomatic
- Insanitary conditions and poor personal hygiene encourage transmission of the infection
- In the small intestine, the parasite hatches into trophozoites, which invade the submucosa to produce flask-shaped ulcers in the colon
- In the portal circulation, the parasite causes liquefactive necrosis in the liver, producing an abscess, the commonest extraintestinal manifestation
- The majority of abscesses occur in the right lobe of the liver
- A mass in the course of the large bowel may indicate an amoeboma

Clinical features

The typical patient with an amoebic liver abscess is a young adult male with a history of insidious onset of non-specific symptoms, such as abdominal pain, anorexia, fever, night sweats, malaise, cough and weight loss. These symptoms gradually progress to more specific symptoms of pain in the right upper abdomen and right shoulder tip, hiccoughs and a non-productive cough. A past history of bloody diarrhoea or travel to an endemic area raises the index of suspicion.

Examination reveals a patient who is toxic and anaemic. The patient will have upper abdominal rigidity, tender hepatomegaly, often with tender and bulging intercostal spaces and overlying skin oedema, a pleural effusion and basal pneumonitis – the last feature is usually a late manifestation. Occasionally, a tinge of jaundice or ascites may be present. Rarely, the patient may present as an emergency owing to the effects of rupture of an abscess into the peritoneal, pleural or pericardial cavity.

Amoeboma

This is a chronic granuloma arising in the large bowel, most commonly seen in the caecum. It is prone to occur in long-standing amoebic infection that has been treated intermittently with drugs without completion of a full course, a situation that arises from indiscriminate self-medication, particularly in resource-poor countries. Hence this is more often seen in such countries.

This can easily be mistaken for a carcinoma. An amoeboma should be suspected when a patient from an endemic area with generalised ill health and pyrexia has a mass in the right iliac fossa with a history of blood-stained mucoid diarrhoea. Such a patient is highly unlikely to have a carcinoma because altered bowel habit is not a feature of right-sided colonic carcinoma. While iron deficiency anaemia is a classical elective presentation of a caecal carcinoma, the same is present in an amoeboma because of chronic malnutrition.

Investigations

The haematological and biochemical investigations reflect the presence of a chronic infective process: anaemia, leukocytosis, raised inflammatory markers – erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) – hypoalbuminaemia and deranged liver function tests, particularly elevated alkaline phosphatase.

Serological tests are more specific, with the majority of patients showing antibodies in serum. These can be detected by tests for complement fixation, indirect haemagglutination (IHA), indirect immunofluorescence, counter-immunoelectrophoresis and enzyme-linked immunosorbent assay (ELISA). These tests are extremely useful in detecting acute infection in non-endemic areas. IHA has a very high sensitivity in acute amoebic liver abscess in non-endemic regions and remains elevated for some time. The persistence of antibodies in a large majority of the population in endemic areas precludes its use as a diagnostic investigation in those locations. A combination of serological tests detecting antibodies in combination with detection of the parasite by antigen detection or DNA polymerase chain reaction is likely to be more beneficial in such cases, though with the limitation of cost and accessibility in developing nations.

While amoebiasis may affect the entire colon, it has a predilection for the caecum and ascending colon. A colonoscopy may reveal discrete exudate-covered areas of ulceration with normal areas in between.

Imaging techniques

On ultrasonography, an abscess cavity in the liver is seen as a hypoechoic or anechoic lesion with ill-defined borders; internal echoes suggest necrotic material or debris (***Figure 6.1***). The investigation is very accurate and is used for aspiration, both diagnostic and therapeutic. When there is doubt about the diagnosis, a computed tomography (CT) scan may be helpful (***Figure 6.2***).

Diagnostic aspiration is of limited value except for establishing the typical colour of the aspirate, which is sterile and odourless unless it is secondarily infected.

A CT scan may show a raised right hemidiaphragm, a pleural effusion and evidence of pneumonitis (***Figure 6.3***).

An 'apple-core' deformity on barium enema would arouse suspicion of a carcinoma. A colonoscopy with biopsy is mandatory because the radiological and macroscopic appearance may be indistinguishable from a carcinoma. In doubtful cases, vigorous medical treatment is given and the patient undergoes colonoscopy again in 3–4 weeks, as these masses are known to

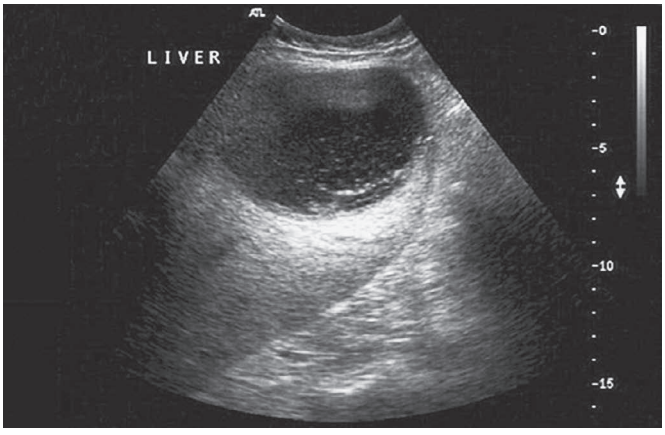

Figure 6.1 Ultrasound of the liver showing a large amoebic liver abscess with necrotic tissue in the right lobe.

regress completely on a full course of drug therapy. If symptoms persist even partially following full medical treatment in a patient who has recently returned from an endemic area, a colonic carcinoma must be excluded forthwith. This is because a dormant colonic carcinoma may become apparent as a result of infestation with amoebic dysentery causing 'traveller's diarrhoea'. However, it must be borne in mind that an amoeboma and a carcinoma can coexist.

Summary box 6.2

Diagnostic pointers for infection with *Entamoeba histolytica*

- Bloody mucoid diarrhoea in a patient from an endemic area or following a recent visit to such a country
- Upper abdominal pain, fever, cough, malaise
- In chronic cases, a mass in the right iliac fossa may be an amoeboma but caecal cancer must be excluded by colonoscopy and biopsy
- Sigmoidoscopy shows typical ulcers – biopsy and scrapes may be diagnostic
- Serological tests are highly sensitive and specific outside endemic areas
- Ultrasonography and CT scans are the imaging methods of choice

Treatment

Medical treatment is very effective and should be the first choice in the elective situation, with surgery being reserved for complications. Metronidazole and tinidazole are the effective drugs. After treatment with metronidazole and tinidazole, diloxanide furoate, a luminal amoebicide that is not effective against hepatic infestation, is used for 10 days to destroy any intestinal amoebae.

Aspiration is carried out when imminent rupture of an abscess is expected, especially when involving the left lobe. Pigtail catheter drainage may be considered in those patients who are not responding to intravenous metronidazole in the first 48–72 hours to improve antibiotic penetration. If there is evidence of secondary infection, appropriate drug treatment is added. The threshold for draining a left liver lobe abscess

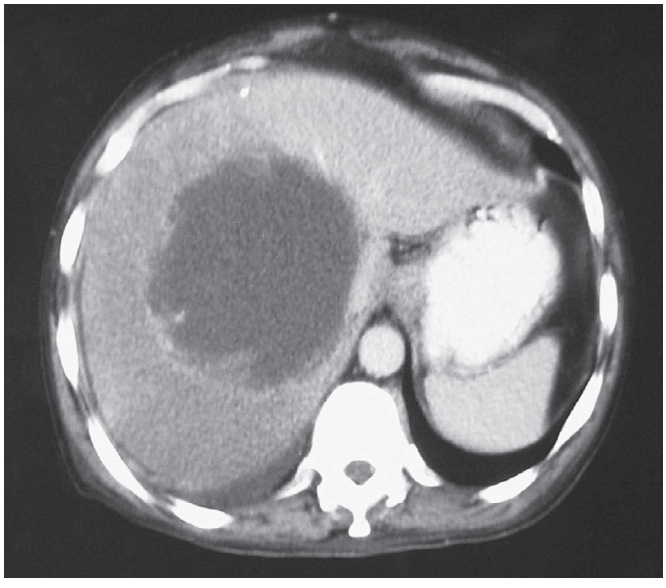

Figure 6.2 Computed tomographic scan showing an amoebic liver abscess in the right lobe.

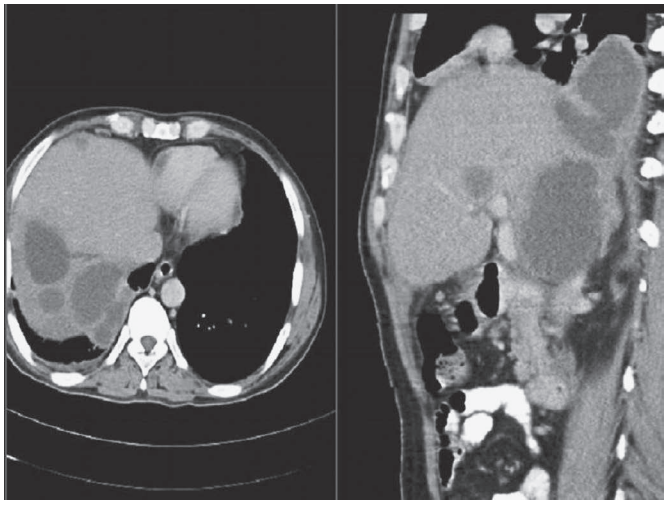

Figure 6.3 Computed tomographic scans showing multiple amoebic liver abscesses with extension into the chest.

should be low, given its propensity for rupture into either the peritoneal, pleural or pericardial cavity.

Surgical treatment should be reserved for the complications of rupture into the pleural (usually the right side), peritoneal or pericardial cavities. Resuscitation, drainage and appropriate lavage with vigorous medical treatment are the key principles. In the large bowel, severe haemorrhage and toxic megacolon are rare complications. In these patients, the general principles of a surgical emergency apply, the principles of management being the same as for any toxic megacolon. Resuscitation is followed by resection of bowel with exteriorisation. Then the patient is given vigorous supportive therapy. All such cases are managed in the intensive care unit, as would any patient with toxic megacolon whatever the cause.

An amoeboma that has not regressed after full medical treatment should be managed with colonic resection, particularly if cancer cannot be excluded.

Summary box 6.3

Amoebiasis: treatment

- Medical treatment is very effective
- For large abscesses, repeated aspiration or pigtail catheter drainage is combined with drug treatment
- Surgical treatment is reserved for complications, such as rupture into the pleural, peritoneal or pericardial cavities
- Acute toxic megacolon and severe haemorrhage are intestinal complications that are treated with intensive supportive therapy followed by resection and exteriorisation: subtotal colectomy with terminal ileostomy and closure of the rectal stump
- When an amoeboma is suspected in a colonic mass, cancer should be excluded by appropriate imaging and biopsy

ROUNDWORM (*ASCARIS LUMBRICOIDES*)

Introduction

Ascaris lumbricoides, commonly called the roundworm, is the commonest intestinal nematode to infect humans and affects a quarter of the world's population. The parasite causes pulmonary symptoms as a larva and intestinal symptoms as an adult worm.

Pathology and life cycle

The fertilised eggs can survive in a hostile environment for a long time. The hot and humid conditions in the tropics are ideally suited for the eggs to turn into embryos. The fertilised eggs are present in soil contaminated with infected faeces, becoming infective in about 3 weeks. Faecal–oral contamination causes human infection.

The eggs are ingested and the larvae are released in the jejunum, from where they travel to the liver via the portal system and the lymphatics. The larvae reach the lungs via the systemic circulation, where they undergo maturation for 2 weeks.

The developed larvae reach the alveoli, are coughed up, swallowed and continue their maturation in the small intestine. Sometimes, the young worms migrate from the tracheobronchial tree into the oesophagus, thus finding their way into the gastrointestinal tract, from where they can migrate to the common bile duct or pancreatic duct. The mature female, once in the small bowel, produces innumerable eggs that are fertilised and thereafter excreted in the stool to perpetuate the life cycle. Eggs in the biliary tract can form a nidus for a stone.

Clinical features

The larval stage in the lungs causes pulmonary symptoms – dry cough, chest pain, dyspnoea and fever – referred to as Loeffler's syndrome. The adult worm can grow up to 45 cm long. Its presence in the small intestine causes malnutrition, failure to thrive, particularly in children, and abdominal pain. Worms that migrate into the common bile duct can produce ascending cholangitis and obstructive jaundice, while features of acute pancreatitis may be caused by a worm in the pancreatic duct.

Small intestinal obstruction can occur, particularly in children, owing to a bolus of adult worms incarcerated in the terminal ileum. This is a surgical emergency. Rarely, perforation of the small bowel may occur from ischaemic pressure necrosis from the bolus of worms.

A high index of suspicion is necessary so as not to miss the diagnosis. If a person from a tropical country, or one who has recently returned after spending some time in an endemic area, presents with pulmonary, gastrointestinal, hepatobiliary and pancreatic symptoms, ascariasis should be high on the list of possible diagnoses.

Investigations

As with most parasitic infestations, an increase in the eosinophil count is common. Stool examination may show ova. Sputum or bronchoscopic washings may show Charcot–Leyden crystals or the larvae.

Chest radiograph may show fluffy exudates in Loeffler's syndrome. A barium meal and follow-through may show a bolus of worms in the ileum or lying freely within the small bowel (***Figure 6.4***). Ultrasonography may show a worm in the gallbladder, the common bile duct (***Figure 6.5***) or pancreatic duct. On magnetic resonance cholangiopancreatography (MRCP), an adult worm may be seen in the common bile duct in a patient presenting with features of obstructive jaundice (***Figure 6.6***). In patients with intestinal obstruction, plain abdominal radiograph may show tubular structures within dilated small bowel, denoting the presence of worms, which would also show up on a contrast CT scan as curvilinear structures.

Summary box 6.4

Ascariasis: pathogenesis

- It is the commonest intestinal nematode affecting humans
- Typically found in a humid atmosphere and poor sanitary conditions, hence is seen in the tropics and resource-poor countries
- Larvae cause pulmonary symptoms; adult worms cause gastrointestinal, biliary and pancreatic symptoms
- Distal ileal obstruction is due to a bolus of worms; ascending cholangitis and obstructive jaundice are due to infestation of the common bile duct
- Acute pancreatitis occurs when a worm is lodged in the pancreatic duct
- Perforation of the small bowel is rare

Wilhelm Loeffler, 1887–1972, Professor of Medicine, Zurich, Switzerland.
Jean Martin Charcot, 1825–1893, French neurologist and Professor of Pathology at Hôpital Universitaire la Pitié-Salpêtrière, Paris, France.
Ernst von Leyden, 1832–1910, Professor of Medicine, Berlin, Germany.

Figure 6.4 Barium meal and follow-through showing roundworms in the course of the small bowel with barium seen inside the worms in an 18-year-old patient who presented with bouts of colicky abdominal pain and bilious vomiting, which settled with conservative management (courtesy of Dr PP Bhattacharyya, Kolkata, India).

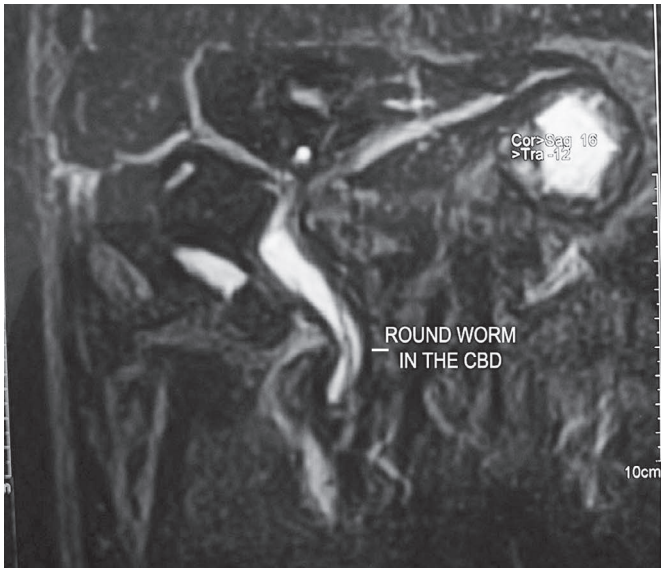

Figure 6.6 Magnetic resonance cholangiopancreatography showing a roundworm in the common bile duct (CBD). The worm could not be removed endoscopically. The patient underwent an open cholecystectomy and exploration of the CBD (this can also be addressed laparoscopically in some centres).

Treatment

The pulmonary phase of the disease is usually self-limiting and requires symptomatic treatment only. For intestinal disease, patients should ideally be under the care of a physician for treatment with anthelminthic drugs. Certain drugs may cause rapid death of the adult worms and, if there are many worms in the terminal ileum, the treatment may actually precipitate acute intestinal obstruction from a bolus of dead worms. Children who present with features of intermittent or subacute obstruction should be given a trial of conservative management in the form of intravenous fluids, nasogastric suction and hypertonic saline enemas. The last of these helps to disentangle the bolus of worms and also increases intestinal motility.

Surgery is reserved for complications, such as intestinal obstruction that has not resolved on a conservative regime, or when perforation is suspected. At laparotomy, the bolus of worms in the terminal ileum is milked through the ileocaecal valve into the colon for natural passage in the

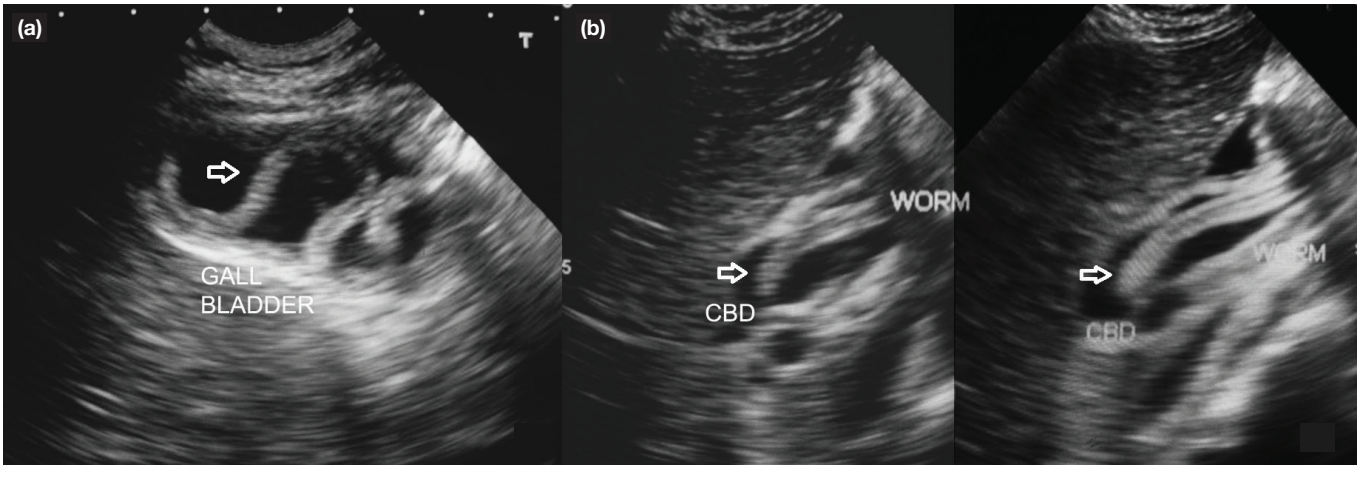

Figure 6.5 Ultrasound scan showing a live worm (arrow) in the gallbladder (a) and the common bile duct (CBD) (b) (courtesy of Dr A Bhattacharyya, Kolkata, India).

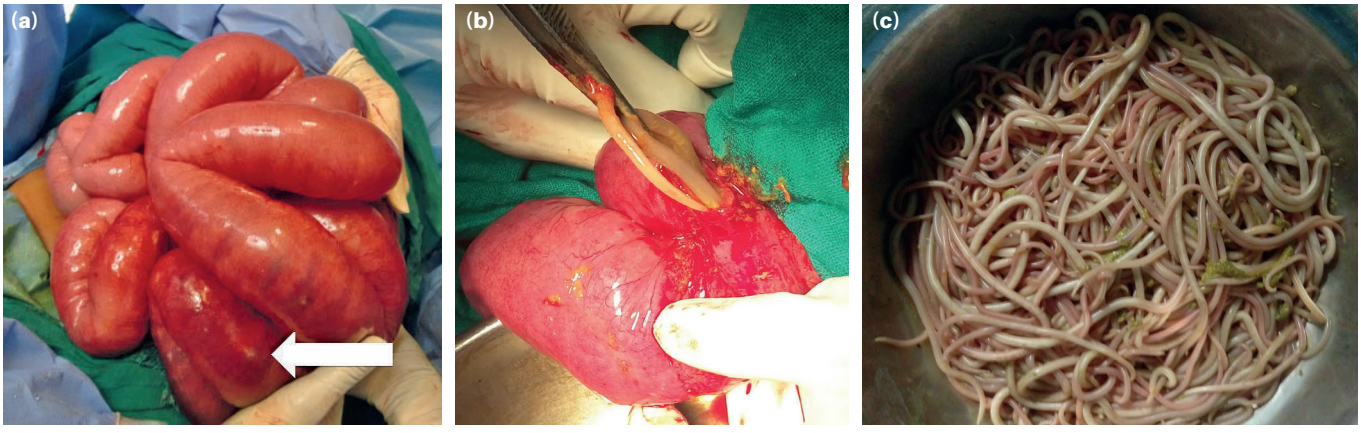

Figure 6.7 (a) Roundworms seen through the bowel wall (arrowed). **(b)** Roundworm being removed through enterotomy. **(c)** Removed roundworms.

stool. Postoperatively, hypertonic saline enemas may help in the extrusion of the worms. Strictures, gangrenous areas or perforations need resection and anastomosis. If the bowel wall is healthy, enterotomy and removal of the worms may be performed (***Figure 6.7***).

Rarely, when perforation occurs as a result of roundworm, the parasites may be found lying free in the peritoneal cavity. It is safer to bring out the site of perforation as an ileostomy because, in the presence of a large number of worms, the closure of an anastomosis may be at risk of breakdown from the activity of the residual worms in the bowel.

When a patient is operated upon as an emergency for a suspected complication of roundworm infestation, the actual diagnosis at operation may turn out to be acute appendicitis, typhoid perforation or a tuberculous stricture and the presence of roundworms is an incidental finding. Such a patient requires the appropriate surgery depending upon the primary pathology.

Common bile duct or pancreatic duct obstruction from a roundworm can be treated by endoscopic removal at endoscopic retrograde cholangiopancreatography (ERCP), failing which laparoscopic or open exploration of the common bile duct is necessary. Cholecystectomy is also carried out. A full course of antiparasitic treatment must follow any surgical intervention.

Summary box 6.5

Ascariasis: diagnosis and management

- Barium meal and follow-through will show worms scattered in the small bowel
- Ultrasonography may show worms in the common bile duct and pancreatic duct
- Plain abdominal radiograph and contrast CT scan will show the worms as tubular or curvilinear structures
- Conservative management with anthelminthics is the first line of treatment even in obstruction
- Surgery is a last resort for acute abdomen – various options are available

ASIATIC CHOLANGIOHEPATITIS

Introduction

This disease, also called oriental cholangiohepatitis, is caused by infestation of the hepatobiliary system by a trematode, *Clonorchis sinensis*. It has a high incidence in the tropical regions of South East Asia, particularly among those living in the major sea ports and near river estuaries. The organism, which is a type of liver fluke, develops in snails that act as an intermediate host. Free swimming from snails, the cercariae penetrate the flesh of freshwater fish, crabs and crayfish, which also act as an intermediate host. Ingestion of infected fish, crabs and crayfish, when eaten raw or improperly cooked, causes the infection in humans and other fish-eating mammals, which are the definitive hosts. Two other parasites, *Opisthorchis*, which has the same life cycle as *Clonorchis*, and *Fasciola*, the metacercariae of which colonise vegetation, can cause similar damage to the biliary channels.

Pathology

In humans, the parasite matures into the adult worm in the intrahepatic biliary radicles, where it may reside for many years. The intrahepatic bile ducts are dilated, with epithelial hyperplasia and periductal fibrosis. These changes may lead to dysplasia, causing cholangiocarcinoma – the most serious and dreaded complication of this parasitic infestation.

The eggs or dead worms may form a nidus for stone formation in the gallbladder or common bile duct, which becomes thickened and much dilated in the late stages. Intrahepatic bile duct stones are also caused by the parasite producing mucin-rich bile. The dilated intrahepatic bile ducts may lead to cholangitis, liver abscess and hepatitis.

Diagnosis

The disease may remain dormant for many years. Clinical features are non-specific and include fever, malaise, anorexia and upper abdominal discomfort. The complete clinical picture can consist of fever with rigors due to ascending cholangitis,

obstructive jaundice, biliary colic and pruritus from stones in the common bile duct. Acute pancreatitis may occur because of obstruction of the pancreatic duct by an adult worm. Particularly when presenting in non-endemic areas, it should be noted that if a person from an endemic area complains of symptoms of biliary tract disease, *Clonorchis* infestation should be high in the differential diagnosis.

In advanced cases, liver function tests are abnormal. Confirmation of the condition is by examination of stool or duodenal aspirate, which may show the eggs or adult worms. Ultrasonography findings may be characteristic, showing uniform dilatation of small peripheral intrahepatic bile ducts with only minimal dilatation of the common hepatic and common bile ducts, although the latter are much more dilated when the obstruction is caused by stones. The thickened duct walls show increased echogenicity and non-shadowing echogenic foci in the bile ducts, representing the worms or eggs. ERCP will confirm these findings.

Summary box 6.6

Asiatic cholangiohepatitis: pathogenesis and diagnosis

- Occurs in Far Eastern tropical zones
- The causative parasite is *Clonorchis sinensis*, *Opisthorchis* or *Fasciola*
- Produces bile duct hyperplasia, intrahepatic duct dilatation and stones
- Increases the risk of cholangiocarcinoma
- May remain dormant for many years
- When active, there are biliary tract symptoms in a generally unwell patient
- Stool examination for eggs or worms is diagnostic
- Ultrasonography of the hepatobiliary system and ERCP is also diagnostic

Treatment

Praziquantel and albendazole are the drugs of choice. However, the surgeon faces a challenge when there are stones not only in the gallbladder but also in the common bile duct. Cholecystectomy with exploration of the common bile duct is performed when indicated; currently, both procedures are performed laparoscopically as a single-stage procedure. Repeated washouts are necessary during the exploration of the common bile duct as there are stones, biliary debris, sludge and mud in the dilated duct. This should be followed by choledochoduodenostomy. As this is a disease with a prolonged and relapsing course, some surgeons prefer to do a choledochojejunostomy to a Roux loop. The Roux loop is brought up to the abdominal wall, referred to as 'an access loop', which allows the interventional radiologist to deal with any future stones.

As a public health measure, people who have emigrated from an endemic area should be offered screening for *Clonorchis* infestation in the form of ultrasonography of the hepatobiliary system. This condition can be diagnosed and treated, and even cured, when it is in its subclinical form. Most importantly, the risk of developing the dreadful disease of cholangiocarcinoma is eliminated.

Summary box 6.7

Asiatic cholangiohepatitis: treatment

- Medical treatment can be curative in the early stages
- Surgical treatment is cholecystectomy, exploration of the common bile duct and some form of biliary–enteric bypass
- Prevention: consider offering hepatobiliary ultrasonography as a screening procedure to recently arrived migrants from endemic areas

FILARIASIS

Introduction

Filariasis is mainly caused by the parasite *Wuchereria bancrofti*, which is transmitted by the mosquito. Variants of the parasite called *Brugia malayi* and *Brugia timori* are responsible for causing the disease in about 10% of those infected. The condition affects more than 120 million people worldwide, two-thirds of whom live in India, China and Indonesia. According to the World Health Organization (WHO), after leprosy, filariasis is the most common cause of long-term disability.

Once the host has been bitten by the mosquito, the matured eggs enter the human circulation to hatch and grow into adult worms; the process of maturation takes almost a year. The adult worms mainly colonise the lymphatic system.

Diagnosis

It is mainly males who are affected because females generally cover a greater part of their bodies with clothing, thus making them less prone to mosquito bites. In the acute presentation, there are episodic attacks of fever with lymphadenitis and lymphangitis.

Occasionally, adult worms may be felt subcutaneously. Chronic manifestations appear after repeated acute attacks over several years. The adult worms cause lymphatic obstruction, resulting in massive lower limb oedema. Obstruction to the cutaneous lymphatics causes skin thickening, not unlike the *peau d'orange* appearance in breast cancer, thus exacerbating the limb swelling. Secondary streptococcal infection is common. Recurrent attacks of lymphangitis cause fibrosis of the lymph channels, resulting in a grossly swollen limb with thickened skin, producing the condition of elephantiasis (***Figure 6.8***). Bilateral lower limb filariasis is often associated with scrotal and penile elephantiasis. Early on, there may be a hydrocele underlying scrotal filariasis (***Figure 6.9***).

César Roux, 1857–1934, Professor of Surgery and Gynaecology, Lausanne, Switzerland, described this method of forming a jejunal conduit in 1908.
Otto Eduard Heinrich Wucherer, 1820–1873, German physician who practised in Brazil.
Joseph Bancroft, 1836–1894, English physician who worked in Australia.
Peau d'orange is French for 'orange peel skin'.

Figure 6.8 Left lower limb filariasis – elephantiasis (courtesy of Professor Ahmed Hassan Fahal, FRCS MD MS, Khartoum, Sudan).

Chyluria and chylous ascites may occur. A mild form of the disease can affect the respiratory tract, causing dry cough, and is referred to as tropical pulmonary eosinophilia. The condition of filariasis is clinically very obvious, and thus investigations in the full-blown case are superfluous. Eosinophilia is common and a nocturnal peripheral blood smear may show the immature forms, or microfilariae. The parasite may also be seen in chylous urine, ascites and hydrocele fluid.

Treatment

Medical treatment with diethylcarbamazine is very effective in the early stages before the gross deformities of elephantiasis have developed. In the early stages of limb swelling, intermittent pneumatic compression helps, but the treatment has to be repeated over a prolonged period.

Summary box 6.8

Filariasis

- Caused by *Wuchereria bancrofti*, which is carried by the mosquito
- Lymphatics are mainly affected, resulting in gross limb swelling
- Eosinophilia occurs; immature worms may be seen in a nocturnal peripheral blood smear
- Gross forms of the disease cause a great deal of disability and misery
- Early cases are very amenable to medical treatment
- Intermittent pneumatic compression gives some relief
- The value of various surgical procedures is largely unproven and hence they are rarely performed

Figure 6.9 Filariasis of the scrotum and penis (courtesy of Professor Ahmed Hassan Fahal, FRCS MD MS, Khartoum, Sudan).

A hydrocele is treated by the usual operation of excision and eversion of the sac with, if necessary, excision of redundant scrotal skin. Operations for reducing the size of the limb are hardly ever done these days because the procedures are so rarely successful.

HYDATID DISEASE

Introduction and pathology

Hydatid disease is caused by *Echinococcus granulosus*, commonly called the dog tapeworm. The disease is globally distributed and, while it is common in the tropics, it is much less common in other countries; for example, in the UK the occasional patient may come from a rural sheep-farming community.

The dog is the definitive host and is the commonest source of infection transmitted to the intermediate hosts – humans, sheep and cattle. In the dog, the adult worm reaches the small intestine and the eggs are passed in the faeces. These eggs are highly resistant to extremes of temperature and may survive for long periods. In the dog's intestine, the cyst wall is digested, allowing the protoscolices to develop into adult worms. Close contact with an infected dog causes contamination by the oral route, with the ovum thus gaining entry into the human gastrointestinal tract.

The cyst is characterised by three layers: an outer **pericyst**, which is derived from compressed host organ tissues; an intermediate hyaline **ectocyst**, which is non-infective; and an inner **endocyst**, which is the germinal membrane and contains viable parasites that can separate, forming daughter cysts. A variant of the disease occurs in colder climates caused by *Echinococcus multilocularis*, in which the cyst spreads from the outset by actual invasion rather than expansion.

Classification

In 2003, the WHO Informal Working Group on Echinococcosis (WHO-IWGE) proposed a standardised ultrasound

classification based on the status of activity of the cyst (*Table 6.1*). This is universally accepted, particularly because it helps to decide on the appropriate management. Three groups have been recognised:

- Group 1: Active group – cysts larger than 2 cm and often fertile.
- Group 2: Transition group – cysts starting to degenerate and entering a transitional stage because of host resistance or treatment but may contain viable protoscolices.
- Group 3: Inactive group – degenerated, partially or totally calcified cysts; unlikely to contain viable protoscolices.

Clinical features

As the parasite can colonise virtually every organ in the body, the condition can be protean in its presentation. When a sheep farmer who is otherwise healthy complains of a gradually enlarging painful mass in the right upper quadrant with the physical findings of a liver swelling, a hydatid liver cyst should be considered. The liver is the organ most often affected. The lung is the next most common. The parasite can affect any organ (*Figures 6.10 and 6.11*) or several organs in the same patient (*Figure 6.12*).

The disease may be asymptomatic and discovered coincidentally at postmortem or when an ultrasonography or CT scan is done for some other condition. Symptomatic disease presents with a swelling causing pressure effects. Thus, a hepatic lesion causes dull pain from stretching of the liver capsule, and a pulmonary lesion, if large enough, causes dyspnoea. Daughter cysts may communicate with the biliary tree, causing obstructive jaundice and all the usual clinical features associated with it in addition to symptoms attributable to a parasitic infestation (*Figure 6.13*). Features of raised intracranial pressure or unexplained headaches in a patient from a sheep-rearing community should raise the suspicion of a cerebral hydatid cyst.

The patient may present as an emergency with severe abdominal pain following minor trauma, when the CT scan may be diagnostic (*Figure 6.14*). Rarely, a patient may present as an emergency with features of anaphylactic shock without any obvious cause. Such a patient may subsequently cough up white material that contains scolices that have travelled into the tracheobronchial tree from rupture of a hepatic hydatid on the diaphragmatic surface of the liver.

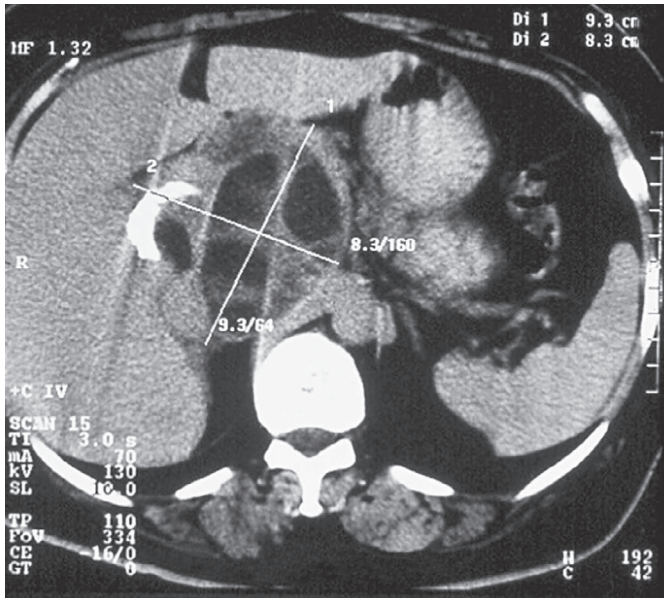

Figure 6.10 Computed tomographic scan showing a hydatid cyst of the pancreas. A differential diagnosis of hydatid cyst or a tumour was considered. At exploration, the patient was found to have a hydatid cyst, which was excised. This was followed by 30 months of treatment with albendazole. The patient remains free of disease.

Diagnosis

There should be a high index of suspicion. Investigations show a raised eosinophil count; serological tests, such as ELISA and immunoelectrophoresis, point towards the diagnosis. Ultrasonography and CT scan are the investigations of choice. The CT scan shows a smooth space-occupying lesion with several septa. Ultrasonography of the biliary tract may show abnormality in the gallbladder and bile ducts, when hydatid infestation of the biliary system should be suspected. An MRCP may even show multiple cysts communicating with the biliary tree (*Figure 6.13*). Ultimately, the diagnosis is made by a combination of good history and clinical examination supplemented by serology and imaging.

TABLE 6.1 Classification of hepatic hydatid cyst

Stage	Description
CL (cystic lesion)	Unilocular anechoic cystic lesion without internal echoes or septations
CE (cystic echinococcosis) 1	Uniformly anechoic cyst with fine internal echoes that represent protoscolices after rupture of a vesicle, called 'hydatid sand'
CE 2	Cyst with internal septation representing the walls of the daughter cyst described as multivesicular, honeycomb, cartwheel or rosette formation
CE 3 (transitional stage) description of daughter cyst	3A: daughter cysts with detached laminated membrane
	3B- daughter cysts inside a solid matrix
CE 4 (inactive/degenerative)	Daughter cysts can no longer be seen Mixture of hypoechoic and hyperechoic features – like a bag of wool
CE 5 (inactive/degenerative)	Calcification of the wall; either partial or complete

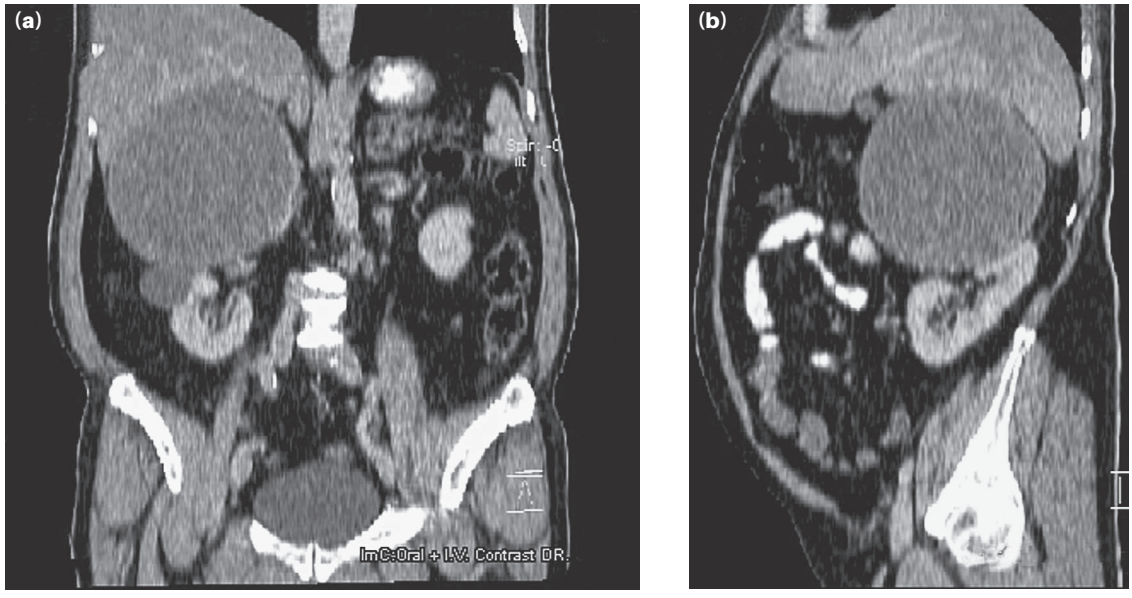

Figure 6.11 Anteroposterior **(a)** and lateral **(b)** views of computed tomographic scans showing a large hydatid cyst of the right adrenal gland. The patient presented with a mass in the right loin and underwent an adrenalectomy (courtesy of Dr PP Bhattacharyya, Kolkata, India).

Summary box 6.9

Hydatid disease: diagnosis

- In the UK, the usual sufferer is a sheep farmer
- While any organ may be involved, the liver is by far the most commonly affected
- Elective clinical presentation is usually in the form of a painful lump arising from the liver
- Anaphylactic shock due to rupture of the hydatid cyst is the emergency presentation
- CT scan is the best imaging technique – the diagnostic feature is a space-occupying lesion with a smooth outline with septa

Treatment

Here, the treatment of hepatic hydatid is outlined because the liver is most commonly affected, but the same general principles apply whichever organ is involved.

These patients should be treated in a tertiary unit where good teamwork between an expert hepatobiliary surgeon, an experienced physician and an interventional radiologist is available. Surgical treatment by minimal access therapy is best summarised by the mnemonic PAIR (puncture, aspiration, injection and reaspiration). This is done after adequate drug treatment with albendazole, although praziquantel has

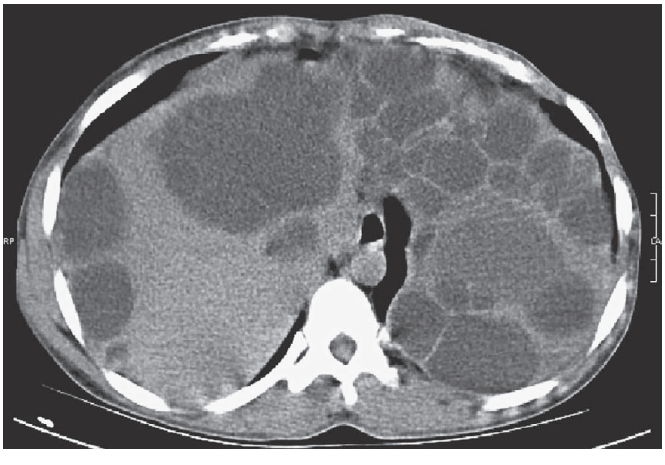

Figure 6.12 Computed tomographic scan showing disseminated hydatid cysts of the abdomen. The patient was started on albendazole but was lost to follow-up (courtesy of Dr PP Bhattacharyya, Kolkata, India).

Figure 6.13 Magnetic resonance cholangiopancreatography showing a large hepatic hydatid cyst with daughter cysts communicating with the common bile duct, causing obstruction and dilatation of the entire biliary tree (courtesy of Dr B Agarwal, New Delhi, India).

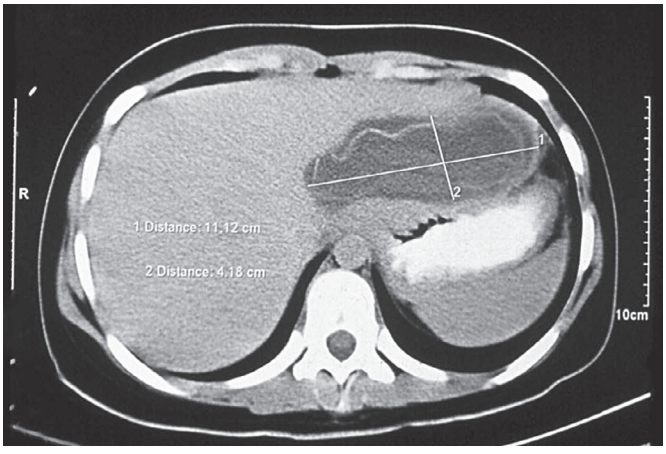

Figure 6.14 Computed tomographic (CT) scan of the upper abdomen showing a hypodense lesion of the left lobe of the liver; the periphery of the lesion shows a double edge. This is the lamellar membrane of the hydatid cyst that separated after trivial injury. The patient was a 14-year-old girl who developed a rash and pain in the upper abdomen after dancing. The rash settled down after a course of antihistamines. The CT scan was performed 2 weeks later for persisting upper abdominal pain.

also been used, both of these drugs being available only on a 'named patient' basis.

Whether the patient is treated only medically or in combination with surgery will depend upon the clinical group (which gives an idea as to the activity of the disease), the number of cysts and their anatomical position. Radical total or partial pericystectomy with omentoplasty or hepatic segmentectomy (especially if the lesion is in a peripheral part of the liver) are some of the surgical options. During the operation, scolicidal agents are used, such as hypertonic saline (15–20%), ethanol (75–95%) or 5% povidone–iodine (although some use a 10% solution). This may cause sclerosing cholangitis if biliary radicles are in communication with the cyst wall. A laparoscopic approach to these procedures is being tried (see next section, *Laparoscopic management*).

Obviously, cysts in other organs need to be treated in accordance with the actual anatomical site, along with the general principles described. An asymptomatic cyst that is inactive (group 3) may be left alone.

Summary box 6.10

Hydatid cyst of the liver: treatment

- Ideally managed in a tertiary unit by a multidisciplinary team of hepatobiliary surgeon, physician and interventional radiologist
- Leave asymptomatic and inactive cysts alone – monitor size by ultrasonography
- Active cysts should first be treated by a full course of albendazole
- Several procedures are available – PAIR, pericystectomy with omentoplasty and hepatic segmentectomy; appropriate management is customised according to the particular patient and organ involved
- Increasingly, a laparoscopic approach is being tried

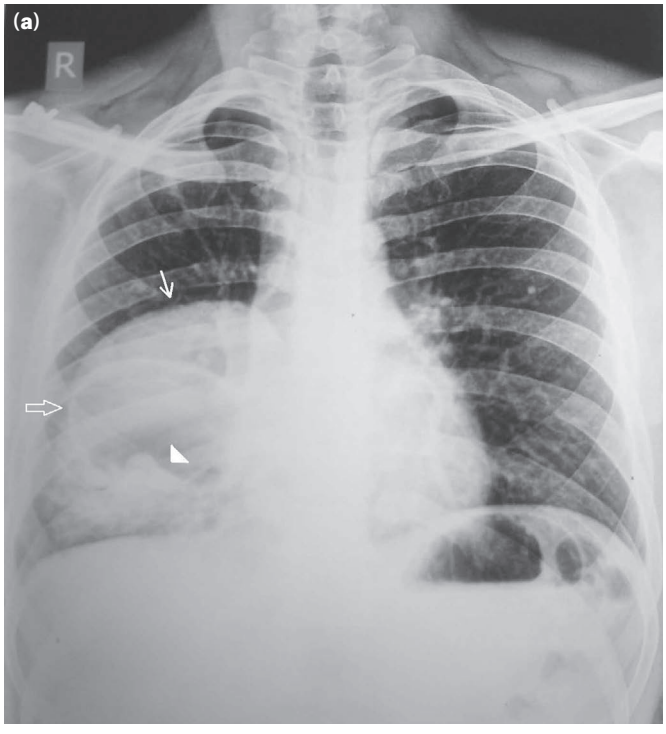
Laparoscopic management

Currently, surgeons trained in minimal access surgery perform hydatid surgery using minimal access. Laparoscopic marsupialisation of the cyst (deroofing), consisting of removal of the cyst containing the endocyst along with daughter cysts, is the most common procedure. In the initial steps, the cyst is aspirated, taking care not to spill any contents, using povidone–iodine or hypertonic saline as a scolicidal agent. Any communication with the biliary tree is oversewn and pedicled omentum is sutured to the margins of the cyst.

If the cyst is small and superficial, a cystopericystectomy is performed at centres experienced enough to do more advanced surgery, removing the entire cyst intact.

Pulmonary hydatid disease

The lung is the second commonest organ affected after the liver. The size of the cyst can vary from very small to a considerable size. The right lung and lower lobes are slightly more often involved. The cyst is usually single, although multiple cysts do occur and concomitant hydatid cysts in other organs, such as the liver, are not unknown. The condition may be silent and found incidentally. Symptomatic patients present with cough, expectoration, fever, chest pain and sometimes haemoptysis. Silent cysts may present as an emergency because of rupture or an allergic reaction.



Uncomplicated cysts present as rounded or oval lesions on chest radiography. Erosion of the bronchioles results in air being introduced between the pericyst and the laminated membrane and gives a fine radiolucent crescent, the 'meniscus' or 'crescent' sign (*Figure 6.15*). This is often regarded as a sign of impending rupture. When the cyst ruptures, the crumpled collapsed endocyst floats like a lily on the residual fluid, giving rise to the 'water-lily' sign on CT scan (*Figure 6.16*). Rupture into the pleural cavity results in pleural effusion. CT scan defines the pathology in greater detail.

The mainstay of treatment of pulmonary hydatid is surgery. Medical treatment is less successful and considered when surgery is not possible because of poor general condition or diffuse disease affecting both lungs, or recurrent or ruptured cysts. The principle of surgery is to preserve as much viable lung tissue as possible. The exact procedure can vary: cystotomy, capitonnage, pericystectomy, segmentectomy or occasionally pneumonectomy.

Summary box 6.11

Pulmonary hydatid disease

- The second most common organ involved
- Size of the cyst has a wide variation
- May present as an incidental finding
- Clinical presentation may be elective or as an emergency because of rupture
- Plain radiograph shows 'meniscus' or 'crescent' sign; CT shows 'water-lily' sign
- Ideal treatment is surgical – various choices are available

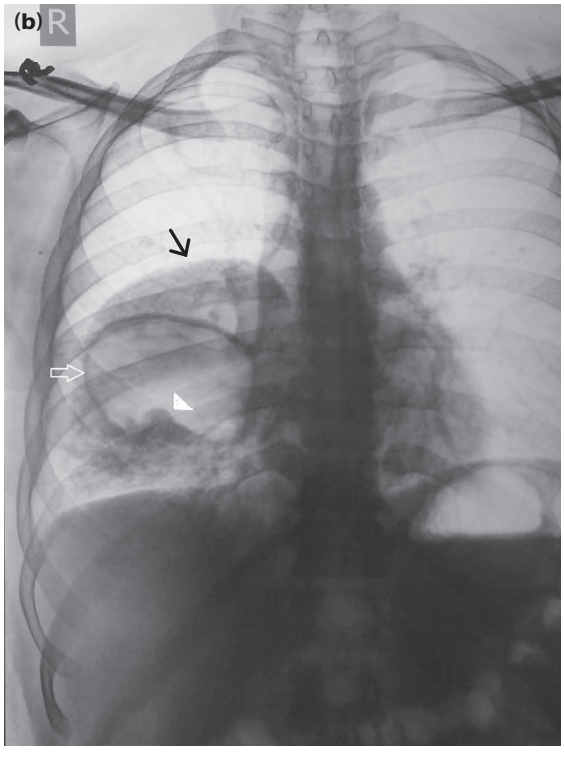


Figure 6.15 Hydatid cysts of the lung, one intact (solid arrow), one ruptured (hollow arrow) showing the lamellar membrane floating like a water lily (solid arrowhead) (courtesy of Professor Saibal Gupta, MS, FRCS, Professor of Cardiovascular Surgery, Kolkata, India and Dr Rupak Bhattacharya, Kolkata, India).

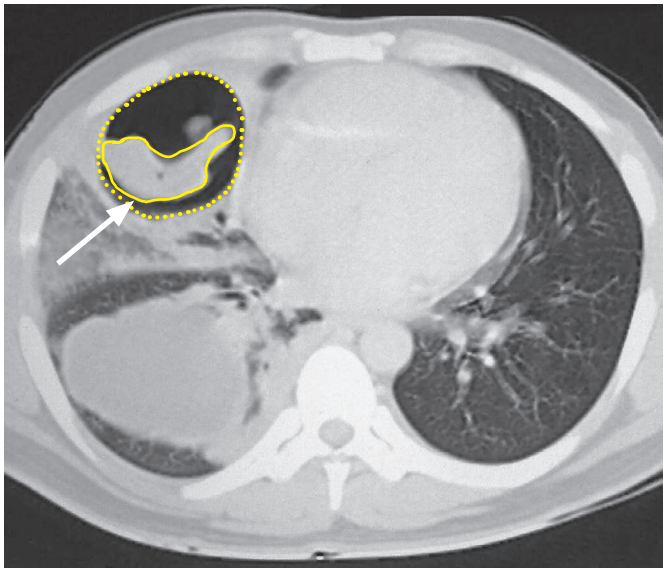

Figure 6.16 Computed tomographic scan showing the 'water-lily' sign (arrow). While on a high-altitude trip a young mountaineer complained of sudden shortness of breath, cough and copious expectoration consisting of clear fluid and flaky material. At first thought to be due to pulmonary oedema, it turned out to be ruptured hydatid cyst, successfully treated by surgery (courtesy of Professor Saibal Gupta, MS, FRCS, Professor of Cardiovascular Surgery, Kolkata, India and Dr Rupak Bhattacharya, Kolkata, India).

LEPROSY

Introduction

Leprosy, also called Hansen's disease, is a chronic infectious disease caused by an acid-fast bacillus, *Mycobacterium leprae*, that is widely prevalent in the tropics. Globally, India, Brazil, Nepal, Mozambique, Angola and Myanmar account for 91% of all cases; India alone accounts for 78% of the world's disease. Patients suffer not only from the primary effects of the disease but also from social discrimination, sadly compounded by use of the word 'leper' for one afflicted with this disease.

Close contact over a long duration (several years) is required for disease transmission. Ignorance of this fact on the part of the general public results in ostracism and social stigma. History records that in the distant past sufferers were made to wear cow bells so that other people could avoid them. The use of the term 'leper', still used metaphorically to denote an outcast, does not help to break down the social barriers that continue to exist against the sufferer.

Pathology

The bacillus inhabits the colder parts of the body; hence, it is found in the nasal mucosa and skin in the region of the ears,

Owing to the stigma attached to the word 'leper', RG Cochrane suggested that the best name for leprosy is 'Hansen's disease'.

Robert Greenhill Cochrane, 1899–1985, medical missionary who became an international authority on leprosy; he devoted his time to leprosy patients in South East Asia, particularly India.

Gerhard Henrik Armauer Hansen, 1841–1912, physician in charge of a leper hospital near Bergen, Norway.

thus involving the facial nerve as it exits from the stylomastoid foramen. The disease is transmitted from the nasal secretions of a patient, the infection being contracted in childhood or early adolescence. After an incubation period of several years, the disease presents with skin, upper respiratory or neurological manifestations. The bacillus is acid fast but weakly so when compared with *Mycobacterium tuberculosis*.

The disease is broadly classified into two groups: lepromatous and tuberculoid. In lepromatous leprosy, there is widespread dissemination of abundant bacilli in the tissues, with macrophages and few lymphocytes. This is a reflection of the poor immune response, resulting in depleted host resistance from the patient. In tuberculoid leprosy, on the other hand, the patient shows a strong immune response with scant bacilli in the tissues, epithelioid granulomas, numerous lymphocytes and giant cells. The tissue damage is inversely proportional to the host's immune response. There are various grades of the disease between the two main spectra called dimorphous or borderline variant.

Summary box 6.12

Mycobacterium leprae: pathology

- Leprosy is a chronic curable infection caused by *M. leprae*
- It occurs mainly in tropical regions and resource-poor countries
- The majority of cases are located in the Indian subcontinent
- Transmission is through nasal secretions, the bacillus inhabiting the colder parts of the body
- It is attributed to poor hygiene and insanitary conditions
- The incubation period is several years
- The initial infection occurs in childhood
- Lepromatous leprosy denotes a poor host immune reaction
- Tuberculoid leprosy occurs when host resistance is stronger than the virulence of the organism

Clinical features and diagnosis

The disease is slowly progressive and affects the skin, upper respiratory tract and peripheral nerves. In tuberculoid leprosy, the damage to tissues occurs early and is localised to one part of the body, with limited deformity of that organ. Neural involvement is characterised by thickening of the nerves, which are tender. There may be asymmetrical well-defined anaesthetic hypopigmented or erythematous macules with elevated edges and a dry and rough surface – lesions called leprids. In lepromatous leprosy, the disease is symmetrical and extensive. Cutaneous involvement occurs in the form of several pale macules that form plaques and nodules called lepromas. The deformities produced are divided into primary, which are caused by leprosy or its reactions, and secondary, resulting from effects such as anaesthesia of the hands and feet. Nodular lesions on the face in the acute phase of the lepromatous variety are known as 'leonine facies' (looking like a lion). Later, there is wrinkling of the skin, giving an aged appearance to a young individual. There is loss of the eyebrows and destruction of the lateral cartilages and septum of the nose with collapse of the nasal bridge and lifting of the tip of the nose (***Figure 6.17***). There may be paralysis of the branches of the facial nerve in the bony canal or of the zygomatic branch. Blindness may be attributed to exposure keratitis or iridocyclitis. Paralysis of the orbicularis oculi causes incomplete closure of the eye, epiphora and conjunctivitis (***Figure 6.18***). The hands are typically clawed (***Figure 6.19***) because of involvement of the ulnar nerve at the elbow and the median nerve at the wrist. Anaesthesia of the hands makes these patients vulnerable to frequent burns and injuries. Similarly, clawing of the toes (***Figure 6.20***) occurs as a result of involvement of the posterior tibial nerve. When the lateral popliteal nerve is affected, it leads to foot drop, and the nerve can be felt to be thickened behind the upper end of the fibula. Anaesthesia of the feet predisposes to trophic ulceration (***Figure 6.21***), chronic infection, contraction and autoamputation. Involvement of the testes causes atrophy, which in turn results in gynaecomastia (***Figure 6.22***). Confirmation of the diagnosis is obtained by a skin smear or skin biopsy, which shows the classical histological and microbiological features.

Summary box 6.13

Leprosy: diagnosis

- Typical clinical features and awareness of the disease should help to make a diagnosis
- The face has an aged look, with collapse of the nasal bridge and ocular changes
- Thickened peripheral nerves, patches of anaesthetic skin, claw hands, foot drop and trophic ulcers are characteristic
- Microbiological examination of the acid-fast bacillus and typical histology on skin biopsy are confirmatory

Treatment

A herbal derivative from the seeds of *Hydnocarpus wightianus* (Chaulmoogra) was the mainstay of treatment, with some success, until the advent of dapsone (diamino-diphenyl sulphone). Dapsone, one of the principal drugs, was a derivative of prontosil red and was discovered by Domagk. This is used according to the WHO guidelines along with rifampicin and clofazimine. During treatment, the patient may develop acute manifestations. These are controlled with steroids. Multiple drug therapy for 12 months is the key to treatment. A team approach between an infectious diseases specialist, plastic surgeon, ophthalmologist, and hand or orthopaedic surgeon is important.

Surgical treatment is indicated in advanced stages of the disease for functional disability of limbs, cosmetic disfigurement of the face and visual problems. These entail major reconstructive surgery, which is the domain of the plastic surgeon.

Gerhard Domagk, 1895–1964, German physician, Lecturer in Pathologic Anatomy, University of Munster, Germany, discovered prontosil in 1935, for which he was awarded the Nobel Prize in Physiology or Medicine in 1939.

Figure 6.17 Lateral view of the face showing collapse of the nasal bridge due to destruction of nasal cartilage by leprosy.

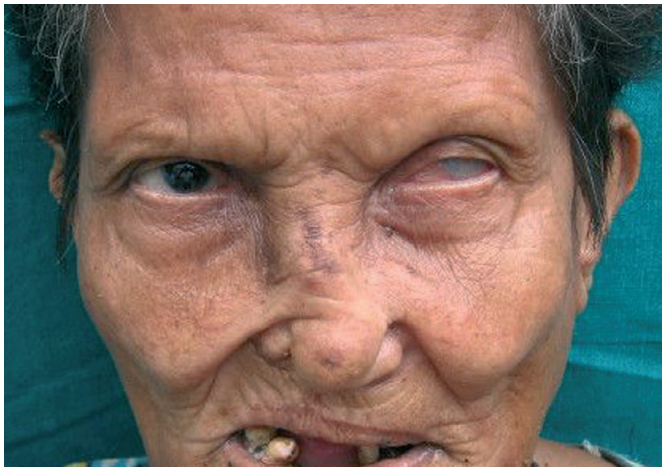

Figure 6.18 Frontal view of the face showing eye changes in leprosy: paralysis of orbicularis oculi and loss of eyebrows.

Surgery for deformities in the hand is aimed at returning the ability to achieve a grasp and a pinch grip. Tendon transfers (pioneered by Brand and Tovey) are used to recreate the function of the lumbricals that have been lost due to damage to the ulnar nerve. In the foot, damage to the common peroneal nerve leads to a foot drop due to paralysis of tibialis

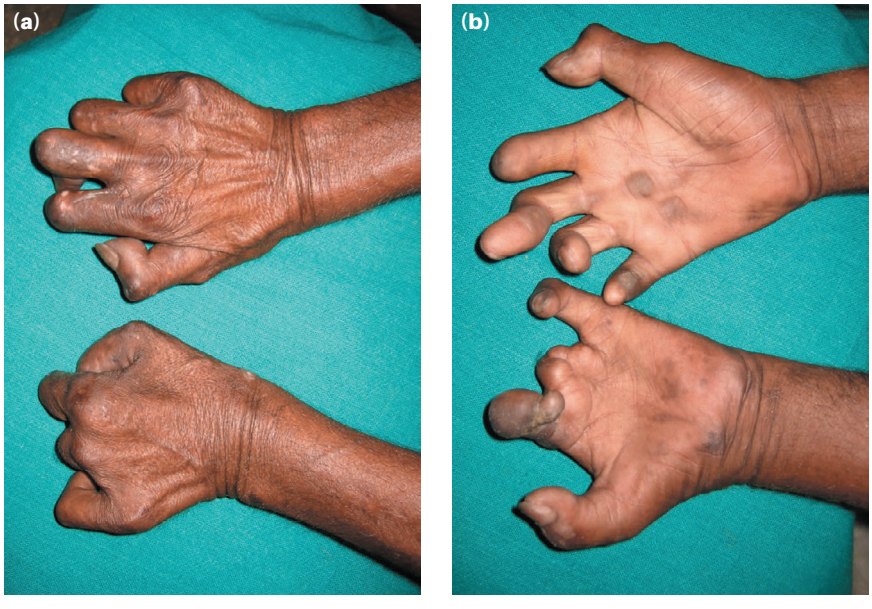

Figure 6.19 (a, b) Typical bilateral claw hand from leprosy due to involvement of the ulnar and median nerves.

Figure 6.20 Claw toes from involvement of the posterior tibial nerve by leprosy; also note autoamputation of toes of the right foot.

Paul Wilson Brand CBE, FRCS, 1914–2003, was born to missionary parents in Southern India, and qualified in London in 1943. He himself was a dedicated missionary who was 'An extraordinary gifted orthopaedic surgeon who straightened crooked hands and unravelled the riddle of leprosy.' As a pioneer in tendon transfer techniques, he established and practised initially in New Life Center, Vellore, South India and Schieffelin Leprosy Research Centre, Karigiri, South India. Initially he trained as a carpenter and builder and maintained that his training as a carpenter helped him in his expertise in tendon transplantation. When he was awarded the CBE, his wife, Margaret, came to know about it when she found a letter from Her Majesty's Government informing him of the award while emptying the pockets of his trousers before they were put into the wash. He later moved to Louisiana State University, Baton Rouge, LA, where he continued his work, and finally to Seattle as Emeritus Professor of Orthopaedics at the University of Washington, Seattle, USA.

Margaret Brand, alongside her husband, Paul Brand, also contributed immensely to the health of leprosy patients by concentrating on research to prevent blindness in leprosy. She became known as 'the woman who first helped lepers to see'.

Frank Tovey OBE, 1921–2019, another English surgeon at about the same time (1951–1967), also performed extensive tendon transfers and facial and other reconstructive surgery on patients with leprosy in southern India in the State of Mysore. In this he was helped by his wife, Winifred, who organised the physiotherapy and rehabilitation of the patients and established village diagnostic and treatment centres.

Figure 6.21 Bilateral trophic ulceration of the feet due to anaesthesia of the soles resulting from leprosy; also note claw toes on the left foot.

anterior. If a foot-drop splint is not adequate, then once again a tendon transfer (tibialis posterior into the dorsum of the foot) will improve function. Ulcers resulting from an insensate foot should be completely debrided followed by protection with a plaster cast.

The general surgeon may be called upon to treat a patient when the deformity is so advanced that amputation is required or an abscess needs drainage as an emergency.

All surgical procedures obviously need to be done under antileprosy drug treatment. This is best achieved by a team approach. Educating patients about the dreadful sequelae of the disease so that they seek medical help early is important. It is also necessary to educate the general public that patients suffering from the disease should not be made social outcasts.

Summary box 6.14

Leprosy: treatment

- Multiple drug therapy for a year
- Team approach
- Surgical reconstruction requires the expertise of a hand surgeon, orthopaedic surgeon and plastic surgeon
- Education of the patient and general public should be the keystone in prevention

MYCETOMA

Introduction

Mycetoma is a chronic, specific, granulomatous, progressive, destructive inflammatory disease that involves the skin, subcutaneous tissues and deeper structures. The causative organism may be true fungi, when the condition is called eumycetoma; when caused by bacteria it is called actinomycetoma.

Figure 6.22 Typical leonine facies and gynaecomastia in leprosy.

The pathognomonic feature is the triad of painless subcutaneous mass, multiple sinuses and seropurulent discharge. It causes tissue destruction, deformity and disability, and death in extreme cases.

Epidemiology and pathogenesis

The condition predominantly occurs in the 'mycetoma belt' that lies between latitudes 15° south and 30° north, comprising the countries of Sudan, Somalia, Senegal, India, Yemen, Mexico, Venezuela, Columbia, Argentina and a few others. The route of infection is inoculation of the organism that is resident in the soil through a traumatised area. Although in the vast majority there is no history of trauma, the portal of entry is always an area of minor unrecognised trauma in a bare-footed individual walking in a terrain full of thorns. Hence the foot is the commonest site affected. Mycetoma is not contagious.

Once the granuloma forms it increases in size, and the overlying skin becomes stretched, smooth, shiny and attached

Figure 6.23 Mycetoma of the foot.

to the lesion. Areas of hypo- or hyperpigmentation sometimes develop. Eventually it invades the deeper structures. This is usually gradual and delayed in eumycetoma. In actinomycetoma, invasion to deeper tissues occurs earlier and is more extensive. The tendons and nerves are spared until late in the disease. This may explain the rarity of neurological and trophic changes even in patients with longstanding disease. Trophic changes are rare because the blood supply is adequate.

Summary box 6.15

Mycetoma: pathogenesis

- Mostly occurs in the 'mycetoma belt'
- There are two types – eumycetoma and actinomycetoma
- Caused by fungi or bacteria entering through a site of trauma, which may not be apparent; hence the foot is most commonly affected
- Produces a chronic, specific, granulomatous, progressive, destructive inflammatory lesion
- Results in tissue destruction, deformity, disability and sometimes death

Clinical presentation

As mycetoma is painless, presentation is late in the majority. It presents as a slowly progressive, painless, subcutaneous swelling commonly at the site of presumed trauma. The swelling is variable in its physical characteristics: firm and rounded, soft and lobulated, rarely cystic and often mobile. Multiple secondary nodules may evolve; they may suppurate and drain through multiple sinus tracts. The sinuses may close transiently after discharge during the active phase of the disease. Fresh adjacent sinuses may open while some of the old ones may heal completely. They coalesce and form abscesses, the discharge being serous, serosanguineous or purulent. During the active phase of the disease the sinuses discharge grains, the colour of which can be black, yellow, white or red depending upon the organism. Pain supervenes when there is secondary bacterial infection.

The common sites affected are those that come into contact with soil during daily activities: the foot in 70% (***Figure 6.23***) and the hand in 12% (***Figure 6.24***). In endemic areas the knee (***Figure 6.25***), arm, leg, head and neck (***Figure 6.26***), thigh and perineum (***Figure 6.27***) can be involved. Rare sites are the chest, abdominal wall, facial bones, mandible, testes, paranasal sinuses and eye.

In some patients there may be areas of local hyperhidrosis over the lesion. This may be due to sympathetic overactivity or increased local temperature due to raised arterial blood flow caused by the chronic inflammation. In the majority of patients, the regional lymph nodes are small and shotty. Lymphadenopathy is common. This may be due to secondary bacterial infection, lymphatic spread of mycetoma or a local immune response to the disease.

The condition remains localised; constitutional disturbances are a sign of secondary bacterial infection. Cachexia and anaemia from malnutrition and sepsis may be seen in late cases. It can be fatal, especially in cases of cranial mycetoma.

Figure 6.24 Mycetoma of the hand.

Figure 6.25 Mycetoma of the knee.

Figure 6.26 Actinomycetoma of the head and neck.

Figure 6.27 Extensive satellite inguinal actinomycetoma from a primary foot lesion involving the anterior abdominal wall and perineum.

Spread

Local spread occurs predominantly along tissue planes. The organism multiplies to form colonies that spread along the fascial planes to skin and underlying structures. Lymphatic spread, more common in actinomycetoma, occurs to the regional lymph nodes, and increases with repeated inadequate surgical excision procedures. During the active phase of the disease, these lymphatic satellites may suppurate and discharge; lymphadenopathy may also be due to secondary bacterial infection. Spread via the bloodstream can occur.

The apparent clinical features of mycetoma are not always a reliable indicator of the extent and spread of the disease. Some small lesions with few sinuses may have many deep connecting tracts, through which the disease can spread quite extensively. Therefore, surgery in mycetoma under local anaesthesia is contraindicated.

Differential diagnosis

Mycetoma should be distinguished from Kaposi's sarcoma, malignant melanoma, fibroma and foreign body (thorn) granuloma. A radiograph that demonstrates the presence of bone destruction in the absence of sinuses is suggestive of tuberculosis. The radiological features of advanced mycetoma are similar to those of primary osteogenic sarcoma. Primary osseous mycetoma is to be differentiated from chronic osteomyelitis, osteoclastoma, bone cysts and syphilitic osteitis. In endemic areas the dictum should be 'any subcutaneous swelling must be considered a mycetoma until proven otherwise'.

Diagnosis

Several imaging techniques are available to confirm the diagnosis: plain radiography, ultrasonography, CT and magnetic resonance imaging (MRI).

Plain radiograph

In the early stages, soft-tissue shadows (often multiple) with calcification and obliteration of the fascial planes may be seen. As the disease progresses, the cortex may be compressed from the outside by the granuloma, leading to bone scalloping. Periosteal reaction with new bone spicules may create a sun-ray appearance and Codman's triangle, not unlike an osteogenic sarcoma (***Figure 6.28***). Late in the disease, there may be multiple punched-out cavities throughout the bone.

Ultrasonography

This can differentiate between eumycetoma and actinomycetoma as well as between mycetoma and other conditions. In eumycetoma, the grains produce numerous sharp bright hyper-reflective echoes. There are multiple thick-walled cavities with absent acoustic enhancement. In actinomycetoma, the findings are similar but the grains are less distinct. The size and extent of the lesion can be accurately determined ultrasonically, a finding useful in planning surgical treatment.

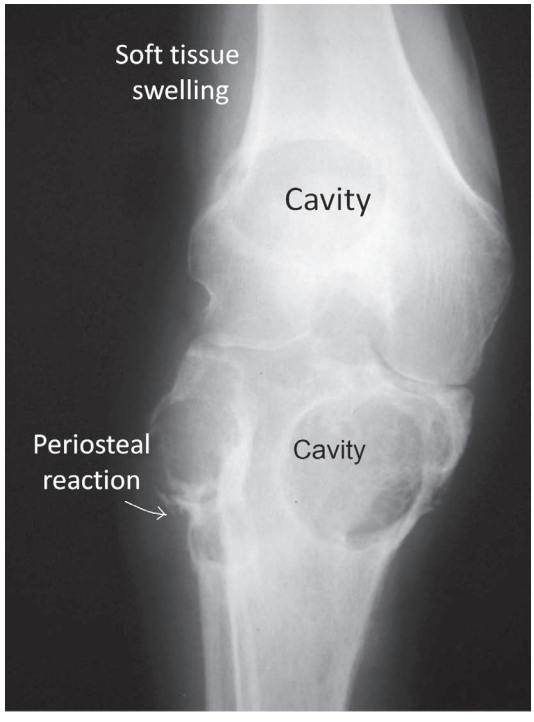

Figure 6.28 Plain radiograph of the knee showing multiple large cavities involving the lower femur, upper tibia and fibula, with well-defined margins and periosteal reaction typical of eumycetoma.

Moritz Kaposi, 1837–1902, Hungarian-born Professor of Dermatology, University of Vienna, Austria, described pigmented sarcoma of the skin in 1872. The viral cause was discovered in 1994.

Ernest Codman, 1869–1940, American surgeon. Codman's triangle can be seen in osteosarcoma, Ewing's sarcoma, subperiosteal abscess and haematoma.

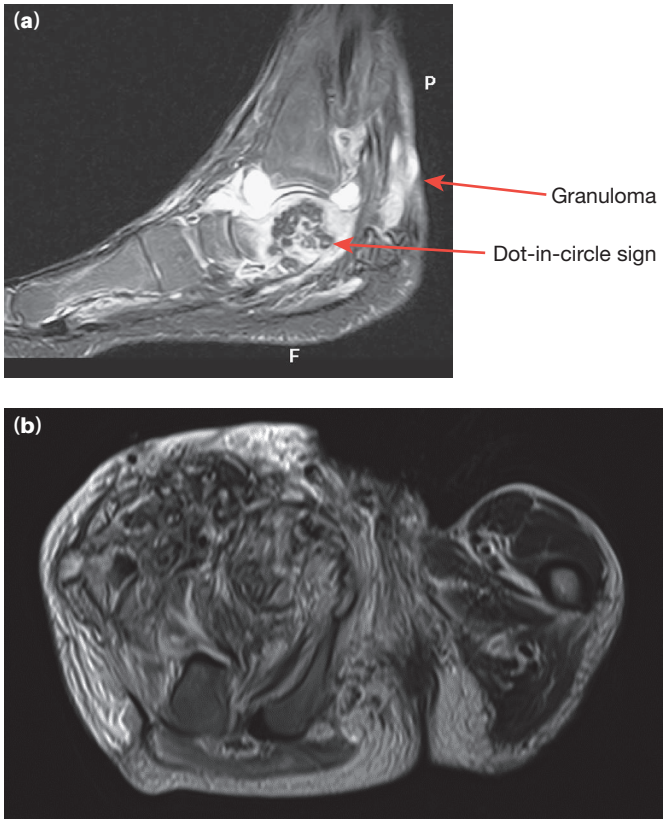

Figure 6.29 (a) Magnetic resonance imaging (MRI) of the foot showing multiple lesions of high signal intensity, which indicates granuloma, interspersed within a low-intensity matrix, which is the fibrous tissue and the 'dot-in-circle' sign, which indicates the presence of grains. (b) MRI showing massive upper thigh and lower abdominal actinomycetoma.

Magnetic resonance imaging

This helps to assess bone destruction, periosteal reaction and particularly soft-tissue involvement (*Figure 6.29*). MRI usually shows multiple 2- to 5-mm lesions of high signal intensity, which indicates the granuloma, interspersed within a low-intensity matrix denoting the fibrous tissue. The 'dot-in-circle' sign, which indicates the presence of grains, is highly characteristic.

Computed tomography

CT findings in mycetoma are not specific but are helpful to detect early bone involvement.

Histopathological diagnosis

Deep biopsy is obtained under general or regional anaesthesia, although the chance of local spread is high. The biopsy should be adequate, contain grains and should be fixed immediately in 10% formal saline.

Three types of host tissue reaction occur against the organism.

- **Type I:** the grains are usually surrounded by a layer of polymorphonuclear leukocytes. The innermost neutrophils are closely attached to the surface of the grain, sometimes invading the grain and causing its fragmentation. The hyphae and cement substance disappear and only remnants of brown pigmented cement are left behind. Outside the zone of neutrophils there is granulation tissue containing macrophages, lymphocytes, plasma cells and few neutrophils. The mononuclear cells increase in number towards the periphery of the lesion. The outermost zone of the lesion consists of fibrous tissue.
- **Type II:** the neutrophils largely disappear and are replaced by macrophages and multinucleated giant cells that engulf the grain material. This consists largely of pigmented cement substance although hyphae are sometimes identified.
- **Type III:** this is characterised by the formation of a well-organised epithelioid granuloma with Langhans-type giant cells. The centre of the granuloma will sometimes contain remnants of fungal material.

Fine-needle aspiration cytology

Fine-needle aspiration cytology (FNAC) can yield an accurate diagnosis and helps in distinguishing between eumycetoma and actinomycetoma. The technique is simple, rapid and sensitive.

Culture

A variety of microorganisms are capable of producing mycetomata that can be identified by their textural description, morphology and biological activities in pure culture. Deep surgical biopsy is always needed to obtain the grains that are the source of culture. The grains extracted through the sinuses are usually contaminated and not viable and hence should be avoided. Several media may be used to isolate and grow these organisms.

In the absence of the classical triad of mycetoma, the demonstration of significant antibody titres against the causative organism may be of diagnostic value and aid follow up. The common serodiagnostic tests are immunoelectrophoresis and ELISA.

Summary box 6.16

Mycetoma: diagnosis

- Usually presents late as it is painless
- Triad of painless subcutaneous mass, multiple sinuses and seropurulent discharge
- Clinical picture may be deceptive as there may be deep-seated extension
- May spread to lymph nodes
- Can be confused with Kaposi's sarcoma
- Radiologically can be mistaken for osteosarcoma
- MRI shows typical 'dot-in-circle' sign
- Open biopsy and FNAC are confirmatory

Theodor Langhans, 1839–1915, Professor of Pathological Anatomy, University of Berne, Switzerland.

Management

Ideally this should be a combined effort between the physician and the surgeon. In actinomycetoma, combined drug therapy with amikacin sulphate and co-trimoxazole in the form of cycles is the treatment of choice. Amoxicillin–clavulanic acid, rifampicin, sulphonamides, gentamicin and kanamycin are used as a second line of treatment. Long-term drug treatment can have serious side effects.

In eumycetoma, ketoconazole, itraconazole and voriconazole are the drugs of choice. They may need to be used for up to a year. Use of these drugs should be closely monitored for side effects. While not curative, these drugs help to localise the disease by forming thickly encapsulated lesions that are then amenable to surgical excision. Medical treatment for both types of mycetoma must continue until the patient is cured and also in the postoperative period.

Surgical treatment

Surgery is indicated for small, localised lesions, resistance to medical treatment or for a better response after medical treatment in patients with massive disease. Excision may need to be much more extensive than suggested at first on clinical appearance because the disease may extend to deeper planes that are not clinically apparent. The surgical options are wide local and debulking excisions and amputations. Amputation, used as a life-saving procedure, is indicated in advanced mycetoma refractory to medical treatment with severe secondary bacterial infection. The amputation rate is 10–25%.

Postoperative medical treatment should continue for an adequate period to prevent recurrence. The recurrence rate varies from 25% to 50%. This can be local or distant, to regional lymph nodes. Recurrence is usually due to inadequate surgical excision, use of local anaesthesia, lack of surgical experience, non-compliance with drugs for financial reasons and lack of health education.

Figure 6.30 Polio affecting predominantly the upper limb muscles with wasting of the intercostal muscles.

Summary box 6.17

Mycetoma: management

- Ideally combined management by physician and surgeon
- Medical treatment with appropriate long-term antibiotics
- In large lesions medical treatment to reduce the size followed by excision
- Beware of serious drug side effects
- Surgery in the form of wide excision and amputation as a life-saving procedure
- High recurrence rate

POLIOMYELITIS

Introduction

Poliomyelitis is an enteroviral infection that sadly still affects children in certain parts of the world – this is in spite of effective vaccination having been universally available for several decades. The virus enters the body by inhalation or ingestion. Clinically, the disease manifests itself in a wide spectrum of symptoms – from a few days of mild fever and headache to the extreme variety consisting of extensive paralysis of the bulbar form that may not be compatible with life because of involvement of the respiratory and pharyngeal muscles.

Diagnosis

The disease targets the anterior horn cells, causing lower motor neurone paralysis. Muscles of the lower limb are affected twice as frequently as those of the upper limb (***Figures 6.30 and 6.31***). Fortunately, only 1–2% of sufferers develop paralytic symptoms but, when they do occur, the disability causes much misery (***Figure 6.32***). When a patient develops fever with muscle weakness, Guillain–Barré syndrome needs to be excluded. The latter has sensory symptoms and signs. Cerebrospinal fluid analysis should help to differentiate the two conditions.

Management

Surgical management is directed mainly towards the rehabilitation of the patient who has residual paralysis, the operations being tailored to the particular individual's disability. Children especially may show improvement in their muscle function for up to 2 years after the onset of the illness. Thereafter, many patients learn to manage their disability by incorporating various manoeuvres ('trick movements') into their daily life. The surgeon must be cautious in considering such a patient for any form of surgery.

Surgical treatment in the chronic form of the disease is the domain of a highly specialised orthopaedic surgeon who needs

Georges Guillain, 1876–1961, Professor of Neurology, The Faculty of Medicine, Paris, France.
Jean Alexandre Barré, 1880–1967, Professor of Neurology, Strasbourg, France.
Guillain and Barré described the condition in a joint paper in 1916 while serving as Medical Officers in the French Army during the First World War.

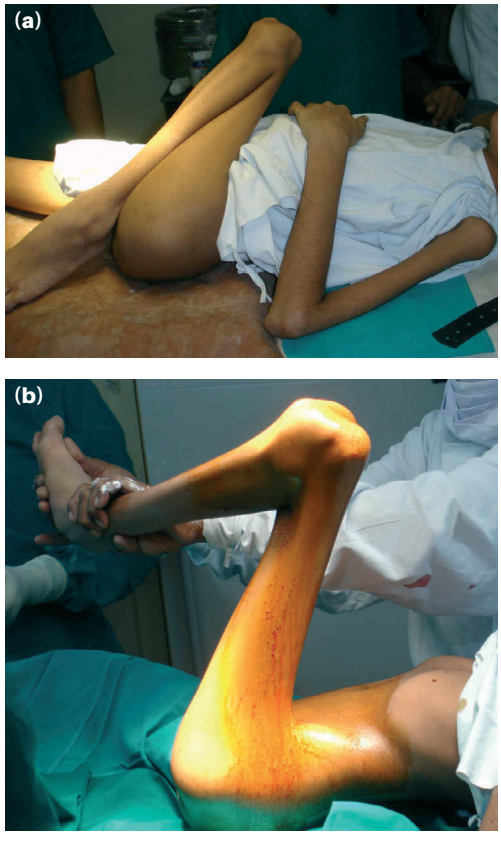

Figure 6.31 (a, b) A 12-year-old patient with polio showing marked wasting of the left upper arm muscles with flexion contractures of the left knee and hip; there is equinus deformity of the foot (courtesy of Dr SM Lakhotia, MS and Dr PK Jain, MD, DA, Kolkata, India).

to work closely with the physiotherapist both in assessing and in rehabilitating the patient. Operations are only considered after a very careful and detailed assessment of the patient's needs. A multidisciplinary team, consisting of the orthopaedic surgeon, neurologist, physiotherapist, orthotist and the family, should decide upon the need for and advisability of any surgical procedure.

A description of the operations for the various disabilities is beyond the scope of this book. The reader should therefore seek surgical details in a specialist textbook. In 2012, WHO declared India a polio-free country.

Summary box 6.18

Poliomyelitis

- A viral illness that is preventable
- Presents with protean manifestations of fever, headache and muscular paralysis without sensory loss, more frequently affecting the lower limbs
- Treatment is mainly medical and supportive in the early stages
- Surgery should only be undertaken after very careful assessment as most patients learn to live with their disabilities
- Surgery is considered for the various types of paralysis in the form of tendon transfers and arthrodesis, which is the domain of a specialist orthopaedic surgeon

Figure 6.32 A young patient with polio showing paralysis of the lower limb and paraspinal muscles causing marked scoliosis and a deformed pelvis.

TROPICAL CHRONIC PANCREATITIS

Introduction

Tropical chronic pancreatitis is a disease affecting the younger generation from poor socioeconomic strata in resource-poor countries, seen mostly in southern India. The aetiology remains obscure, with malnutrition, dietary, familial and genetic factors being possible causes. Alcohol ingestion does not play a part in the aetiology.

Aetiology and pathology

Cassava (tapioca) is a root vegetable that is readily available and inexpensive and is therefore consumed as a staple diet by people from a poor background. It contains derivatives of cyanide that are detoxified in the liver by sulphur-containing amino acids. The less well off among the population lack such amino acids in the diet. This results in cyanogen toxicity, causing the disease. Several members of the same family have been known to suffer from this condition; this strengthens the theory that cassava toxicity is an important cause because family members eat the same food.

Macroscopically, the pancreas is firm and nodular with extensive periductal fibrosis, with intraductal calcium carbonate stones of different sizes and shapes that may show branches and resemble a staghorn. The ducts are dilated. Microscopically, intralobular, interlobular and periductal fibrosis is the predominant feature, with plasma cell and lymphocyte infiltration. There is a high incidence of pancreatic cancer in these patients.

Summary box 6.19

Pathology of tropical chronic pancreatitis

- Almost exclusively occurs in resource-poor countries and is due to malnutrition; alcohol is not a cause
- Cassava ingestion is regarded as an aetiological factor because of its high content of cyanide compounds
- Dilatation of pancreatic ducts with large intraductal stones
- Fibrosis of the pancreas as a whole
- A high incidence of pancreatic cancer in those affected by the disease

Diagnosis

The patient, usually male, is almost always below the age of 40 years and from a poor socioeconomic background. The clinical presentation is abdominal pain, thirst, polyuria and features of gross pancreatic insufficiency causing steatorrhoea and malnutrition. The patient looks ill and emaciated.

Initial routine blood and urine tests confirm that the patient has type 1 diabetes mellitus. This is known as fibrocalculous pancreatic diabetes, a label that is aptly descriptive of the typical pathological changes. Serum amylase is usually normal; in an acute exacerbation, it may be elevated. A plain abdominal radiograph shows typical pancreatic calcification in the form of discrete stones in the duct (*Figure 6.33*). Ultrasonography and CT scanning of the pancreas confirm the diagnosis. An ERCP, as an investigation, should only be done when the procedure is also being considered as a therapeutic manoeuvre for removal of ductal stones in the pancreatic head by papillotomy.

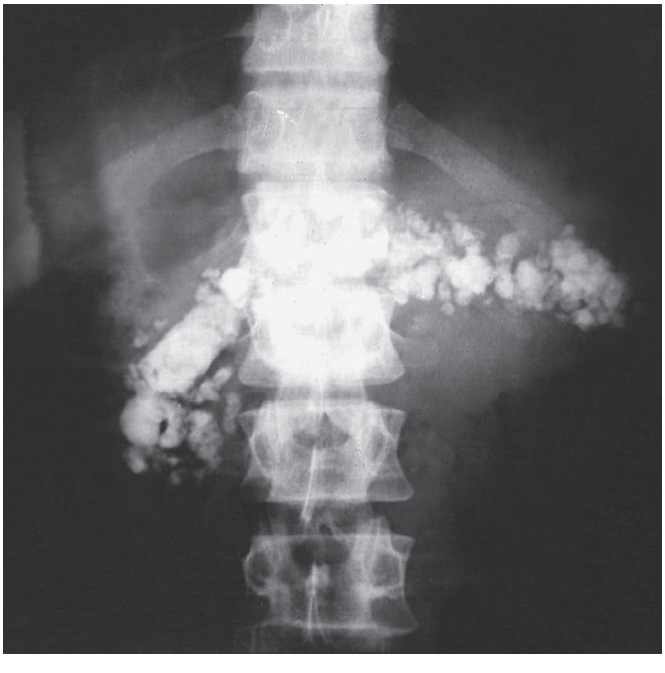

Figure 6.33 Plain radiograph of the abdomen showing large stones along the main pancreatic duct typical of tropical chronic pancreatitis (courtesy of Dr V Mohan, Chennai, India).

Summary box 6.20

Diagnosis of tropical chronic pancreatitis

- The usual sufferer is a type 1 diabetic under 40 years of age
- Serum amylase may be elevated in an acute exacerbation
- Plain radiograph shows stones along the pancreatic duct
- Ultrasonography and CT scan of the pancreas confirm the diagnosis
- ERCP should be used as an investigation only when combined with a therapeutic procedure

Treatment

The treatment is mainly medical, with exocrine support using pancreatic enzymes, treatment of diabetes with insulin and the management of malnutrition. Treatment of pain should be along the lines of the usual analgesic ladder: non-opioids, followed by weak and then strong opioids and, finally, referral to a pain clinic.

Surgical treatment is necessary for intractable pain, particularly when there are stones in a dilated duct. Removal of the stones, with a side-to-side pancreaticojejunostomy to a Roux loop, is the procedure of choice. As most patients are young, pancreatic resection is only very rarely considered, and only as a last resort, when all available methods of pain relief have been exhausted.

Summary box 6.21

Treatment of tropical chronic pancreatitis

- Mainly medical – pain relief, insulin for diabetes and pancreatic supplements for malnutrition
- Surgery is reserved for intractable pain when all other methods have been exhausted
- Operations are side-to-side pancreaticojejunostomy; resection in extreme cases

TUBERCULOSIS

Although tuberculosis can affect all systems in the body, in the tropical world the surgeon is most often faced with tuberculosis affecting the cervical lymph nodes and the small intestine. Therefore, in this chapter tuberculous cervical lymphadenitis and tuberculosis of the small bowel will be described.

TUBERCULOUS CERVICAL LYMPHADENITIS

Introduction

This is common in the Indian subcontinent. A young person who has recently arrived from an endemic area, presenting with cervical lymphadenopathy, should be diagnosed as having tuberculous lymphadenitis unless otherwise proven. With acquired immune deficiency syndrome (AIDS) being globally prevalent, this is not as rare in the West in the indigenous population as it used to be.

Figure 6.34 Cervical tuberculous: cold abscess about to burst.

Figure 6.35 Cervical tuberculous ulcer with typical overhanging edges (courtesy of Professor Ahmed Hassan Fahal, FRCS MD MS, Khartoum, Sudan).

Diagnosis

Any of the cervical group of lymph nodes (jugulodigastric, submandibular, supraclavicular, posterior triangle) can be involved. The patient has the usual general manifestations of tuberculosis: evening pyrexia, cough (maybe from pulmonary tuberculosis) and malaise; if the sufferer is a child, failure to thrive is a significant finding. Locally there will be regional lymphadenopathy where the lymph nodes may be matted; in late stages a cold abscess may form – a painless, fluctuant, mass which is not warm; significantly there are no signs of inflammation (***Figure 6.34***), hence it is called a 'cold abscess'. This is a clinical manifestation of underlying caseation.

Left untreated, the cold abscess, initially deep to the deep fascia, bursts through into the space just beneath the superficial fascia. This produces a bilocular mass with cross-fluctuation. This is called a 'collar-stud' abscess. Eventually this may burst through the skin, discharging pus and forming a tuberculous sinus and eventually might ulcerate (***Figure 6.35***). The latter typically has watery discharge with undermined edges as the tubercle bacilli destroy the subcutaneous tissue faster than the rest and thrive in the relatively anoxic environment.

Investigations

Raised ESR and CRP, low haemoglobin and a positive Mantoux test are usual, although the last is not significant in a patient from an endemic area. The Mantoux test (tuberculin skin test), although in use for over a hundred years, has now been superseded by interferon-gamma (IFN-γ) release assays. This is an *in vitro* blood test of cellular immune response. Antigens unique to *M. tuberculosis* are used to stimulate and measure T-cell release of IFN-γ. This helps to earmark patients who have latent or subclinical tuberculosis and thus will benefit from treatment.

Sputum for culture and sensitivity (the result may take several weeks) and staining by the Ziehl–Neelsen method for acid-fast bacilli (the result is obtained much earlier) should be carried out.

Specific investigations would include aspiration of the pus from a cold abscess for culture and sensitivity. If the mass is still in the early stages of adenitis, excision biopsy should be done. Here, part of the lymph nodes should be sent fresh and unfixed to the laboratory, which should be warned of the arrival of the specimen so that the tissue can be appropriately processed immediately.

Summary box 6.22

Tuberculous cervical lymphadenitis

- This is a common condition at any age
- A matted lymph nodal mass is the typical clinical feature
- In later stages the mass may be cystic, denoting an abscess
- The abscess denotes underlying caseation and does not show any features of inflammation – hence called a cold abscess
- Ultimately the abscess may burst, forming a sinus
- Diagnosis is clinched by culture of pus and biopsy of the lymph node
- Involvement of other systems must be excluded
- Treatment is mainly medical

Treatment

This must be combined management between the physician and the surgeon. Tuberculous infection at other sites must

A collar-stud abscess is so-called because it resembles a collar stud (which has two parts) used in shirts with detachable collars, now largely out of fashion.
Charles Mantoux, 1877–1947, physician, Le Cannet, Alpes Maritimes, France, described the intradermal tuberculin skin test in 1908.
Franz Heinrich Paul Ziehl, 1857–1926, German bacteriologist and professor in Lübeck, Germany. With pathologist **Friedrich Neelsen**, he developed the Ziehl–Neelsen stain, also known as the acid-fast stain, which is used to identify acid-fast bacteria.
Friedrich Carl Adolf Neelsen, 1854–1898, pathologist and professor at the Institute of Pathology, University of Rostock, Germany.

be excluded and suitably managed. Medical treatment is the mainstay. The reader is asked to look up details of medical treatment in an appropriate source.

TUBERCULOSIS OF SMALL INTESTINE

Introduction

Infection by *M. tuberculosis* is common in the tropics. In these days of international travel and increased migration, tuberculosis in general and intestinal tuberculosis in particular are no longer clinical curiosities in non-endemic countries. Any patient, particularly one who has recently arrived from an endemic area and who has features of generalised ill health and altered bowel habit, should arouse suspicion for intestinal tuberculosis. The increased prevalence of human immunodeficiency virus (HIV) infection worldwide has also made tuberculosis more common. The infection is transmitted by swallowing of infected sputum in a patient with pulmonary tuberculosis, by drinking infected unpasteurised milk or by a haematogenous route.

Pathology

There are two types: ulcerative and hyperplastic. In both types, there may be marked mesenteric lymphadenopathy.

- **Ulcerative type:** The organism colonises the lymphatics of the terminal ileum, causing transverse ulcers with typical undermined edges. The serosa is usually studded with tubercles. Histology shows caseating granuloma with giant cells (***Figure 6.36***). This pathological entity, referred to as the ulcerative type, denotes a severe form of the disease in which the virulence of the organism overwhelms host resistance. The ulcers heal by fibrosis and transverse ulcers lead to multiple strictures that may present later with luminal narrowing and intestinal obstruction.
- **Hyperplastic type:** This occurs when host resistance has the upper hand over the virulence of the organism. There is a marked inflammatory reaction causing hyperplasia and thickening of the terminal ileum because of its abundance of lymphoid follicles, thus resulting in narrowing of the lumen and obstruction. Macroscopically, this type may be confused with Crohn's disease. Ileocaecal tuberculosis (***Figure 6.37***) may present with a right iliac fossa mass and features of intestinal obstruction. As a result of fibrosis, there is shortening of the bowel with the caecum being pulled up into a subhepatic position with resultant widening of the ileocaecal angle beyond 90°.

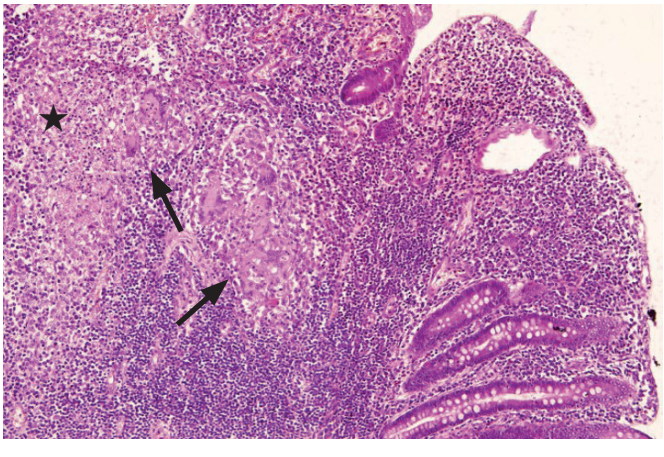

Figure 6.36 Histology of ileocaecal tuberculosis showing epithelioid cell granuloma (black arrows) with caseation (star) (courtesy of Dr AK Mandal, New Delhi, India).

Summary box 6.23

Tuberculosis: pathology

- Increasingly being seen in non-endemic areas, mostly among immigrants from endemic areas
- Two types are recognised – ulcerative and hyperplastic
- The ulcerative type occurs when the virulence of the organism is greater than the host defence and forms strictures
- The opposite occurs in the hyperplastic type and presents with a mass
- Small bowel strictures are common in the ulcerative type, presenting with obstructive symptoms, while the hyperplastic type mainly affects the ileocaecal area and presents with a right iliac fossa mass and obstructive symptoms
- In peritoneal tuberculosis, the parietal and visceral peritoneum is studded with tubercles
- Localised areas of ascites (loculated) depicts peritoneal involvement
- Encasement of bowel in a fibrotic sac (cocoon) may be seen in the plastic type of peritoneal tuberculosis, which presents with obstruction
- The lungs and other organs, particularly of the genitourinary system, may also be involved simultaneously

Clinical features

Patients present electively with weight loss, chronic cough, malaise, evening rise in temperature with sweating, vague abdominal pain with distension and alternating constipation and diarrhoea. As an emergency, they present with features of distal small bowel obstruction from strictures of the small bowel, particularly the terminal ileum. Rarely, a patient may present with features of peritonitis from perforation of a tuberculous ulcer in the small bowel (***Figure 6.37***).

Examination shows a chronically ill patient with a 'doughy' feel to the abdomen from areas of localised ascites. In the hyperplastic type, a mass may be felt in the right iliac fossa. In addition, some patients may present with fistula-*in-ano*, which is typically multiple with undermined edges and watery discharge.

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932 along with Leon Ginzburg and Gordon Oppenheimer.

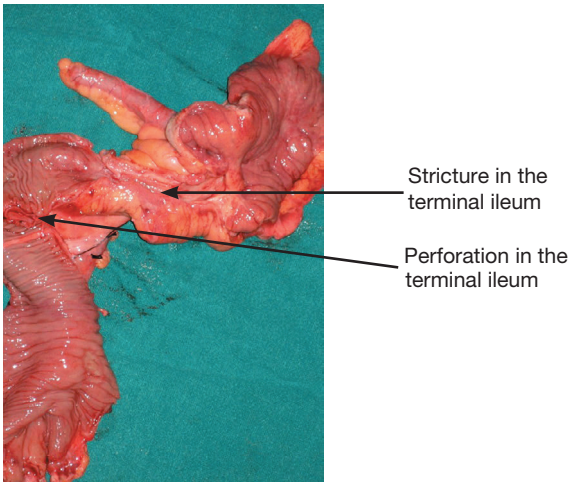

Figure 6.37 Emergency limited ileocolic resection: specimen showing a tuberculous stricture in the terminal ileum and perforation of a transverse ulcer just proximal to the stricture.

As this is a disease mainly seen in certain resource-poor countries, patients may present late as an emergency from intestinal obstruction. Abdominal pain and distension, constipation and bilious and faeculent vomiting are typical of such a patient, who is usually *in extremis*.

There may be involvement of other systems, such as the genitourinary tract, when the patient complains of frequency of micturition. Clinical examination does not show any abnormality. The genitourinary tract should then be investigated.

Summary box 6.24

Tuberculosis: clinical features

- Intestinal tuberculosis should be suspected in any patient from an endemic area who presents with weight loss, malaise, evening fever, cough, alternating constipation and diarrhoea and intermittent abdominal pain with distension
- The abdomen has a doughy feel; a mass may be found in the right iliac fossa
- The emergency patient presents with features of distal small bowel obstruction – abdominal pain, distension, bilious and faeculent vomiting
- Peritonitis from a perforated tuberculous ulcer in the small bowel can be another emergency presentation, though rare

Investigations

General investigations are the same as those for suspected tuberculosis anywhere in the body. They have been detailed in the previous section under investigations for tuberculous cervical adenitis.

A barium meal and follow-through (or small bowel enema) shows strictures of the small bowel, particularly the ileum, typically with a high subhepatic caecum with the narrow ileum entering the caecum directly from below upwards in a straight line rather than at an angle (***Figures 6.38 and 6.39a***). Laparoscopy reveals the typical picture of tubercles on the bowel serosa, multiple strictures, a high caecum, enlarged lymph nodes, areas of caseation and ascites. Culture of the ascitic fluid may be helpful. A chest radiograph is essential (***Figure 6.39b***) as there may be features of pulmonary tuberculosis.

If the patient complains of urinary symptoms, urine is sent for microscopy and culture; the finding of sterile pyuria should alert the clinician to the possibility of tuberculosis of the urinary tract, when the appropriate investigations should be done. A flexible cystoscopy would be very useful in the presence of sterile pyuria. A contracted bladder ('thimble' bladder) with ureteric orifices that are in-drawn ('golf-hole' ureter) may be seen; these changes are due to fibrosis.

In the patient presenting as an abdominal emergency, urea and electrolytes may show evidence of gross dehydration. A plain abdominal radiograph shows typical small bowel obstruction – valvulae conniventes (concertina effect) of dilated jejunum and featureless ileum with evidence of fluid between the loops.

Summary box 6.25

Intestinal tuberculosis: investigations

- Raised inflammatory markers, anaemia and positive sputum culture
- IFN-γ release assays for subclinical infection
- Ultrasonography of the abdomen may show localised areas of ascites
- Chest radiograph shows pulmonary infiltration
- Barium meal and follow-through shows multiple small bowel strictures particularly in the ileum, with a subhepatic caecum
- If symptoms warrant, the genitourinary tract is also investigated

Treatment

On completion of medical treatment, the patient's small bowel is reimaged to look for significant strictures. If the patient has features of subacute intermittent obstruction, bowel resection, in the form of limited ileocolic resection with anastomosis between the terminal ileum and ascending colon for ileocolic hyperplastic disease, strictureplasty for single ileal stricture, bowel resection for multiple closely placed strictures or right hemicolectomy for extensive ileocolic disease precluding limited resection, is performed as deemed appropriate. The surgical principles and options in the elective patient are very similar to those for Crohn's disease, where resections should be kept as conservative as possible.

The emergency patient presents a great challenge. Such a patient is usually from a poor socioeconomic background, hence the late presentation of acute, distal, small bowel obstruction. The patient is extremely ill from dehydration, malnutrition, anaemia and probably active pulmonary tuberculosis. Vigorous resuscitation should precede the operation. At laparotomy, the minimum life-saving procedure is carried out, such as a resection of diseased segment with proximal ileostomy and distal ileal or colonic mucus fistula to avoid anastomosis, which has a high chance of leaking in the presence of active infection and poor general condition. If, however, the general condition of the patient permits, a one-stage resection and anastomosis may rarely be performed.

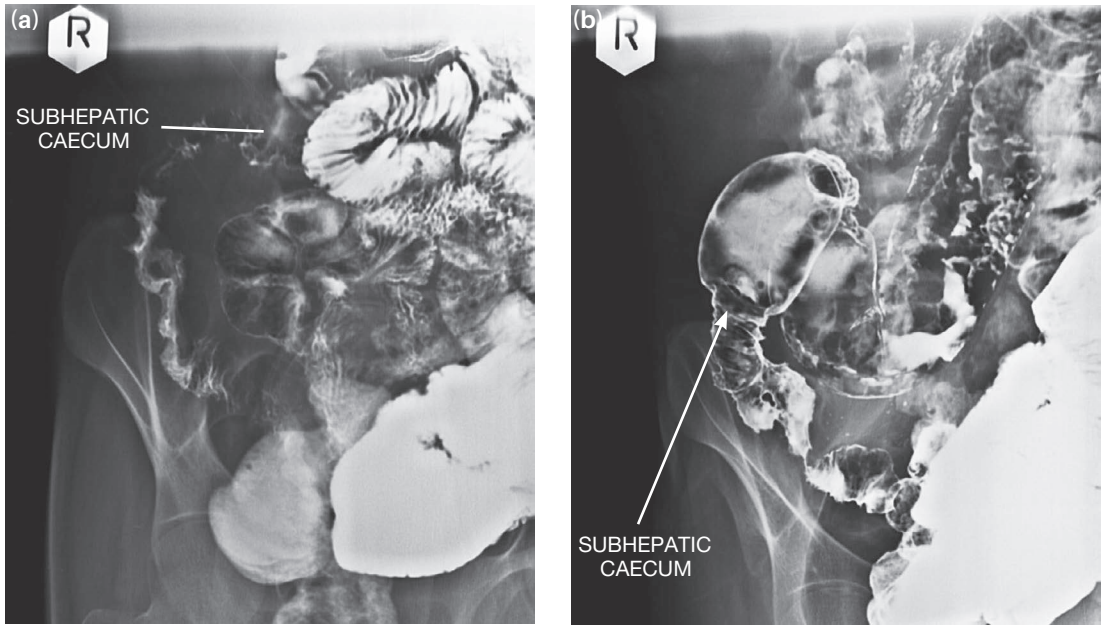

Figure 6.38 (a, b) Series of a barium meal and follow-through showing strictures in the ileum, with the caecum pulled up into a subhepatic position.

Thereafter, the patient should ideally be under the combined care of the physician and surgeon for a full course of standard multidrug antitubercular chemotherapy (intensive and maintenance phases) and improvement in nutritional status, which may take up to 6–12 months. The patient who had a simple bypass procedure is reassessed and, when the disease is no longer active (as evidenced by return to normal inflammatory markers, weight gain, negative sputum culture), an elective right hemicolectomy is done to remove the blind loop. This may be supplemented with strictureplasty for short strictures at intervals or resection of a segment with several strictures.

Perforation is treated by thorough resuscitation followed by resection of the affected segment. Anastomosis is performed, provided it is regarded as safe to do so, when peritoneal

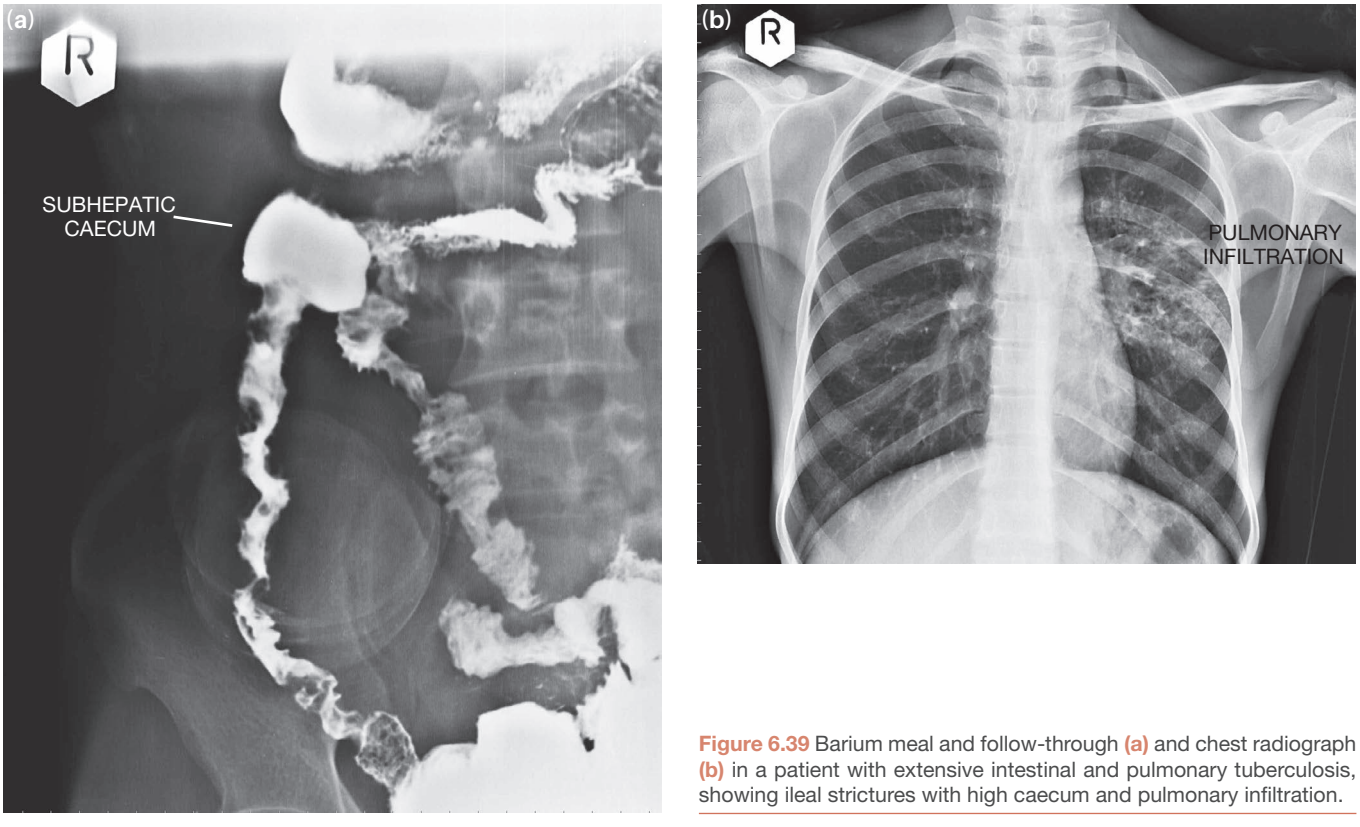

Figure 6.39 Barium meal and follow-through **(a)** and chest radiograph **(b)** in a patient with extensive intestinal and pulmonary tuberculosis, showing ileal strictures with high caecum and pulmonary infiltration.

contamination is minimal and widespread disease is not encountered; otherwise, as a first stage, resection and ileostomy are performed followed by restoration of bowel continuity as a second stage later on after a full course of antitubercular chemotherapy and improvement in nutritional status.

Summary box 6.26

Tuberculosis: treatment

- Patients should ideally be under the combined care of a physician and surgeon
- Vigorous supportive and full drug treatment are mandatory in all cases
- Symptomatic strictures are treated by the appropriate resection, e.g. local ileocolic resection or strictureplasty or resection as an elective procedure once the disease is completely under control
- Acute intestinal obstruction from distal ileal stricture is treated by thorough resuscitation followed by resection with ileostomy or primary anastomosis
- One-stage resection and anastomosis can rarely be considered if the patient's general condition permits
- Perforation is treated by appropriate local resection and anastomosis or ileostomy if the condition of the patient is very poor; this is later followed by restoration of bowel continuity after the patient has fully recovered with antitubercular chemotherapy

TYPHOID

Introduction

Typhoid fever is caused by *Salmonella* Typhi, also called the typhoid bacillus, a Gram-negative organism. Like most infections occurring in the tropics, the organism gains entry into the human gastrointestinal tract as a result of poor hygiene and inadequate sanitation. It is a disease normally managed by physicians, but the surgeon may be called upon to treat the patient with typhoid fever because of perforation of a typhoid ulcer.

Pathology

Following ingestion of contaminated food or water, the organism colonises the Peyer's patches in the terminal ileum, causing hyperplasia of the lymphoid follicles followed by necrosis and ulceration. The microscopic picture shows erythrophagocytosis with histiocytic proliferation (***Figure 6.40***). If the patient is left untreated or inadequately treated, the ulcers may lead to perforation and bleeding. The bowel may perforate at several sites, including the large bowel.

Diagnosis

A typical patient is from an endemic area or has recently visited such a country and suffers from a high temperature for 2–3 weeks. The patient may be toxic with abdominal distension from paralytic ileus and may have melaena due to haemorrhage from a typhoid ulcer; this can lead to hypovolaemia.

Blood and stool cultures confirm the nature of the infection and exclude malaria. Although obsolete in some parts of the world, the Widal test is still done on the Indian subcontinent. The test looks for the presence of agglutinins to O and H antigens of *Salmonella* Typhi and Paratyphi in the patient's serum. In endemic areas, laboratory facilities may sometimes be limited. Certain other tests have been developed that identify sensitive and specific markers for typhoid fever. Practical and cheap kits are available for their rapid detection that need no special expertise and equipment. These are MultiTest Dip-S-Ticks to detect immunoglobulin G (IgG), Tubex to detect immunoglobulin M (IgM) and TyphiDot to detect IgG and IgM. These tests are particularly valuable when blood cultures are negative (as a result of prehospital treatment or self-medication with antibiotics) or facilities for such an investigation are not available.

In the second or third week of the illness, if there is severe generalised abdominal pain, this indicates a perforated typhoid ulcer unless otherwise proven. The patient, who is already very ill, deteriorates further with classical features of peritonitis. An erect chest radiograph or a lateral decubitus film (in the very ill, as they usually are) will show free gas in the peritoneal cavity. In fact, any patient being treated for typhoid fever who shows a sudden deterioration accompanied by abdominal signs should be considered to have a typhoid perforation until proven otherwise.

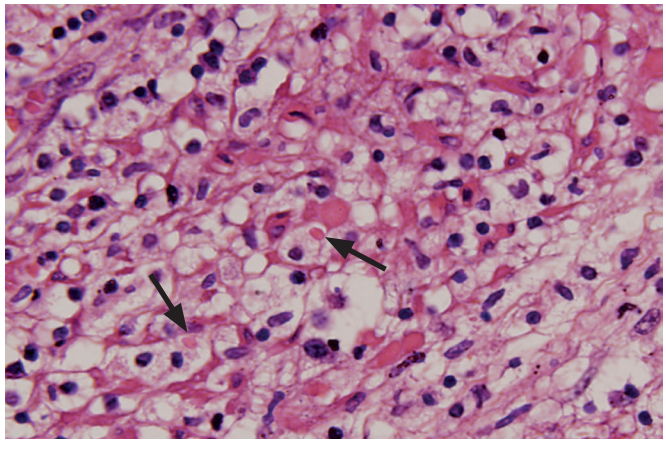

Figure 6.40 Histology of enteric perforation of the small intestine showing erythrophagocytosis (arrows) with predominantly histiocytic proliferation (courtesy of Dr AK Mandal, New Delhi, India).

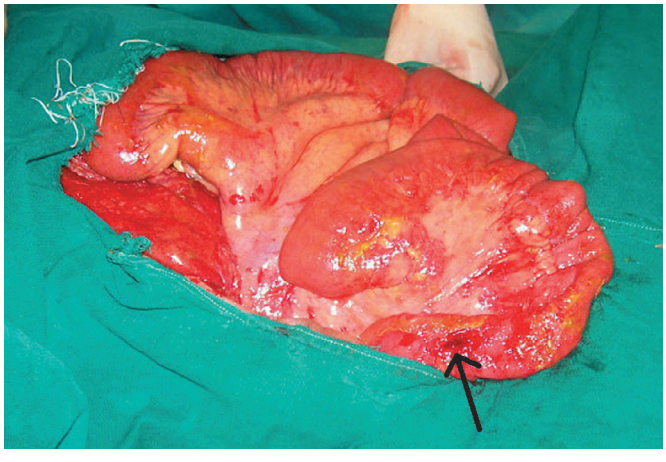
Daniel Elmer Salmon, 1850–1914, veterinary pathologist, Chief of the Bureau of Animal Industry, Washington, DC, USA.
Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.
Georges Fernand Isidore Widal, 1862–1929, Professor of Internal Pathology, and later of Clinical Medicine, The Faculty of Medicine, Paris, France.

Summary box 6.27



Diagnosis of bowel perforation secondary to typhoid

- The patient presents in, or has recently visited, an endemic area
- The patient has persistent high temperature and is very toxic
- Positive blood or stool cultures for *Salmonella* Typhi and the patient is already on treatment for typhoid
- After the second week, signs of peritonitis usually denote perforation, which is confirmed by the presence of free gas seen on a radiograph

Treatment

Vigorous resuscitation with intravenous fluids and antibiotics in an intensive care unit gives the best chance of stabilising the patient's condition. Metronidazole, cephalosporins and gentamicin are used in combination. Chloramphenicol, despite its potential side effect of aplastic anaemia, is still used occasionally in resource-poor countries. Laparotomy is then carried out.

Several surgical options are available, and the most appropriate operative procedure should be chosen judiciously depending upon the general condition of the patient, the site of perforation, the number of perforations and the degree of peritoneal soiling. The alternatives are closure of the perforation (***Figure 6.41***) after freshening the edges, wedge resection of the ulcer area and closure, resection of bowel with or without anastomosis (exteriorisation), closure of the perforation and side-to-side ileotransverse anastomosis, ileostomy or colostomy where the perforated bowel is exteriorised after refashioning the edges.

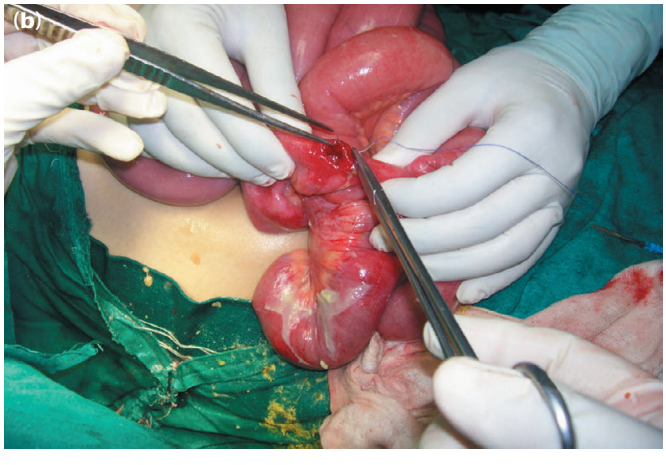


Figure 6.41 (a, b) Typhoid perforation of the terminal ileum (arrow in **(a)**).

After closing an ileal perforation, the surgeon should look for other sites of perforation or necrotic patches in the small or large bowel that might imminently perforate, and deal with them appropriately. Thorough peritoneal lavage is essential. The linea alba is closed, leaving the rest of the abdominal wound open for delayed closure, as wound infection is almost inevitable and dehiscence not uncommon. In the presence of rampant infection, laparostomy may be a good alternative.

When a typhoid perforation occurs within the first week of illness, the prognosis is better than if it occurs after the second or third week because, in the early stages, the patient is less nutritionally compromised and the body's defences are more robust. Furthermore, the shorter the interval between diagnosis and operation, the better the prognosis.

Summary box 6.28

Treatment of bowel perforation from typhoid

- Manage in intensive care
- Resuscitate and give intravenous antibiotics
- Laparotomy – choice of various procedures
- Commonest site of perforation is the terminal ileum
- Having found a perforation, always look for others
- In the very ill patient, consider some form of exteriorisation
- Close the peritoneum and leave the wound open for secondary closure

ACKNOWLEDGEMENT

The authors acknowledge the contribution of Professor Ahmed Hassan Fahal MBBS, FRCS, FRCSI, FRCSG, MD, MS, FRCP (London), Professor of Surgery, University of Khartoum, Khartoum, Sudan, in the section relating to Mycetoma.

PART 1 | Basic principles

CHAPTER 7

Basic surgical skills

Learning objectives

To understand:

- The importance of safe patient positioning
- The steps involved in surgical site preparation
- The principles of surgical exposure and laparoscopic access
- Surgical craft and wound closure
- Haemostasis and electrosurgery
- The role of drains in surgery

INTRODUCTION

Successful outcomes in surgery depend on knowledge, skills and judgement. While this chapter focuses on technical skills, the importance of surgical preparedness in the form of appropriate safety checks, correct positioning and non-technical skills such as communication and teamwork cannot be overstated.

Patient safety and transfer to the operating table

Patient safety is of paramount importance. The safe transfer and positioning of the patient is a responsibility that is shared by the anaesthetist, surgeon, nurse and operating department practitioners. The anaesthetist managing the airway usually coordinates the transfer of the patient by calling the count. The transfer of the patient is a critical moment during which there is a significant risk of falls and injuries, not to mention injury to operating theatre personnel. Additional care and specialised equipment may be required when transferring patients who are obese or emaciated and those at extremes of age.

POSITIONING ON THE OPERATING TABLE

Summary box 7.1

Objectives of correct surgical positioning

- Facilitate safe anaesthesia and surgery
- Reduce adverse physiological insults
- Optimise surgical exposure and ergonomics
- Maintain patient's dignity by avoiding unnecessary exposure

Summary box 7.2

Pre-positioning planning

- Final checks of the operating table and accessories
- Optimum positioning of laparoscopic stacks, electrosurgical unit, surgical ancillaries and nursing trolley
- Passive diathermy leads and underbody heating blankets placed appropriately
- Age, body habitus and joint mobility to be considered
- Compromise between perfect surgical positioning and physiologically permissible positioning needs to be reached

Supine position

This is the most common position for general surgical procedures. The patient's arms may be placed by their side or extended to afford access to intravenous and arterial cannulae. This is a versatile position and can be modified as follows:

- Rose's position: slight neck extension for head and neck surgery.
- Shoulder and arm extended: to assist in axillary and breast surgery.
- Trendelenburg position: the head end of the table is tilted down on an incline with the patient's knees slightly flexed. This is often used in pelvic procedures and when resuscitating a patient in shock (*Figure 7.1*).
- Reverse Trendelenburg position: the head end of the table is tilted up, thereby placing the head higher than the feet (*Figure 7.2*).

In advanced laparoscopic surgery, exaggerated and frequent position changes during the course of the operation are used to enhance surgical exposure. An excellent example

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895), Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

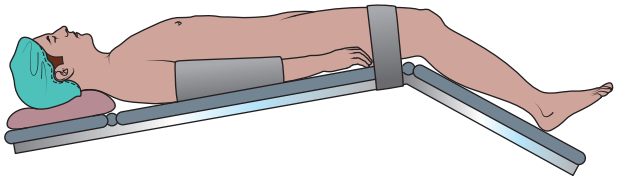

Figure 7.1 Trendelenburg position.

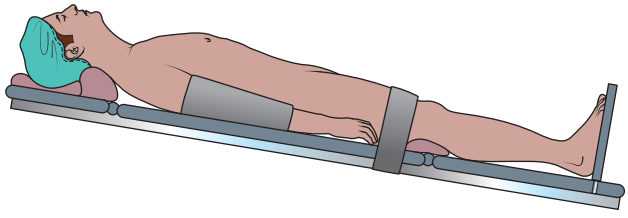

Figure 7.2 Reverse Trendelenburg position.

Figure 7.3 Secure positioning in complex laparoscopic procedures is aided with shoulder and side supports, straps and stirrups.

would be in laparoscopic resection of the rectum, wherein the table is tilted to the right to aid in left colon mobilisation; a neutral or reverse Trendelenburg position is used to mobilise the transverse colon; and pelvic dissection is completed with a steep Trendelenburg position. This can only be achieved if the patient is well positioned and secured (*Figure 7.3*).

Straps and supports to secure the patient

- The safety belt to prevent the patient from sliding off the table is placed 5 cm above the knee and never over the abdomen.
- Shoulder supports are used if the Trendelenburg position is necessary.
- Side supports to prevent lateral displacement of the patient are essential if the table needs to be tilted laterally.
- Foot support is required for the reverse Trendelenburg position.
- Alternatively, vacuum-activated positioning systems that gently conform to the contours of the patient's body can be used.

Potential complications specific to supine positioning

- Ulnar, axillary, peroneal and brachial neuropraxia.
  - To reduce the risk of brachial plexus injury, the arm should not be hyperextended (abducted by greater than 90°). Pronation of the extended arm causes traction of the brachial plexus and also causes pressure on the ulnar nerve.
- Pressure necrosis of the heels, shoulder, sacral region and scalp.
- Steep Trendelenburg position can cause respiratory compromise and raise intracranial and intraocular pressure.

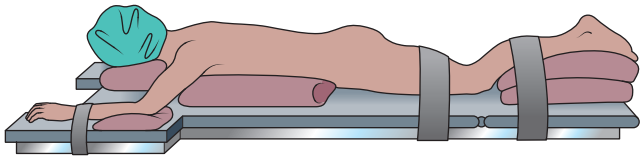

Figure 7.4 Prone position. Padded material is placed under the axillae and extends down to the iliac crest to facilitate breathing.

Prone position

In the prone position (*Figure 7.4*), the patient is intubated and then log-rolled onto the operating bed with the assistance of at least four members of the team. This position is used in spinal surgery and in certain general surgical procedures, e.g. extralevator abdominoperineal excision for rectal cancer.

A common modification of the prone position is the jack-knife position, which offers excellent access to the perineum.

Key points

- Axillary and lateral chest rolls are essential to aid in the movement of the chest, abdomen and diaphragm.
- Female breasts and male genitalia have to be carefully positioned.
- Arms may be placed by the side of the head by reversing the arm boards with care taken to avoid shoulder dislocation.
- Toes should be elevated off the bed by placing pads under the shins.
- Specially designed pillows with a hollow to accommodate the face and endotracheal tube, while gently supporting the forehead and chin, are also used.

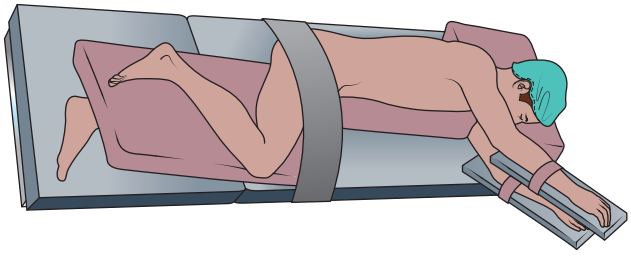

Figure 7.5 Left lateral position with the patient safely stabilised using stirrups and straps.

Potential complications

- Brachial plexus injury and shoulder dislocation.
- Facial trauma, including blindness secondary to vascular congestion of the eye.
- Pressure necrosis of the breasts, external genitalia and pressure-bearing bony prominences.
- Displacement of the endotracheal tube

Lateral position

Left or right lateral positioning (*Figure 7.5*) are useful alternatives to prone positioning in many circumstances, such as the drainage of perianal or pilonidal abscesses. The lateral position also allows for good access to the thorax when performing a lateral thoracotomy. A modified lateral position, commonly referred to as the 'kidney position', can aid in urological and retroperitoneal procedures by increasing the distance between the costal margin and the iliac bone. This is achieved by 'breaking the table' or angulating the table with the summit near the middle of the table and the two ends sloping away.

Key points

- The lower leg is slightly flexed at the knee, a pillow is placed between both the legs and the upper leg is flexed in a more exaggerated position.
- The arms are usually placed in stirrups.
- Maintaining cervical alignment of the head is very important.

Potential complications

- Respiratory complications secondary to preferential ventilation of one lung over the other and accidental endobronchial migration of the tube.
- Traction injury of the brachial plexus and ulnar nerve injury.
- Corneal abrasions and ocular trauma.

Lithotomy and Lloyd-Davies position

This is commonly employed for gynaecological, perineal and urological procedures. The patient is positioned supine with the legs flexed at the hip and knee and placed in stirrups. In the lithotomy position the hips are flexed to 90°; however, the degree of hip and knee flexion can be controlled depending upon the type of procedure performed (*Figure 7.3*). The Lloyd-Davies position is a modification of the lithotomy position with hips minimally flexed to around 15° with a 30° head-down tilt.

Key points

- Both legs are simultaneously placed in the stirrups.
- The fingers should not extend past the edge of the table as they can be crushed or even amputated accidentally.
- The legs should not be externally rotated or unduly abducted.
- Sequential compression devices may be useful to prevent venous stasis, especially in major operations.

Potential complications

- Venous and arterial insufficiency in long procedures can lead to limb ischaemia and compartment syndrome, besides having a higher chance of deep venous thrombosis.
- Digital amputation at the edge of the bed.
- Hyperflexion can cause damage to the sciatic nerve.
- Saphenous and peroneal neuropraxia when legs are placed in the stirrups.

PREPARATION OF THE SURGICAL SITE

Correct skin preparation can reduce surgical site infection (SSI). The steps involved in preparing the skin prior to making an incision are described below.

Removal of metals and other foreign bodies

Removal of piercings and rings from the surgical site is important as they often act as a nidus for infection; metallic objects could also potentially lead to thermal injury when diathermy is used. In addition, finger rings or toe rings can cause digital vascular compromise if there is postoperative oedema following operations on the extremities.

Hair removal from the surgical site

Hair is removed from the surgical site when it is deemed to interfere with the operation; it also makes postoperative plaster or dressing changes relatively pain free. However, removal of hair causes microabrasions and can potentially cause cellulitis and SSI.

Timing of hair removal

The ideal time and place for hair removal is on the operating table after a dose of prophylactic antibiotic is given. Preoperative removal of hair outside the confines of the operating room is discouraged.

Method of hair removal

Skin clippers with disposable blades are preferred as they are safe and result in the fewest SSIs. Shaving using a razor blade is discouraged as unintended microincisions caused by the blade often result in exaggerated skin infection and inflammation.

Skin antisepsis

Skin antisepsis removes transient organisms and dirt, thereby preventing SSI. The principles involved in skin antisepsis are as follows.

- The use of alcohol-based antiseptic solution is recommended. The World Health Organization recommends the use of chlorhexidine alcohol; however, the clinical difference between povidone–iodine and chlorhexidine is marginal and therefore the use of any alcohol-based antiseptic solution is acceptable.
- Extensions of the main incision, additional incisions and drain placement have to be factored in when planning the preparation of the surgical site.
- A slender cotton-tipped swab can be used to clean the umbilicus when preparing for an abdominal procedure.
- In contaminated or dirty wounds it is advisable to start from an area of lower bacterial contamination and move towards a region with greater contamination. However, in clean procedures, starting from the area where skin incision is likely to be made and working towards the periphery is advised.
- Using concentric circles, horizontal or vertical lines do not make a difference in preventing SSI.
- It is important to allow the antiseptic solution to dry and to avoid dripping of the solution onto the diathermy electrodes or pooling under the patient.

Draping

Draping is the process of forming a sterile perimeter around the operating site using disposable or reusable sterile sheets. The drape sheets ideally serve to form a fluid-resistant barrier; they are antistatic, flame resistant, lint free and, although waterproof, are porous enough to prevent heat build-up.

Each procedure has a unique method of draping; this is beyond the scope of this chapter. However, a few practical considerations are discussed below.

- The drapes are usually placed over the periphery of the area that has been painted, once the antiseptic solution has dried. This can be aided by dabbing the perimeter with a sterile cloth or waiting for the antiseptic solution to dry.
- It is advisable to stand an arm's length away from the operating table and spread the drapes with arms extended.
- Avoid reaching across the operating table to drape.
- Sharp towel clips pierce the drapes and thereby contaminate the sterile field; they should be avoided if possible.
- If there is any doubt that there could be a breach in sterile technique, then it is advisable to redo the process or at least replace/cover the offending drape.
- Draping non-disposable equipment such as laparoscopic cords, ultrasonic devices, image intensifiers and light handles may be required. Prefabricated, customised drapes are preferred where possible.
- The routine use of transparent adhesive skin drapes (with or without antibiotic impregnation) over the surgical site cannot be recommended based on the available literature.

Summary box 7.3

Salient features in preparing the operative area

- Remove metal rings and piercings from the surgical field
- Hair removal is advised only if it interferes with surgery
- Hair clippers are preferred to razor blades
- Alcohol-based povidone–iodine or chlorhexidine solution for skin antisepsis
- Drape the perimeter of the operative field using sterile drapes

SURGICAL EXPOSURE AND WOUND APPROXIMATION

Skin incisions

Skin incisions (***Figure 7.6***) are made using a scalpel with the blade pressed firmly down at right angles to the skin and then drawn gently across the skin in the desired direction to create a clean incision. It is important not to incise the skin obliquely as such a shearing mechanism can lead to necrosis of the undercut edge. The incision is facilitated by tension being applied across the line of the incision by the fingers of the non-dominant hand, but the surgeon must ensure that at no time is the scalpel blade directed at their own fingers as any slip may result in a self-inflicted injury. Blades for skin incisions usually have a curved cutting margin, while those used for an arteriotomy, abscess drainage or drain site insertion have a sharp tip (***Figure 7.7***). Scalpels should at all times be passed in a kidney dish rather than by a direct hand-to-hand process as this can lead to a needle stick-like injury.

When planning a skin incision a few factors should be considered:

1 **Skin tension lines and cosmesis**. Langer's lines (representing the orientation of dermal collagen fibres) have been used to guide skin incision placement; however, the clinical relevance of these lines has been questioned. The use of relaxed skin tension lines (RSTLs), which follow creases formed when the skin is pinched and relaxed, have increasingly been employed to guide skin incision placement, especially in the head and neck. In practice, placing incisions based on natural body creases and wrinkles can reduce tension on the suture line and camouflage scars.

Karl Ritter von Edenberg Langer, 1819–1887, Professor of Anatomy, Vienna, Austria, described these lines in 1862.

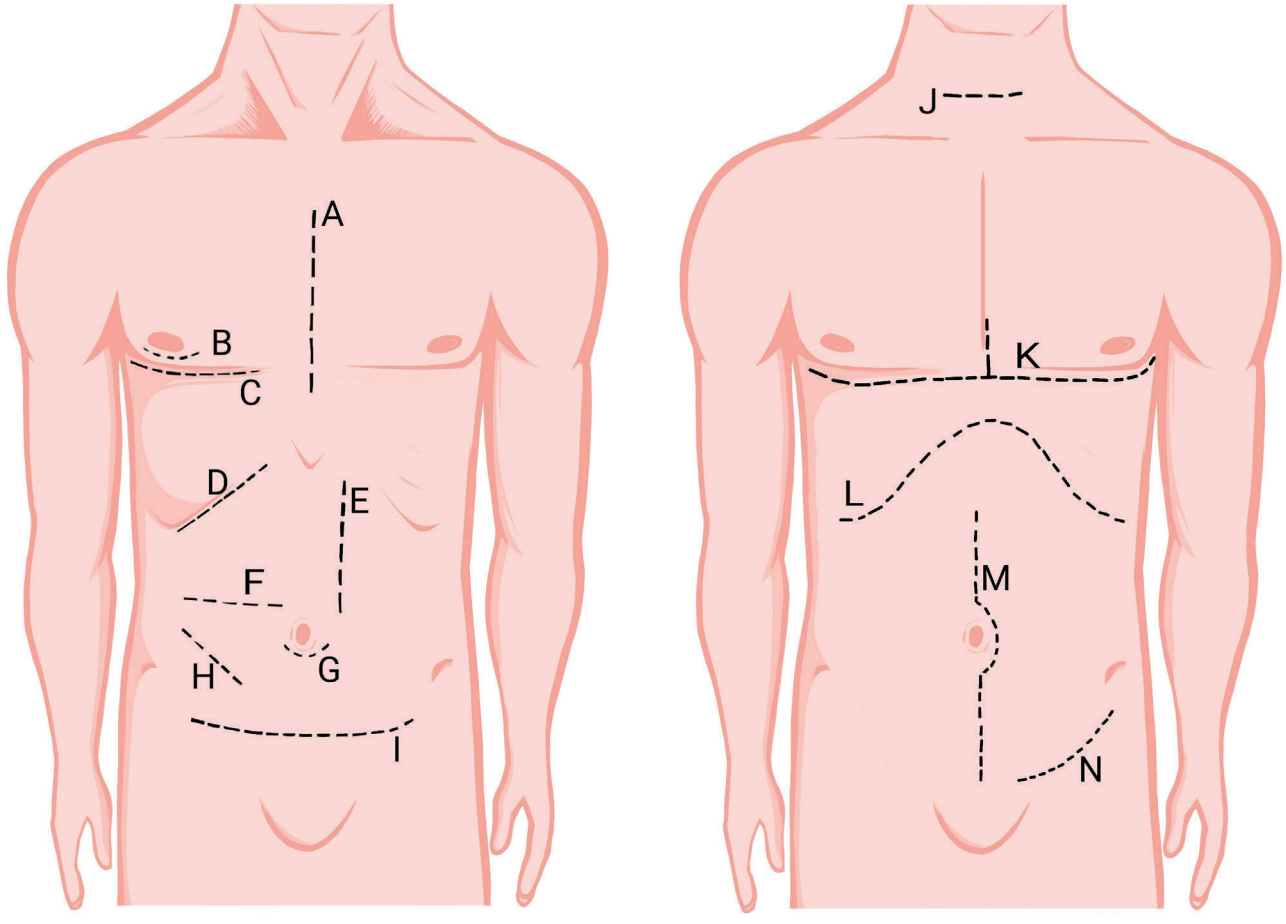

Figure 7.6 Skin incisions in general surgery. A, sternotomy; B, periareolar; C, inframammary; D, subcostal; E, paramedian; F, transverse; G, periumbilical; H, McBurney's; I, Pfannenstiel; J, Kocher's incision for thyroidectomy; K, clamshell thoracotomy; L, chevron incision; M, midline incision; N, inguinal incision (courtesy of Dr Vinay Timothy Kuruvilla).

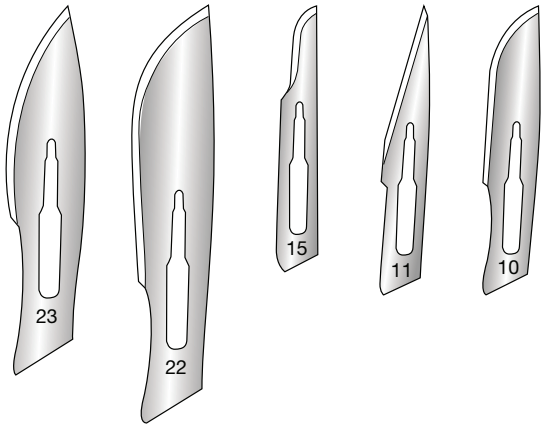

Figure 7.7 Scalpel blade sizes and shapes. The 22-blade is often used for abdominal incisions, the 11-blade for arteriotomy and abscess drainage and the 15-blade for minor surgical procedures.

2 **Anatomical structure**. Incisions should avoid bony prominences and take into consideration underlying structures, such as nerves and vessels. Surface landmarks, previous operations and body habitus also need to be considered.

3 **Adequate access for the procedure**. The incision must be functionally effective as any compromise purely on cosmetic grounds may render the operation ineffective or even dangerous.

Occasionally, it may be necessary to excise a circular skin lesion. An elliptical rather than a circular incision is preferred to enhance tension-free, aesthetic tissue approximation, remembering the rule of thumb that 'an elliptical incision must be at least three times as long as it is wide for the wound to heal without tension'. Occasionally, 'dog ears' remain in the corner of elliptical incisions despite adequate care having been

Charles McBurney, 1854–1913, Professor of Surgery, Columbia College of Physicians and Surgeons, New York, NY, USA. In 1889 McBurney published a paper on appendicitis in which he stated 'I believe that in every case the seat of greatest pain "determined by the pressure of one finger" has been very exactly between an inch and a half and two inches from the anterior spinous process of the ilium on a straight line drawn from that process to the umbilicus.'
Hermann Johann Pfannenstiel, 1862–1909, gynaecologist, Breslau, Germany (now Wrocław, Poland), described this incision in 1900.
Emil Theodor Kocher, 1841–1917, Professor of Surgery, Berne, Switzerland. In 1909, he was awarded the Nobel Prize in Physiology or Medicine for his work on the thyroid.

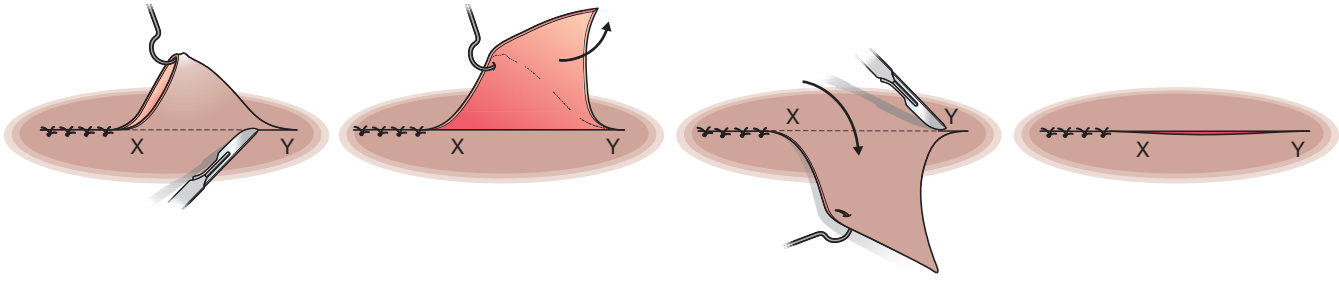

Figure 7.8 Dealing with a 'dog ear' at the corner of an elliptical incision.

taken during the formation and primary closure of an elliptical wound. In these situations, it is advisable to pick up the 'dog ear' with a skin hook and excise it as shown in ***Figure 7.8***. This allows for a satisfactory cosmetic outcome.

Surgical access to the abdomen in general surgery

Access to the abdominal cavity can be achieved in many ways and the exposure required will depend on the surgical pathology anticipated, procedure performed and expertise of the surgeon (***Summary box 7.4***).

Summary box 7.4

Surgical exposure of the abdomen

Open surgical exposure

- Intraperitoneal access
  - Longitudinal
  - Transverse
  - Oblique
  - Pelvic
- Retroperitoneal access – flank incision
- Multicompartment access – thoracoabdominal incisions

Laparoscopic exposure

- Multiport, single port, hand-assisted laparoscopy

Scalpel versus diathermy?

Abdominal incisions can be made using a scalpel or diathermy. Recent data suggest that there is no difference with regards to SSI, blood loss or operative time between the two; however, using diathermy resulted in a lower requirement for postoperative analgesia. Usually, it is down to the surgeon's preference as there appears to be no clinically discernible difference.

Transverse versus longitudinal?

Transverse incisions result in less pain, better pulmonary function and fewer incisional hernias but have higher wound infection rates. However, as a rule of thumb, the midline laparotomy is preferred for most emergency procedures as this is quicker to perform and is more versatile.

The steps in performing a midline laparotomy are detailed below. Every incision should be made with closure in mind and based on the suspected site of pathology: an upper midline, lower midline or mid-midline laparotomy incision can be made and extended as required.

1. The first step is to make a skin incision using landmarks such as the xiphisternum, umbilicus and pubic symphysis as reference (***Figure 7.9a***).
2. The subcutaneous tissue is then dissected away, exposing the rectus and the linea alba (***Figure 7.9b***).
3. The linea alba is longitudinally incised close to the umbilical cicatrix to prevent straying into the rectus sheath on either side, thereby exposing the pre-peritoneal fat (***Figure 7.9c***).
4. The pre-peritoneal fat is divided carefully and the peritoneum is picked up between two haemostats and incised using scissors (***Figure 7.9d***).
5. Once the peritoneum is entered, the surgeon's fingers are usually inserted into the peritoneal cavity and the desired length of the peritoneal cavity is opened (***Figure 7.9e***).

Re-entry incisions

Avoid railroading and criss-crossing incisions as they can lead to skin necrosis; it is better to make an incision through the previous scar or excise the scar in total. Extending the skin incision past the previous scar to enter the peritoneal cavity at a virgin plane may help avoid inadvertent injury to the underlying viscera, which may be adherent to the scar.

Laparoscopic access and port placement

There are two fundamental ways to access the abdomen laparoscopically:

1. the open technique (Hasson's or modified Hasson's)
2. the closed technique (Veress needle and/or visual entry trocar).

The advantages and complication rates of each of these techniques are not significantly different; therefore, the technique that the surgeon is most accustomed to should be used.

Harrith Hasson, 1931–2012, Professor of Gynaecology, Chicago, IL, USA.
Janos Veress, 1903–1979, surgeon, Hungary.

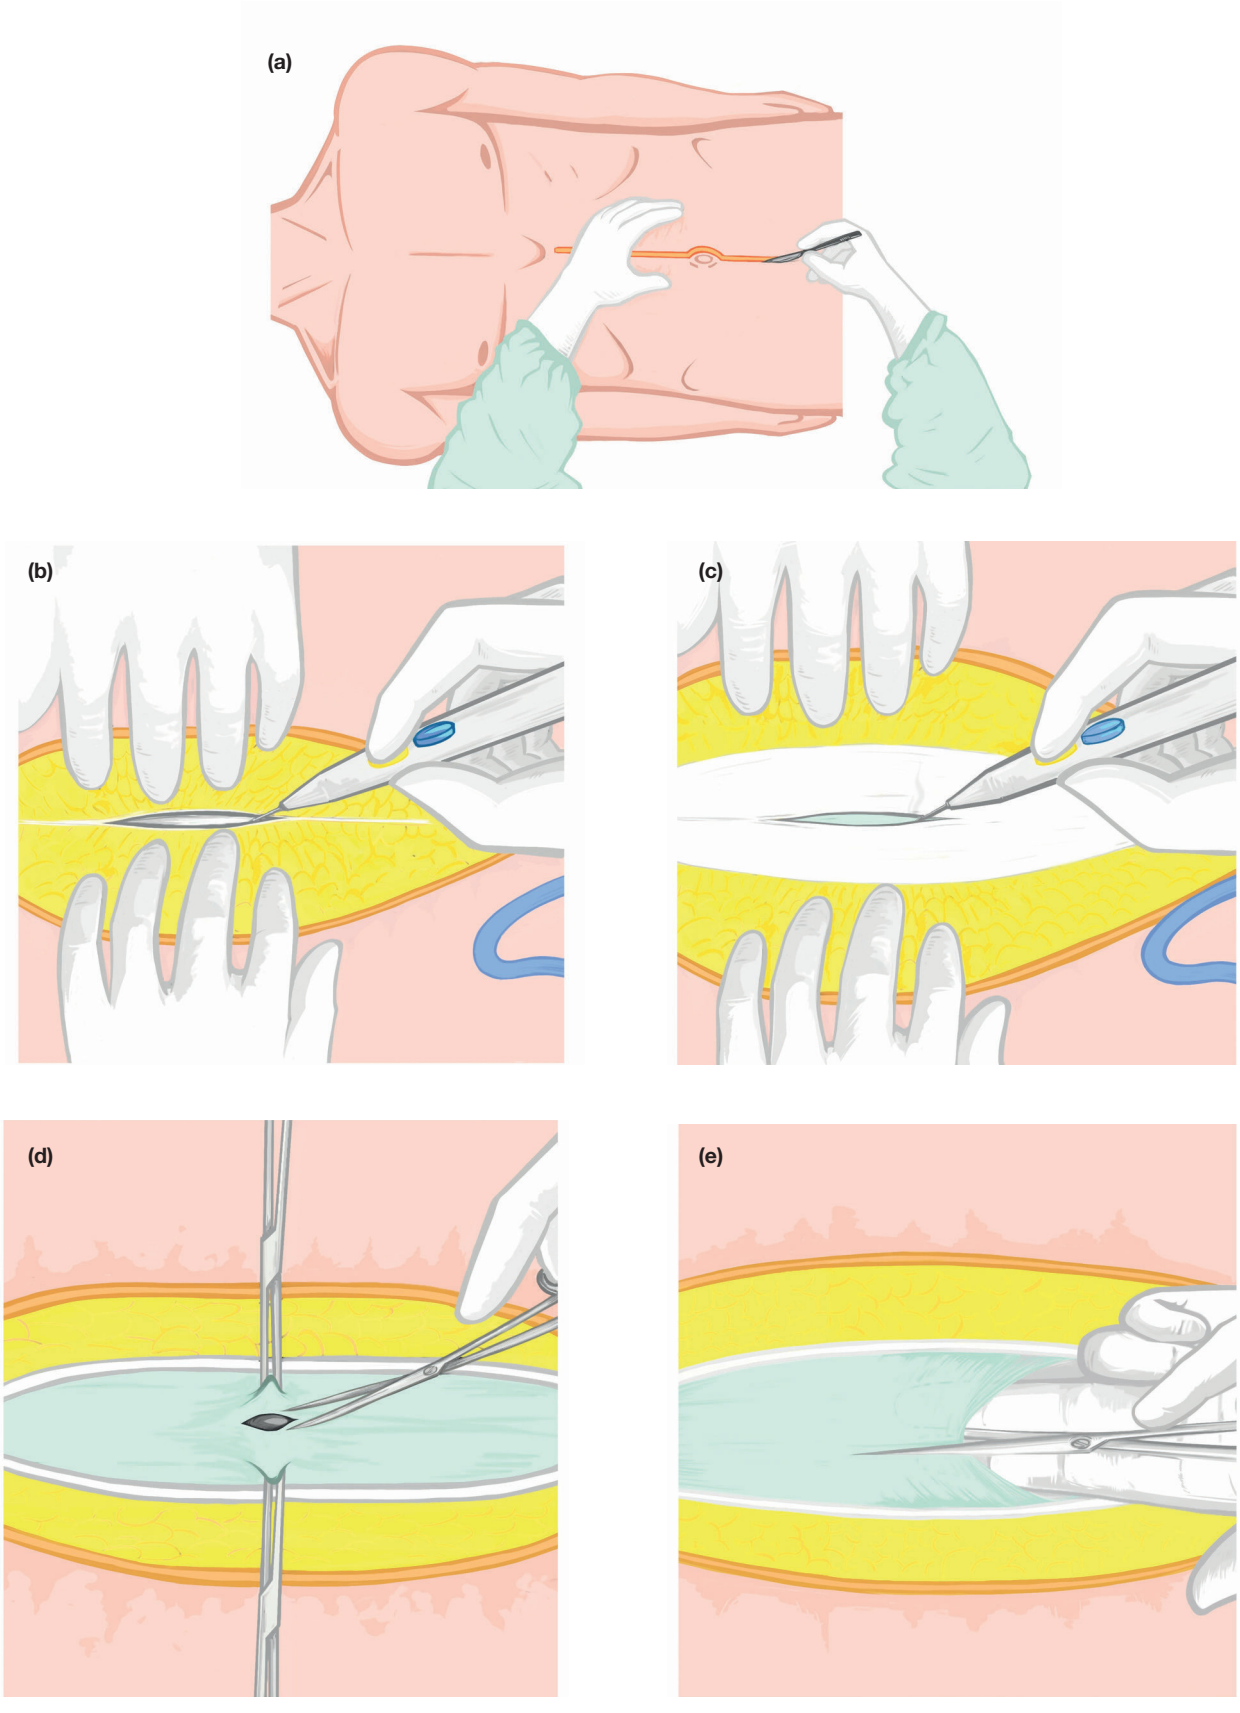

Figure 7.9 Midline laparotomy incision. **(a)** Skin incision; **(b)** subcutaneous fat is incised; **(c)** linea alba is opened to expose peritoneum; **(d)** peritoneum is picked up between haemostats and incised; **(e)** peritoneal cavity opened (courtesy of Dr Vinay Timothy Kuruvilla).

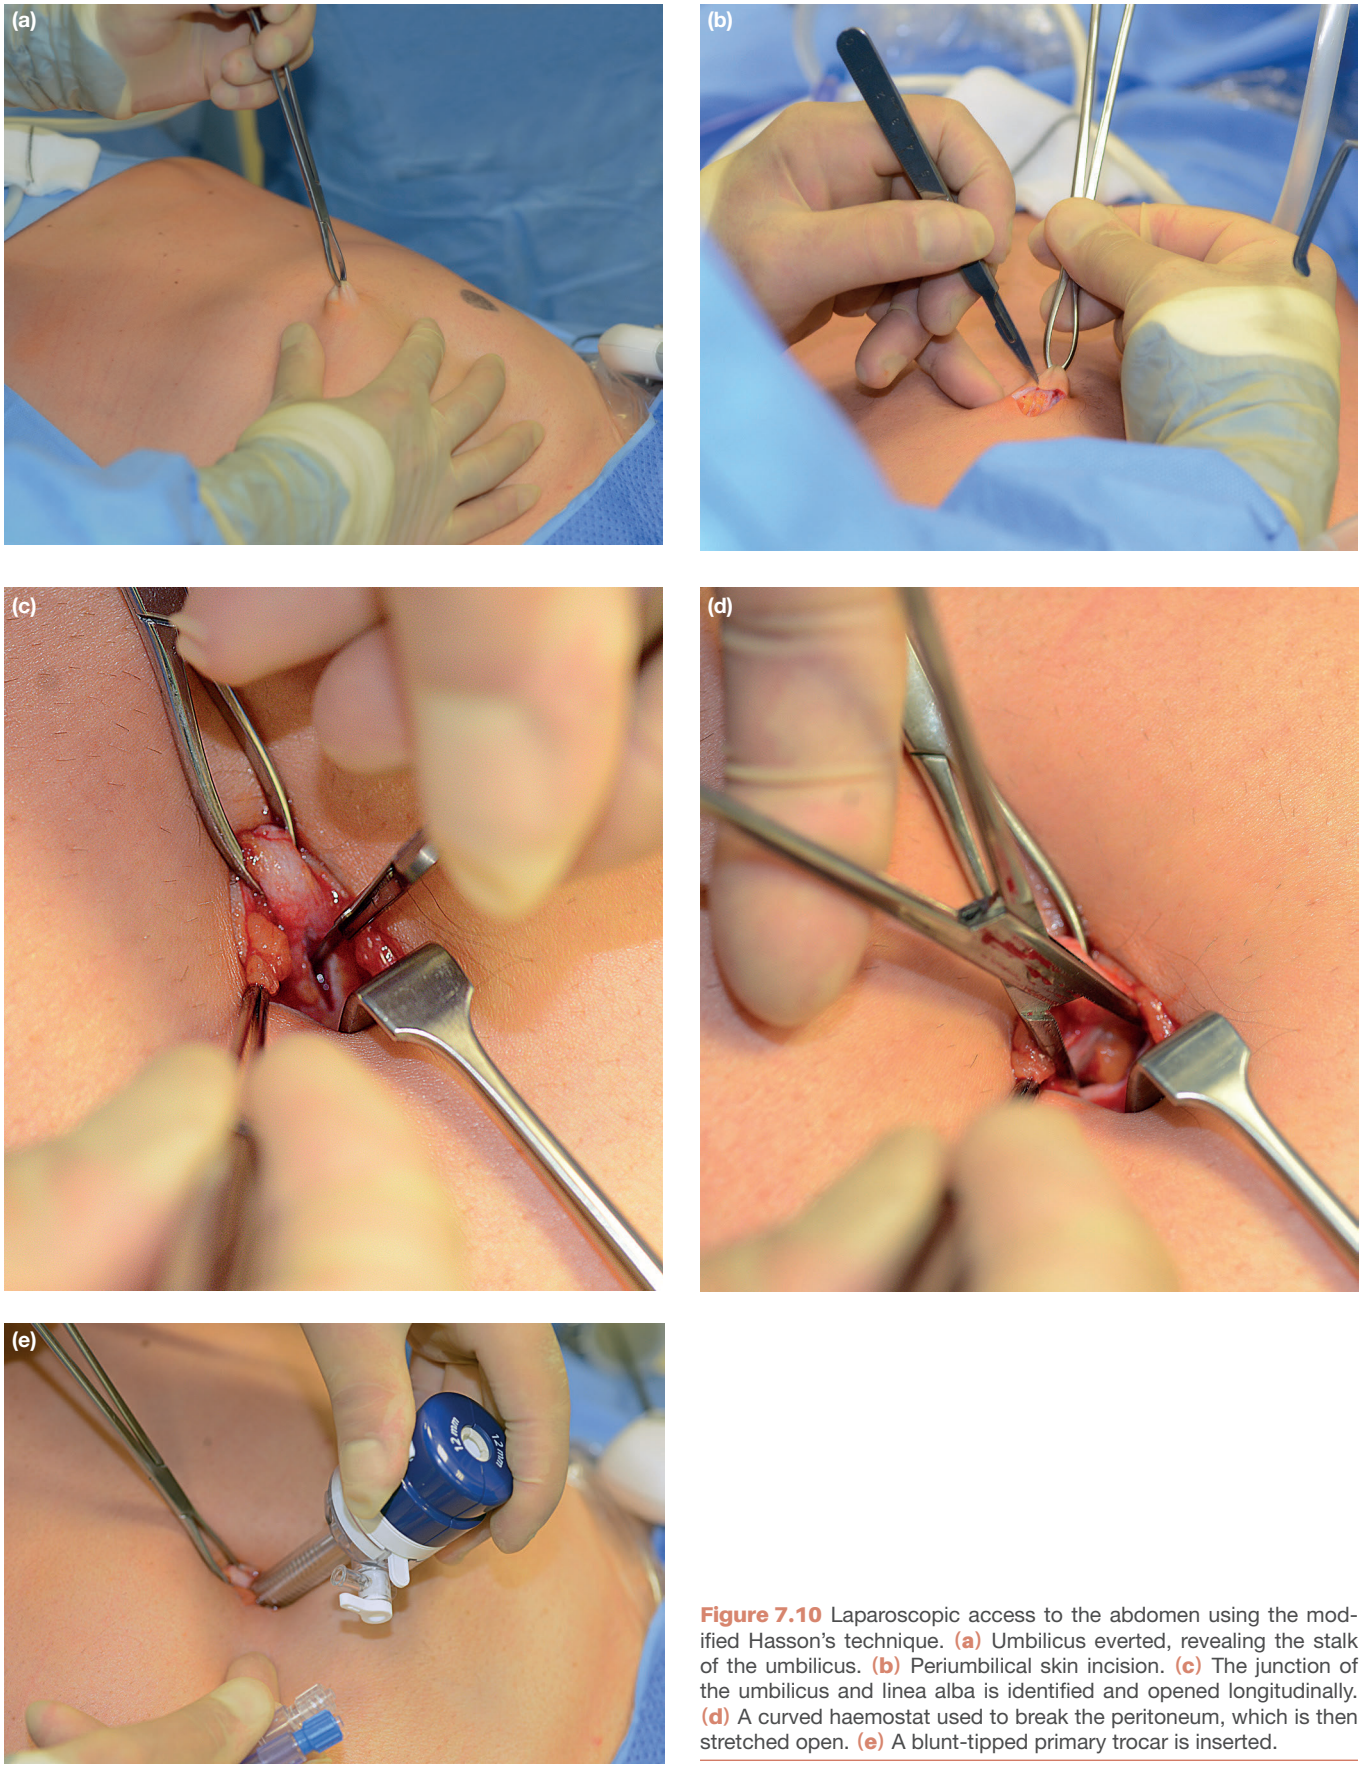

Figure 7.10 Laparoscopic access to the abdomen using the modified Hasson's technique. **(a)** Umbilicus everted, revealing the stalk of the umbilicus. **(b)** Periumbilical skin incision. **(c)** The junction of the umbilicus and linea alba is identified and opened longitudinally. **(d)** A curved haemostat used to break the peritoneum, which is then stretched open. **(e)** A blunt-tipped primary trocar is inserted.

However, a competent laparoscopic surgeon should be familiar with both techniques to provide access as directed by circumstances such as pregnancy, scars from previous operations or as dictated by disease pathology.

Blind trocar insertion with or without Veress needle insufflation is avoided.

Open Hasson's technique for laparoscopic primary trocar insertion

In most cases, the umbilicus is the preferred site for a 10–12-mm initial port placement (*Figure 7.10a–e*).

1. The umbilical cicatrix is everted with a toothed tissue-grasping forceps. It is important to grasp the cicatrix directly as this is closest to the adherent peritoneum. Counter-traction is maintained throughout the subsequent steps until the primary trocar is inserted.
2. The umbilical stalk is palpated inferior to the everted cicatrix while maintaining cephalad traction.
3. A curved 10–12-mm transverse incision is made inferior to the cicatrix.
4. The umbilical stalk is exposed with sharp and blunt dissection to reveal the decussation (crossing) of fibres just above its junction with the linea alba.
5. A 5-mm vertical incision is made through the decussation with an 11-blade scalpel, taking care only to incise the fascia at this point and not to enter the peritoneum.
6. A blunt haemostat angled away from the bowel and major vessels is then pushed through the pre-peritoneal fat and peritoneum; the surgeon will feel a 'pop' as the instrument enters the peritoneal cavity.
7. A blunt-tipped 10- or 12-mm trocar is pushed through the same point of insertion of the haemostat and in the same direction.
8. The laparoscopic camera is used to confirm successful placement in the peritoneal cavity before insufflation with CO_2 gas.
9. CO_2 gas insufflation is commenced at low flow (1–4 litres per minute) and increased to a maximum pressure of 15 mmHg and with a maximum flow rate of 20 L/min.
10. For the patient with scars from previous abdominal surgery, the safest technique is an open approach at Palmer's point, 3 cm below the left subcostal margin in the mid-clavicular line. Adequate lighting and good assistance with retraction are essential.

Veress needle and optical entry

A Veress needle is a spring-loaded needle that consists of an outer sharp bevel that cuts through tissue. Once the needle enters the peritoneal cavity, owing to the loss of resistance the spring-loaded blunt inner stylet deploys and prevents inadvertent injury to the bowel or blood vessels. The Veress needle can be inserted in the umbilical region or in other regions of the abdomen, such as Palmer's point.

The steps involved in Veress needle insertion are as follows (*Figure 7.11*).

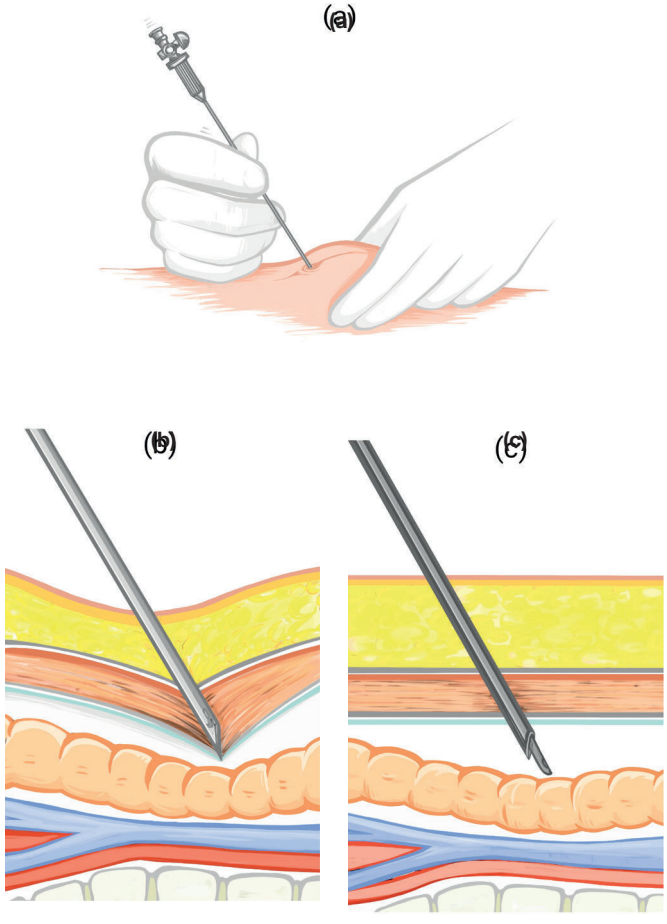

Figure 7.11 Veress needle to establish pneumoperitoneum (courtesy of Dr Vinay Timothy Kuruvilla).

1. A 10-mm incision in Palmer's point (3 cm below the left costal margin, in the mid-clavicular plane) is the location preferred by many surgeons for Veress needle insertion.
2. The needle is advanced until it reaches the muscle. The abdominal wall is then lifted and the needle advanced through the oblique muscles.
3. Classically, a 'pop' is heard and a 'give' felt on successful insertion into the peritoneal cavity.
4. The intraperitoneal placement is confirmed using a combination of the following techniques.
   - The hanging drop method, wherein a drop of water is placed in the hub of the needle; on elevating the abdominal wall the resultant loss of intra-abdominal pressure would result in the drop emptying into the abdominal cavity.
   - Free flow of saline into the peritoneal cavity and no return of bowel content or blood on aspiration.
   - Abdominal pressure reading of less than 10 mmHg.
5. Once the position is confirmed CO_2 insufflation at a slow pace is commenced until the target pressure is reached. The needle is now removed.

Raol Palmer, 1904–1945, gynaecologist, France.

6 Optical primary port placement after Veress needle insufflation:
   - The primary port is placed by following the Veress needle track. A visual entry port is recommended as it allows for a more controlled entry under vision. This technique involves the placement of a 0° laparoscope through a transparent optical port, which is tunnelled into the abdomen under vision. The port is advanced with a twisting motion while the camera is held steady.
   - The layers of the abdominal wall musculature are seen. When the peritoneal cavity (distended beforehand using the Veress needle) is entered the omentum and intra-abdominal viscera are seen and a gush of air is heard and felt. The 0° camera is subsequently replaced with an appropriate 30° camera if required.
   - It is also common practice to use the optical entry method without prior insufflation using a Veress needle.

The basic principles of secondary port (trocar) placement in laparoscopic surgery are as follows:

1 All secondary trocars should be inserted under direct vision to avoid damage to bowel, bladder and blood vessels. A two-handed or controlled single-handed technique should be used to avoid sudden movement, resulting in plunging of the trocar intraperitoneally.
2 Trocars should always be inserted perpendicular to the abdominal wall. Oblique insertion results in increased pressure or torque while instruments are used, which causes fatigue for the surgeon and increased trauma to the patient's abdominal wall. This is of particular relevance in obese patients.
3 A hand's breadth (the patient's hand) either side of the midline represents the extent of the rectus sheath, which contains the epigastric vessels. By placing non-midline trocars lateral to the rectus sheath, usually in the midclavicular line, the epigastric vessels can be avoided.
4 Where possible, smaller diameter trocars should be used as they are associated with less postoperative pain, a lower incidence of port site incisional hernia and better cosmesis. All port sites above 5 mm in diameter should undergo suture closure of the fascial layers to reduce the possibility of port site hernia.
5 All secondary trocars should be removed under direct vision to observe for port site bleeding.

Summary box 7.5

The benefits of laparoscopic surgery

- Less postoperative pain
- Better cosmesis
- Earlier return to normal physiology
- Shorter hospital stays
- Fewer intraoperative adhesions created
- Better perception of anatomy as image is often magnified

WOUND CLOSURE AND SUTURING TECHNIQUE

The suturing of an incision or wound needs to take into consideration the site and tissues involved. There is no ideal wound closure technique that would be appropriate for all situations, and the ideal suture has yet to be produced, although many of the desired characteristics are listed in *Summary box 7.6*.

Summary box 7.6

Suture material: desired characteristics

- Easy to handle
- Predictable behaviour in tissues
- Predictable tensile strength
- Sterile
- Glides through tissues easily
- Secure knotting ability
- Inexpensive
- Minimal tissue reaction
- Non-capillary
- Non-allergenic
- Non-carcinogenic

Clean wounds with a good blood supply heal by primary intention and so closure simply requires accurate apposition of the wound edges. However, if a wound is left open, it heals by secondary intention through the formation of granulation tissue, which is tissue composed of capillaries, fibroblasts and inflammatory cells. Wound contraction and epithelialisation assist in ultimate healing, but the process may take several weeks or months. Delayed primary closure or tertiary intention is utilised when there is a high probability of the wound being infected. The wound is left open for a few days and if the infective process is resolved then the wound is closed to heal by primary intention. Skin grafting is another form of tertiary intention healing.

Summary box 7.7

Types of wound healing

- Primary intention – clean wounds that are often sutured together
- Secondary intention – healthy granulation tissue filling up an open wound
- Tertiary intention – delayed closure or skin grafting

Suture characteristics

There are five characteristics of any suture material that need to be considered:

1 **Physical structure**: monofilament or multifilament.
   - Monofilament sutures are smooth and tend to slide through tissues easily, but are more difficult to knot effectively. Such material can be easily damaged by gripping it with a needle holder and this can lead to fracture of the suture.
   - Multifilament or braided sutures are much easier to knot but have a surface area of several thousand times that of monofilament sutures and thus have a capillary

action and interstices where bacteria may lodge and be responsible for persistent infection or sinuses. To overcome some of these problems, certain materials are produced as a braided suture that is coated with silicone to make it smooth.

2 **Strength**: the strength of a suture depends upon its constituent material, thickness and its response to various tissues and circumstances. Suture material thickness is classified according to its diameter in tenths of a millimetre. The tensile strength of a suture can be expressed as the force required to break it when pulling the two ends apart. Absorbable sutures show decay of this strength with time. Although the material may last in the tissues for the stated period in the manufacturer's product profile, its tensile strength cannot be relied on *in vivo* for this entire period.

Materials such as catgut (no longer in use in the UK) have a tensile strength of only about a week while polydioxanone sulphate (PDS) will remain strong in the tissues for several weeks. However, even non-absorbable sutures do not necessarily maintain their strength indefinitely. Non-absorbable materials of synthetic origin, such as polypropylene, probably retain their tensile strength indefinitely, whereas non-absorbable materials of biological origin, such as silk, will fragment with time and lose their strength, and such materials should never be used in vascular anastomoses for fear of late fistula formation.

3 **Tensile behaviour**: suture materials behave differently depending upon their deformability and flexibility. Some may be 'elastic', in which case the material will return to its original length once any tension is released, while others may be 'plastic', in which case this phenomenon does not occur. Many synthetic materials demonstrate 'memory', which means they keep curling up in the shape that they adopted within the packaging. A sharp but gentle pull on the suture material helps to diminish this memory, but the more memory a suture material has, the less is the knot security.

4 **Absorbability**: suture materials may be non-absorbable (*Table 7.1*) or absorbable (*Table 7.2*).

5 **Biological behaviour**: the biological behaviour of suture materials within the tissues depends upon the constituent raw material. Biological or natural sutures, such as catgut, are proteolysed, but this involves a process that is not entirely predictable and can cause local irritation; therefore, such materials are seldom used. Man-made synthetic polymers are hydrolysed and their disappearance in the tissues is more predictable. The presence of pus, urine or faeces influences the final result and renders the outcome more unpredictable.

Needles

Most needles in present practice are eyeless, or 'atraumatic', with the suture material embedded within the shank of the needle. The needle has three main parts:

1 shank;
2 body;
3 point.

The needle should be grasped by the needle holder approximately one-third of the way back from the rear of the needle, avoiding both the shank and the point.

The body of the needle is either round, triangular or flattened. Round-bodied needles gradually taper to a point, while triangular needles have cutting edges along all three sides. The point of the needle can be round with a tapered end, conventional cutting, which has the cutting edge facing the inside of the needle's curvature, or reversed cutting, in which the cutting edge is on the outside.

Round-bodied needles are designed to separate tissue fibres rather than cut through them and are commonly used in intestinal and cardiovascular surgery. Cutting needles are used where tough or dense tissue needs to be sutured, such as skin and fascia. Blunt-ended needles are now being advocated in certain situations, such as the closure of the abdominal wall, to diminish the risk of needle-stick injuries in this era of virally transmitted disorders. The choice of needle shape tends to be dictated by the accessibility of the tissue to be sutured, and the more confined the operative space, the more curved the needle. Hand-held straight needles may be used on skin, although today it is advocated that needle holders should be used in all cases to reduce the risk of needle-stick injuries.

Half-circle needles are commonly utilised in the gastrointestinal tract, while J-shaped needles, quarter-circle needles and compound curvature needles are used in special situations such as the laparoscopic port site closure, eye and oral cavity, respectively. The size of the needle tends to correspond with the gauge of the suture material, although it is possible to get similar sutures with differing needle sizes (*Figure 7.12*).

When choosing suture materials, there are certain specific requirements depending on the tissue to be sutured.

- Vascular anastomoses require smooth, non-absorbable, non-elastic material.
- Biliary anastomoses require an absorbable material that will not promote tissue reaction or stone formation.
- When using absorbable material, always be mindful that certain tissues require wound support for longer than others; for example, muscular aponeuroses compared with subcutaneous tissues.
- Bowel anastomosis is usually performed using polyglactin, PDS or polypropylene based on the surgeon's preference.
- The size of the needle and suture size used depends on the tissue that is approximated (*Table 7.3*).

TABLE 7.3 Size of suture material.

Metric (EurPh)	Range of diameter (mm)	USP ('old')
1	0.100–0.149	5–0
1.5	0.150–0.199	4–0
2	0.200–0.249	3–0
3	0.300–0.349	2–0
3.5	0.350–0.399	0
4	0.400–0.499	1
5	0.500–0.599	2

TABLE 7.1 Non-absorbable suture materials.

Suture	Silk	Linen	Surgical steel	Nylon	Polyester	Polypropylene
Frequent uses	Ligation and suturing when long-term tissue support is necessary. For securing drains externally	Ligation and suturing in gastrointestinal surgery. No longer in common use in most centres	Closure of sternotomy wounds. Previously found favour for tendon and hernia repairs	General surgical use, e.g. skin closure, abdominal wall mass closure, hernia repair, plastic surgery, neurosurgery, microsurgery, ophthalmic surgery	Cardiovascular, ophthalmic, plastic and general surgery	Cardiovascular surgery, plastic surgery, ophthalmic surgery, general surgical subcuticular skin closure
Contraindications	Not for use with vascular prostheses or in tissues requiring prolonged approximation under stress. Risk of infection and tissue reaction makes silk unsuitable for routine skin closure	Not advised for use with vascular prostheses	Should not be used in conjunction with prosthesis of different metal	None	None	None
Tissue reaction	Moderate to high Not recommended. Consider suitable absorbable or non-absorbable	Moderate	Minimal	Low	Low	Low
Absorption rate	Fibrous encapsulation in body at 2–3 weeks. Absorbed slowly over 1–2 years	Non-absorbable. Remains encapsulated in body tissues	Non-absorbable. Remains encapsulated in body tissues	Degrades at approximately 15–20% per year	Non-absorbable: remains encapsulated in body tissues	Non-absorbable: remains encapsulated in body tissues
Tensile strength	Loses 20% when wet; 80–100% lost by 6 months. Because of tissue reactions and unpredictability, silk is increasingly not recommended	Stronger when wet. Loses 50% at 6 months; 30% remains at 2 years	Infinite (>1 year)	Loses 15–20% per year	Infinite (>1 year)	Infinite (>1 year)
Raw material	Natural protein. Raw silk from silkworm	Long staple flax fibres	An alloy of iron, nickel and chromium	Polyamide polymer	Polyester (polyethylene terephthalate)	Polymer of propylene
Types	Braided or twisted multifilament. Dyed or undyed. Coated (with wax or silicone) or uncoated	Twisted	Monofilament or multifilament	Monofilament or braided multifilament. Dyed or undyed	Monofilament or braided multifilament. Dyed or undyed. Coated (polybutylate or silicone) or uncoated	Monofilament. Dyed or undyed
Common name	Silk	Linen	Steel	Ethilon®, Dafilon®	Ethibond®	Prolene®, Premilene®

TABLE 7.2 Absorbable suture materials.

Suture	Catgut	Catgut	Polyglactin	Polydioxanone (PDS)	Polyglycaprone
Frequent uses	Ligate superficial vessels, suture subcutaneous tissues. Stomas and other tissues that heal rapidly	As for plain catgut	General surgical use where absorbable sutures required, e.g. gut anastomoses, vascular ligatures. Has become the 'workhorse' suture for many applications in most general surgical practices, including undyed for subcuticular wound closures. Ophthalmic surgery	Uses as for other absorbable sutures, in particular where slightly longer wound support is required	Subcuticular in skin, ligation, gastrointestinal and muscle surgery
Contraindications	Not for use in tissues that heal slowly and require prolonged support. Synthetic absorbables are superior	As for plain catgut. Synthetic absorbables are superior	Not advised for use in tissues that require prolonged approximation under stress	Not for use in association with heart valves or synthetic grafts, or in situations in which prolonged tissue approximation under stress is required	No use for extended support
Tissue reaction	High	Moderate	Mild	Mild	Mild
Absorption rate	Phagocytosis and enzymatic degradation within 7–10 days	Phagocytosis and enzymatic degradation within 90 days	Hydrolysis minimal until 5–6 weeks. Complete absorption 60–90 days	Hydrolysis minimal at 90 days. Complete absorption at 180 days	90–120 days
Tensile strength retention *in vivo*	Lost within 7–10 days. Marked patient variability Unpredictable and not recommended	Lost within 21–28 days. Marked patient variability. Unpredictable and not recommended	Approximately 60% remains at 2 weeks. Approximately 30% remains at 3 weeks	Approximately 70% remains at 2 weeks. Approximately 50% remains at 4 weeks. Approximately 14% remains at 8 weeks	21 days maximum
Raw material	Collagen derived from healthy sheep or cattle	Collagen derived from healthy sheep or cattle. Tanned with chromium salts to improve handling and to resist degradation in tissue	Copolymer of lactide and glycolide in a ratio of 90:10, coated with polyglactin and calcium stearate	Polyester polymer	Copolymer of glycolite and caprolactone
Types	Plain	Chromic	Braided multifilament	Monofilament. Dyed or undyed	Monofilament
Common name	Catgut	Chromic catgut	Vicryl®, Novosyn®	PDS	Monocryl®, Monosyn®

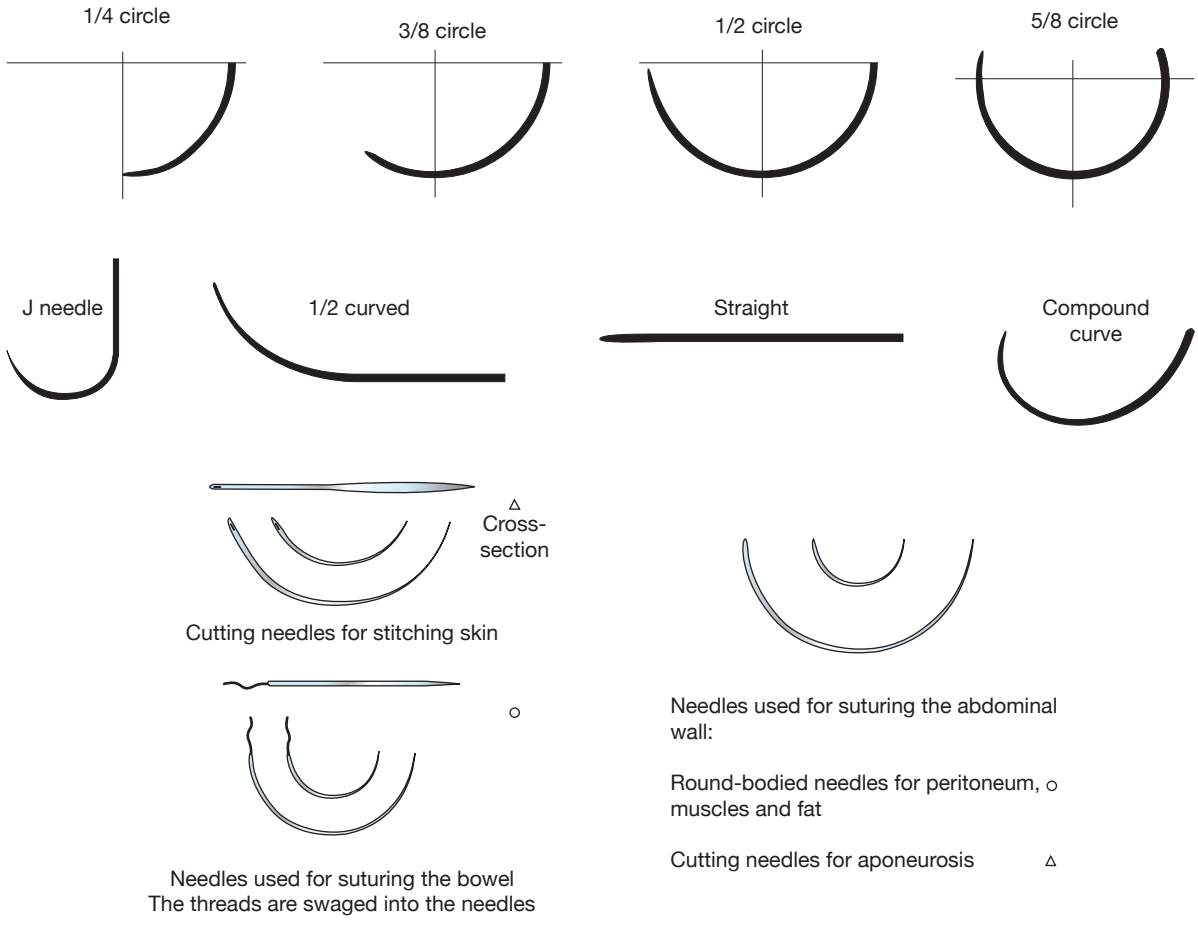

Figure 7.12 Types of needle.

Suture techniques

There are four frequently used suture techniques.

1 **Interrupted sutures**. Interrupted sutures require the needle to be inserted at right angles to the incision and then to pass through both aspects of the suture line and exit again at right angles (***Figure 7.13a***). The needle needs to be rotated through the tissues rather than to be dragged through for fear of enlarging the needle hole. As a guide, the distance from the point of the needle to the edge of the wound should be approximately the same as the depth of the tissue being sutured, and each successive suture should be placed at twice this distance apart (***Figure 7.13b***). Each suture should reach into the depths of the wound and be placed at right angles to the axis of the wound. In linear wounds, it is sometimes easier to insert the middle suture first and then to complete the closure by successively inserting sutures, halving the remaining deficits in the wound length.

2 **Continuous sutures**. For a continuous suture, the first suture is inserted in an identical manner to an interrupted suture, but the rest of the sutures are inserted in a continuous manner until the far end of the wound is reached (***Figure 7.14***). Each throw of the continuous suture should be inserted at right angles to the wound and this will mean that the externally observed suture material will usually lie diagonal to the axis of the wound. It is important to have an assistant who will follow the suture, keeping it at the same tension to avoid either purse stringing the wound by too much tension or leaving the suture material too slack. There is more danger of producing too much tension by using too little suture length than there is of leaving the suture line too lax. Postoperative oedema will often take up any slack in the suture material. At the far end of the wound, this suture line should be secured either by using an Aberdeen knot or by tying the free end to the loop of the last suture to be inserted.

3 **Mattress sutures**. Mattress sutures may be either vertical or horizontal and tend to be used to produce either eversion or inversion of a wound edge (***Figure 7.15***). The initial suture is inserted as for an interrupted suture, but then the needle moves either horizontally or vertically and traverses both edges of the wound once again. Such sutures are very useful in producing an accurate approximation of wound edges, especially when the edges to be anastomosed are irregular in depth or disposition.

4 **Subcuticular suture**. This technique is used in skin where a cosmetic appearance is important and where the skin edges may be approximated easily (***Figure 7.16***). The suture material used may be either absorbable or

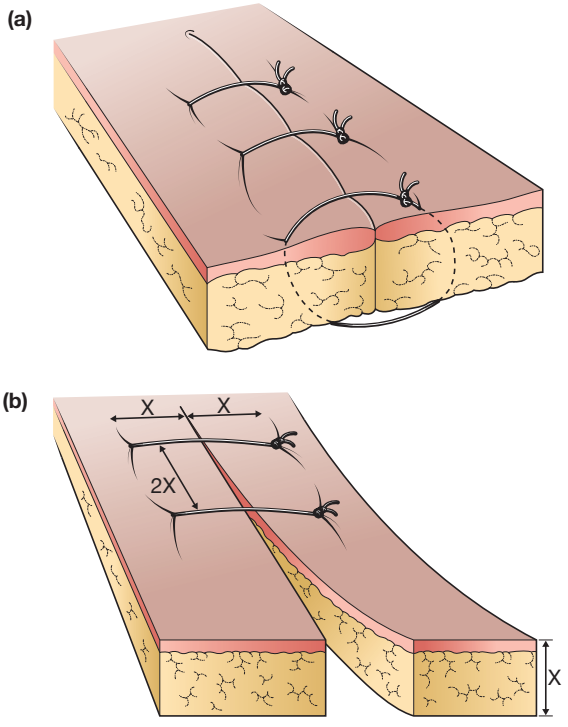

Figure 7.13 **(a)** Interrupted suture technique. Reproduced with permission from Royal College of Surgeons of England. **(b)** The siting of sutures. As a rule of thumb, the distance of insertion from the edge of the wound should correspond to the thickness of the tissue being sutured (×). Each successive suture should be placed at twice this distance apart (2×).

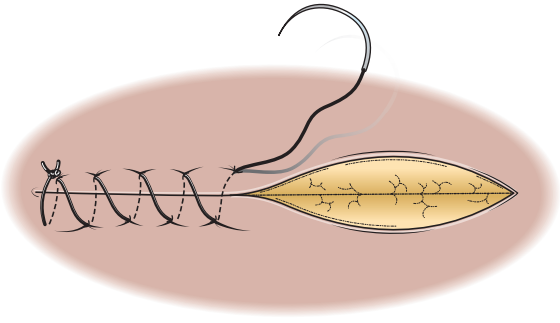

Figure 7.14 Continuous suture technique.

non-absorbable. For non-absorbable sutures, the ends may be secured using a collar and bead, or tied loosely over the wound. When absorbable sutures are used, the ends may be secured using a buried knot. Small bites of the subcuticular tissues are taken on alternate sites of the wound and then gently pulled together, thus approximating the wound edges without the risk of the cross-hatched markings of interrupted sutures.

Knotting techniques

Knot tying is one of the most fundamental techniques in surgery and a poorly constructed knot may jeopardise an otherwise successful surgical procedure. The general principles behind knot tying are as follows:

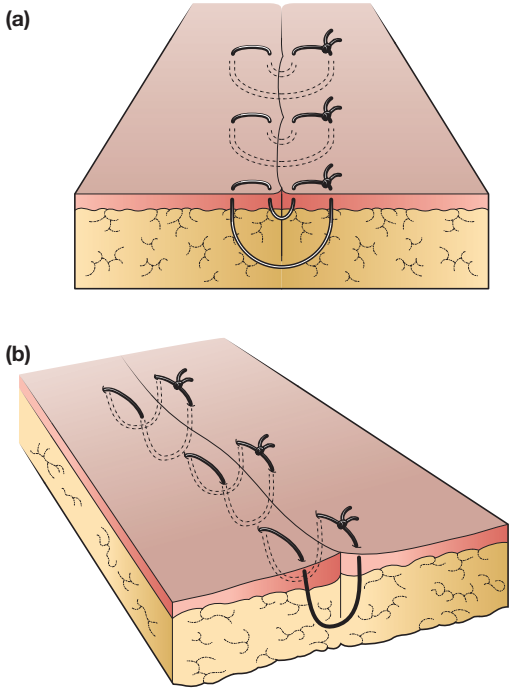

Figure 7.15 Mattress suture techniques.

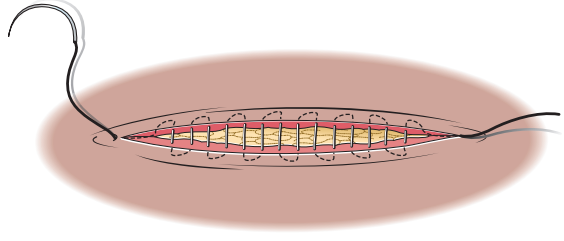

Figure 7.16 Subcuticular suture technique.

- The knot must be tied firmly, but without strangulating the tissues.
- The knot must be as small as possible to minimise the amount of foreign material.
- The knot must be tightened without exerting any tension or pressure on the tissues being ligated, i.e. the knot should be bedded down carefully, only exerting pressure against counter-pressure from the index finger or thumb.
- The suture material must not be 'sawed' as this weakens the thread and cuts through delicate tissue like a cheese wire.
- The suture material must be laid square during tying; otherwise, tension during tightening may cause breakage or fracture of the thread.
- When tying an instrument knot, the thread should only be grasped at the free end, as gripping the thread with the needle holder can damage the material, resulting in breakage or fracture.
- The standard surgical knot is the reef knot with a third throw for security, although with monofilament sutures six throws are required for security.
- When added security is required, a surgeon's knot using a two-throw technique is advisable to prevent slippage.

- When using a continuous suture technique, an Aberdeen knot may be used for the final knot.
- When the suture is cut after knotting, the ends should be left about 1–2 mm long to prevent unravelling. This is particularly important when using monofilament material.

Abdominal wall closure and laparoscopic port closure

Abdominal wound closure technique

The surgical technique involved in abdominal wall closure varies from hospital to hospital with practice heavily influenced by local opinion and training exposure. The objective of abdominal wall closure is to provide a tension-free closure with adequate strength to prevent early dehiscence or an incisional hernia in the long term.

Most abdominal incisions are closed such that the rectus sheath or linea alba is approximated in a continuous manner using delayed absorbable or non-absorbable sutures employing a five-eighths circle, round-bodied, blunt-tipped needle. However, despite a plethora of meta-analyses certain controversies abound.

- **Layered versus mass closure of the abdomen**. Abdominal wounds can be closed either by closing all layers of the abdomen (musculoaponeurotic layers avoiding skin) together or by closing individual layers of the rectus sheath. An alternative would be to approximate only the anterior rectus sheath in situations where mass closure is not feasible (*Figure 7.17*).
- **Continuous versus interrupted sutures**. Simple continuous sutures theoretically seem to be better than interrupted sutures as the tension is evenly distributed, resulting in less ischaemia; in addition, they are quicker to perform. The literature supporting this practice is, however, sparse.
- **Absorbable versus delayed absorbable versus non-absorbable suture material**. Delayed absorbable monofilament material such as PDS is usually the suture material of choice. In patients with multiple previous operations, non-absorbable material such as nylon or polypropylene may be an alternative.
- **Big bites, big needle versus small bites, small needle**. Abdominal closure is commonly performed by placing the sutures 1 cm apart from each other and 1 cm from the fascial edge. Recent studies have shown decreased incisional hernia when the interval between sutures is reduced to 0.5 cm and performed using a smaller sized needle (2.0 PDS as opposed to the much larger 1 PDS). It is argued that the larger needle causes buttonhole defects when compared with the entry point of a narrow needle and thread. This, coupled with the increased distance between bites, causes the suture to act like a cheese wire through the tissue, thereby slackening the stitch and resulting in hernia.

Despite these variations in practice it is important to provide a tension-free approximation, to avoid subcutaneous fat (as the fat is likely to necrose) and, if employing a continuous suturing technique, to start from the inferior and superior ends with two separate sutures and meet in the middle to aid in better visualisation of the final stitches.

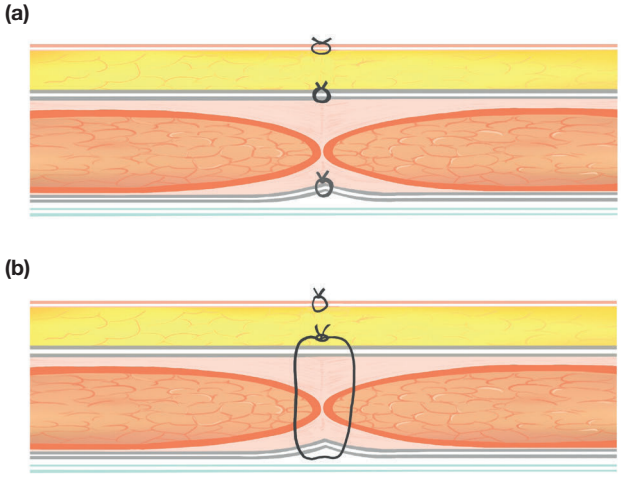

Figure 7.17 Abdominal closure techniques. **(a)** Layered closure. **(b)** Mass closure of all musculoaponeurotic layers (courtesy of Dr Vinay Timothy Kuruvilla).

Alternatives to sutures

Skin adhesive strips

Self-adhesive tapes may be used where there is no tension and the wound is clean; for example, adhesive strips are used following clean procedures on the face.

Tissue glue

Tissue glue can be used as a means of primary tissue apposition or as an adjunct to sutures. Some specific uses have been described such as closing a laceration on the forehead of a fractious child in Accident and Emergency, thus dispensing with local anaesthetic and sutures.

Staples

There is a wide range of mechanical devices that can be used to staple skin, bowel or even major vascular pedicles. Most of these devices are disposable and relatively expensive, but their cost is offset by the saving of operative time.

Removal of skin staples or sutures

The timing of removal of non-absorbable sutures depends on the anatomic location, tension with which the wound was closed and the operation performed. It is customary for the operating surgeon to specify the time of suture removal in the operative notes.

While early removal can minimise unsightly scars and prevent sutures from being embedded in the skin, removing them prematurely can result in wound dehiscence.

As a rule, facial sutures are removed in 3–5 days after the operation, neck sutures in 5–7 days and abdominal sutures between 10 and 14 days.

Basic haemostatic methods and the principles of electrosurgery

Bleeding encountered during an operation can be arterial, venous or capillary. Surgical haemorrhage is categorised as primary (during the operation), reactionary (24–48 hours postoperatively) or secondary (days to weeks postoperatively).

Reactionary haemorrhage is usually a consequence of a slipped ligature or when a vessel injury is missed with bleeding temporarily stopped owing to a combination of vasoconstriction and hypotension. In the postoperative period, once blood pressure improves bleeding will ensue. Secondary haemorrhage is often a manifestation of a deep-seated infection eroding into a blood vessel.

As depicted in ***Summary box 7.8***, it is obvious that there is a plethora of devices and techniques to help control surgical bleeding; however, there can be no substitute for adequate preoperative preparation, careful management of antiplatelets and anticoagulants and meticulous surgical technique.

When establishing haemostasis, care should be taken to avoid damage to adjacent nerves and organs, prevent unintentional vascular thrombosis and avoid adjacent tissue injury. Plunging clamps and suturing blindly in pools of blood may cause more damage than serving any purpose.

The appropriate use of different techniques to control haemorrhage will depend on the site of bleeding, the extent of bleeding and the surgical pathology encountered.

Summary box 7.8

Common haemostatic technique used intraoperatively

Mechanical

- Digital pressure
- Ligatures
- Haemostatic clamps and ligating clips
- Vascular stapling devices
- Wound packing
- Bone wax
- Image-guided embolisation

Thermal

- Electrosurgery
- Cryosurgery
- Argon beam coagulation
- Vessel sealing devices

Chemical or topical haemostatic agents

- Physical: absorbable collagen, gelatin, oxidised cellulose
- Biological: topical thrombin, fibrin sealant, tranexamic acid

ELECTROSURGERY

Electrosurgery employs high-frequency electrical current to assist in making surgical incisions, dissection of tissue and achieving haemostasis. Its widespread use in open, laparoscopic and intraluminal endoscopic surgery such as transurethral resection of the prostate have made it an indispensable part of the surgeon's armamentarium.

Despite its uses many avoidable accidents have occurred. It is therefore vital for a surgeon to have a sound understanding of the principles of electrosurgery to facilitate safe surgery (***Summary box 7.9***).

Summary box 7.9

Safe electrosurgery

- Always check diathermy setting before use
- Use the safest, lowest diathermy current setting
- Be careful when diathermy is used near other metallic instruments
- Employ the diathermy intermittently and for brief spells
- Use bipolar diathermy and advanced vessel-sealing devices where appropriate
- Smoke extractors to remove bio-aerosolised particles are essential

The principles of electrosurgery

Electric current is defined as the flow of charged particles through a circuit. Alternating current (AC), a type of current wherein current periodically changes direction, is solely employed in electrosurgery. The time taken to complete one positive and one negative alternation is called one cycle. Frequency, measured in Hertz (Hz), denotes the number of such cycles in 1 second; the more the cycles, the higher the frequency.

Electrosurgical units (ESUs) work by converting electrical frequencies from the wall outlet (50–60 Hz) to high frequencies ranging from 500 000 to 3 000 000 Hz. When current passes through a conductor at such high frequencies, energy is converted to heat, which is used to cut or coagulate tissue.

It is important to bear in mind that human muscle and nerves are stimulated at frequencies below 10 000 Hz; therefore, ESUs must convert electrical frequency to a much higher frequency.

Monopolar and bipolar diathermy

In monopolar surgery (***Figure 7.18a***), the electrical current created in the ESU passes through a single electrode (diathermy pencil) to the tissue, causing the desired tissue effect (cut or coagulation). To complete the cycle, the current then passes through the tissues and returns via a very large surface plate (the indifferent electrode or dispersive cable) back to the earth pole of the generator.

In bipolar diathermy (***Figure 7.18b***), the two active electrodes are usually represented by the limbs of a pair of diathermy forceps, blades of scissors or graspers. Both forceps ends are therefore active and current flows between them and only the tissue held between the limbs of the forceps heats up. This form of diathermy is used when working in sensitive areas (e.g. near the recurrent laryngeal nerve in thyroid surgery) or in patients with implantable electrical devices, as current can interfere with these devices. A separate return electrode (the indifferent electrode) to return current is not needed.

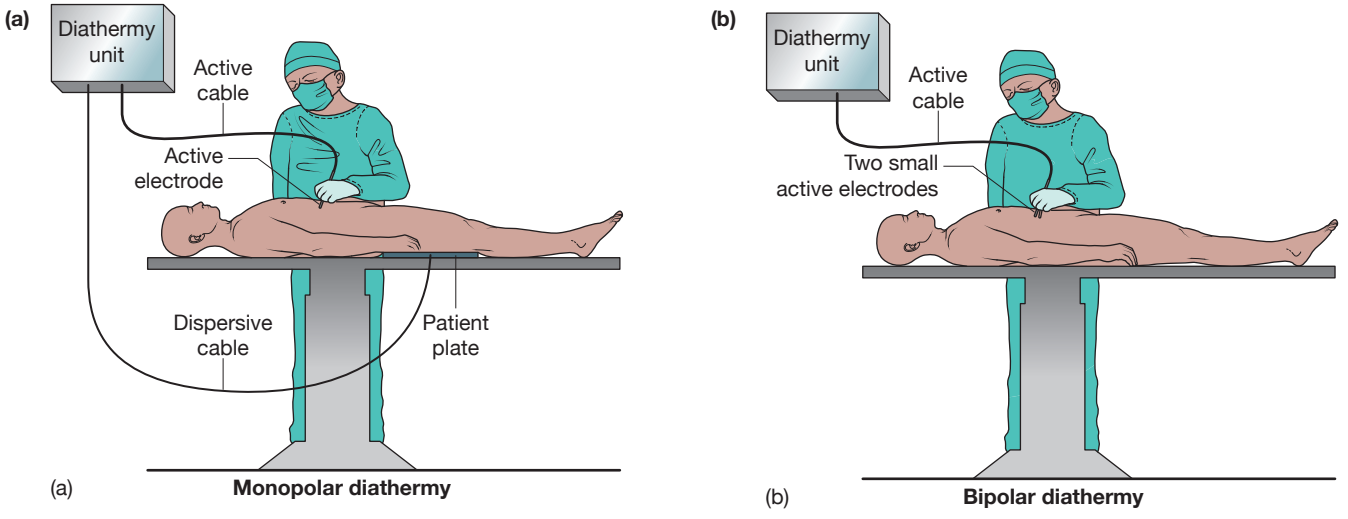

Figure 7.18 The principles of diathermy. **(a)** Monopolar diathermy. **(b)** Bipolar diathermy.

TABLE 7.4 Comparison of cutting and coagulation of tissue using diathermy.

Cutting	Coagulation
Lower voltage current	Higher voltage current
Continuous (current is 'on' 100% of the time when used)	Interrupted (current flows 6% of the time and off for the remaining 94%)
Energy concentrated over a small area	Energy dispersed over a large area
Tissue is heated rapidly and to a higher temperature, causing vaporisation of tissue and thereby resulting in 'cutting' tissue	The modulated current allows the tissue to cool slightly, so tissue heating is slower than with cutting mode. This causes a dehydration effect (loss of cellular fluid and protein denaturation), resulting in coagulation of tissue. Dehydration is not as effective as vaporisation for cutting tissue but is ideal for haemostasis. Bleeding is stopped by a combination of the distortion of the walls of the blood vessel, coagulation of the plasma proteins and stimulation of the clotting cascade
Minimal lateral spread and collateral damage	Extensive lateral spread
Cutting divides tissue by generating sparks, which arc to the tissue; this is most efficient when the tip is held just above the tissue	Similar to cutting and works best when held just above the tissue, with no contact or minimal contact with tissue
Uses: clean cut of tissue To be used to dissect and divide tissue and not just to make skin incisions	Uses: coagulation and achieving haemostasis

The effects of diathermy

Diathermy (*Figure 7.19*) can be used for two basic purposes (*Table 7.4*):

1 coagulation: to achieve haemostasis;
2 cutting: incision and dissection of tissues during surgery.

Several 'blend' options are also available, combining various proportions of the two main modalities.

Hazards of diathermy

Burns

These are the most common type of diathermy accidents and occur when the current flows in some way other than that which the surgeon intended; they are far more common in monopolar than bipolar diathermy. Diathermy can also cause thermal injury to the surgeon and theatre staff.

These may occur as a result of:

- Faulty application of the indifferent electrode (footplate) with an inadequate contact area.
- The patient being earthed by touching any metal object, e.g. the Mayo table, the bar of an anaesthetic screen or a leg touching the metal stirrups used in maintaining the lithotomy position.
- Faulty insulation of the diathermy leads.
- Inadvertent activity such as the accidental activation of the diathermy or accidental contact of the active electrode with other metal instruments, such as retractors or towel clips.

A hole in the glove can also result in burns to the fingers, double gloving may help prevent this.

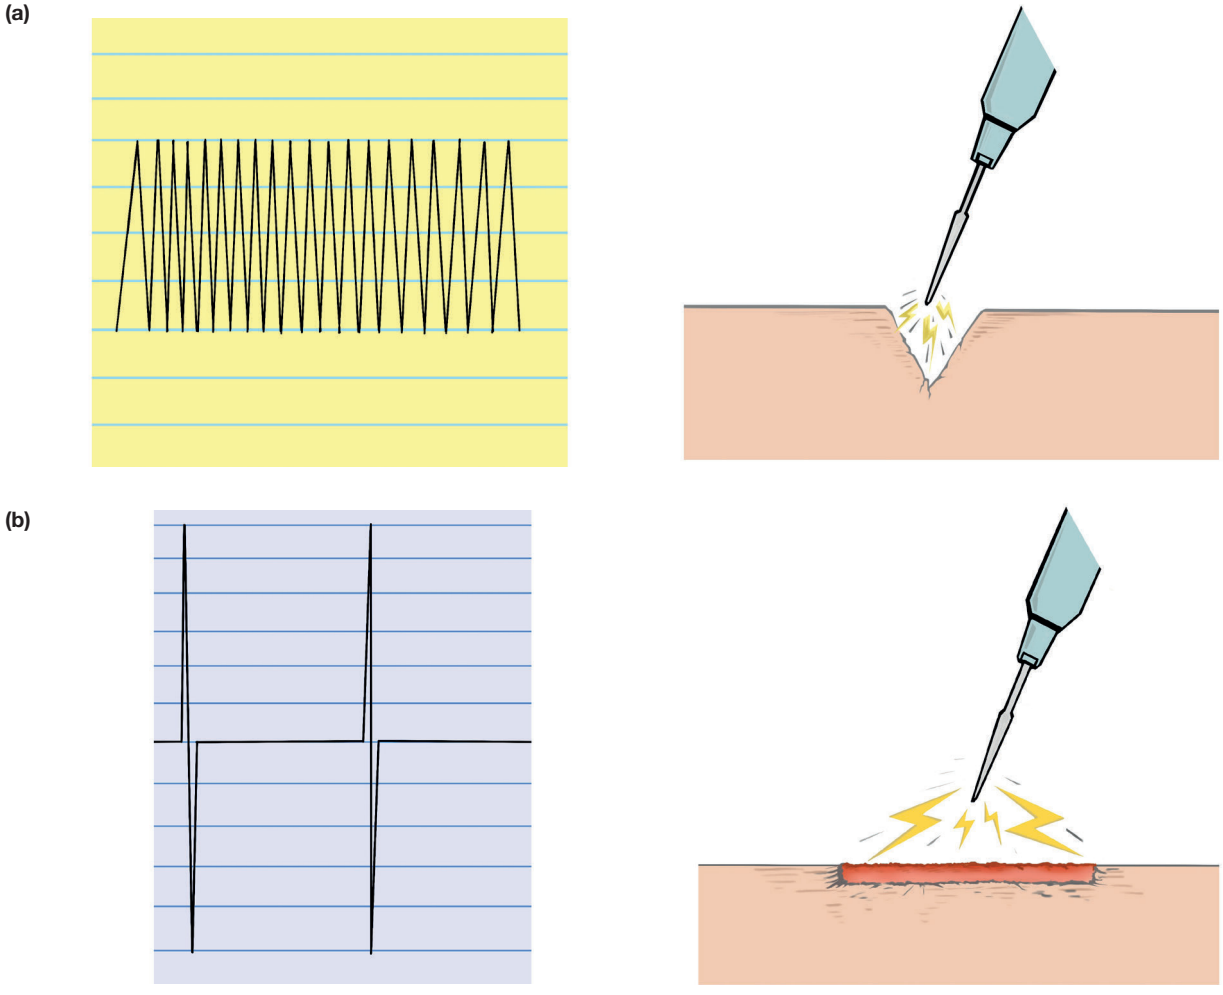

Figure 7.19 (a) Cutting and (b) coagulation of tissue using monopolar diathermy (courtesy of Dr Vinay Timothy Kuruvilla).

Electrocution

Today, diathermy machines are manufactured to very high safety standards, which minimise the risk. However, as with any electrical instrument, there must be regular and expert servicing.

Explosion

Sparks from the diathermy unit can ignite volatile or inflammable gas or fluid within the theatre. Alcohol-based skin preparation can catch fire if allowed to pool on or around the patient. It may be difficult to detect these flames early on as they may be invisible under the bright operating theatre lights.

Channelling

Channelling of current happens when current is applied to tissues that have a narrow stalk, resulting in a 'bottleneck' causing current to concentrate and thereby damage or char tissue. Channelling is also used to describe a phenomenon wherein distant tissues may be affected if current contacts and then travels through tissue, resulting in unintentional coagulation of distant tissue. For example:

- coagulation of the penis in a child undergoing circumcision;
- coagulation of the spermatic cord when the electrode is applied to the testis.

In such situations, diathermy should not be used; if it is necessary, then bipolar diathermy should be employed.

Interference with implantable electronic devices

Diathermy currents can interfere with the working of a gastric or cardiac pacemaker, implantable cardioverter defibrillator, cochlear implants, etc. The use of an ultrasonic scalpel and bipolar diathermy are relatively safer; it may be prudent to liaise with the cardiology team and the anaesthetist pre-emptively in such circumstances.

Occupational hazard from surgical smoke

Viral particles, bacteria, respiratory and ophthalmic irritants and carcinogens have been identified in surgical smoke from diathermy devices. Universal precautions, smoke evacuation systems or simple suction devices can be used to minimise the risk to theatre personnel.

Laparoscopic surgery and diathermy injuries

Diathermy burns are a particular hazard in laparoscopic surgery owing to a relative lack of visibility of the entire instrument. Such burns may occur by:

- faulty insulation of any of the laparoscopic instruments or equipment;
- intraperitoneal contact of the diathermy with another metal instrument while activating the pedal (direct coupling);
- inadvertent activation of the pedal while the diathermy tip is out of the vision of the camera;
- retained heat in the diathermy tip touching susceptible structures, such as the bowel.

Advanced vessel-sealing devices

Advanced laparoscopic procedures have driven a parallel explosion in novel technologies that facilitate the performance of such procedures. This is particularly the case for vessel-sealing devices. Monopolar diathermy still plays a vital and effective role in laparoscopic surgery, but has limitations in terms of sealing larger blood vessels and is accompanied by the risks outlined above. Therefore surgeons have increasingly used advanced energy devices to facilitate dissection and to seal and divide blood vessels up to 7 mm in diameter.

Furthermore, it is suggested that the use of advanced vessel-sealing devices reduces operative time and thus recovery is enhanced.

There are three main types of advanced energy devices: bipolar electrosurgery, ultrasonic electrosurgery and combination devices. In all cases, the surgeon needs to be aware of the characteristics of these devices and their capacity to cause thermal injury in order to use them safely.

Bipolar electrosurgery devices

Advanced bipolar tissue fusion technology is a vessel-sealing system that is used in both open and laparoscopic surgery by fusing the vessel walls to create a permanent seal. It uses a combination of pressure and energy to create vessel fusion that can withstand up to three times the normal systolic pressure. New technology such as the LigaSure™ system (Medtronic) involves advanced bipolar technology that uses the body's collagen and elastin to both seal and divide, allowing surgeons to reduce instrument handling when dissecting, ligating and grasping – a valuable asset particularly during laparoscopic surgery. The feedback-sensing technology incorporated in the instrument is designed to manage the energy delivery in a precise manner and results in automatic discontinuation of energy once the seal is complete, thus removing any concern that the surgeon has to use guesswork as to when the seal is complete. The newer instruments actively monitor tissue impedance and provide a real-time adjustment of the energy being delivered. Using this technology, LigaSure can seal vessels of up to 7 mm diameter, with an average seal time of 2–4 seconds, as well as pedicles, tissue bundles and lymphatics with a consistent controlled and predictable effect on tissue, including less desiccation.

Ultrasonic energy devices

The harmonic scalpel is an instrument that uses ultrasound technology to cut tissues while simultaneously sealing them. It utilises a hand-held ultrasound transducer and scalpel that is controlled by a hand switch or foot pedal. During use, the scalpel vibrates in the 20 000–50 000-Hz range and cuts through tissues, effecting haemostasis by sealing vessels and tissues by means of protein denaturation caused by vibration rather than heat (in a similar manner to whisking an egg white). It provides cutting precision, even through thickened scar tissue, and visibility is enhanced because less smoke is created by this system during use compared with routine electrosurgery.

Currently, the harmonic scalpel is in common use during laparoscopic procedures, as well as open surgery, such as thyroidectomy, and several plastic surgery operations, e.g. cosmetic breast surgery. There are several such devices on the market, which vary in form and function.

Combination energy devices

In the last 5 years, technology has evolved concerning both harmonic and bipolar advanced energy devices. One product, the Thunderbeat STM (Olympus), has combined both modalities in a single device. By simultaneously using ultrasonic vibration and bipolar diathermy, this device can seal and divide arteries and veins up to 7 mm in diameter in a shorter amount of time with no smoke or mist.

TOPICAL HAEMOSTATIC AGENTS

Physical or biological topical haemostatic agents are considered adjuncts to traditional mechanical and electrosurgical techniques. The physical agents commonly used are absorbable gelatin, absorbable collagen and oxidised cellulose and function by providing a scaffold that encourages fibrin deposition and accelerates clot formation; they can also soak up as much as 40 times their weight in blood, providing tamponade and compression.

Biological topical haemostatic agents such as thrombin and fibrin sealants encourage clot formation and are often injected or sprayed over the bleeding site. A combination of the above can also be used.

DRAINS IN SURGERY

In 1887 Lawson Tait suggested 'when in doubt drain!'. This edict has been criticised and the value of routine drain placement has been scrutinised.

Drains are inserted to allow fluid that might collect in a body cavity to drain freely to the surface. The fluid to be drained may include blood, serum, pus, urine, faeces, bile, lymph or air. Drains may also be used for wound irrigation in certain circumstances. Their use can be regarded as prophylactic or therapeutic, depending on the circumstance warranting their insertion. Abdominal drains are usually placed in the pelvis to drain collections as this is the most dependent area. Other locations are usually dictated by the pathology and procedure performed.

Robert Lawson Tait, 1845–1899, surgeon, Birmingham, UK.

Classification of drains

- **Open drains** (*Figure 7.20a*). These aid in passive drainage of a cavity based on gravity by forming a channel between the body and the external environment. They are often unsightly, require frequent dressing changes and may act as a conduit that enhances bacterial colonisation. The Penrose and corrugated drains are examples of an open drain used in debrided wounds and abscess cavities.
- **Closed drains:**
  - **Suctioned (active)** (*Figure 7.20b*). These maintain negative pressure, thereby actively suctioning out fluid and/or obliterating dead space and preventing fluid accumulation. Caution must be exercised when used adjacent to vital structures. A suction drain is often used after ventral hernia repair, following axillary dissections and in head and neck surgery.
  - **Non-suctioned (passive)** (*Figure 7.20c*). Use capillary action and gravity to drain fluid. The most common examples are urinary catheters, nasogastric drainage systems and a Robinson's drain, which is used within the abdominal cavity to help to evacuate fluid without sucking viscera or omentum.

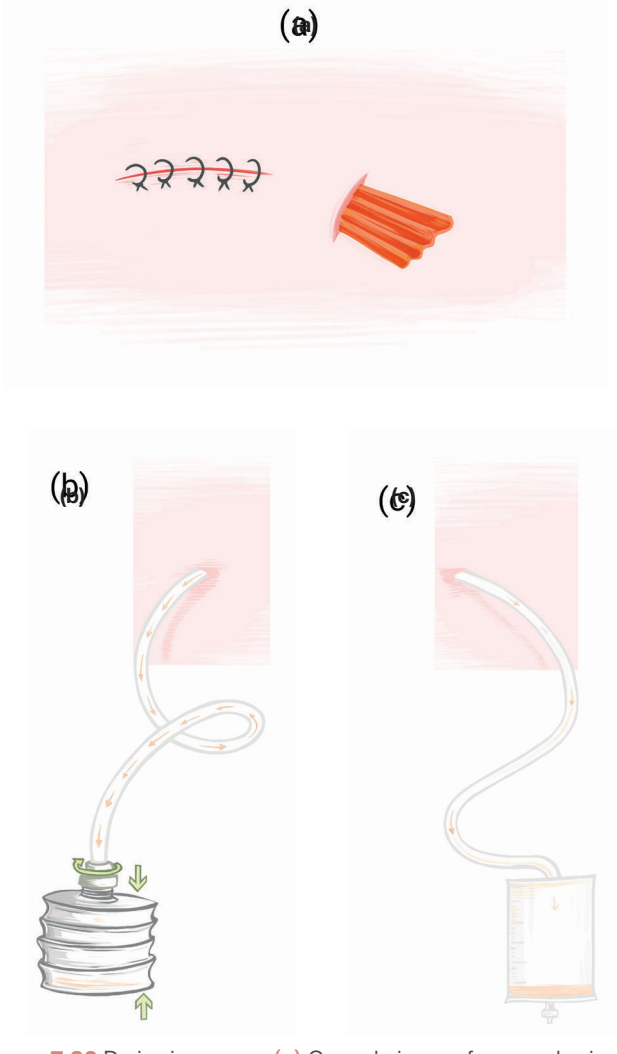

Figure 7.20 Drains in surgery. **(a)** Open drainage of a wound using a corrugated drain. **(b)** A closed suction drain using a vacuum-assisted drainage system. **(c)** A closed, non-suction drain commonly used to drain the abdominal cavity (courtesy of Dr Vinay Timothy Kuruvilla).

The role of drains in modern surgery

The routine use of surgical drains has generated much controversy. Protagonists suggest that the use of drains may:

- help remove the collection of purulent material, blood, serous fluid, bile, chyle, pancreatic or intestinal secretions;
- act as a signal for postoperative haemorrhage or anastomotic leakages
- provide a track for long-term drainage.

However, detractors claim that the presence of a drain may:

- increase intra-abdominal and wound infections by introducing skin bacteria into the peritoneal cavity;
- delay recovery and increase hospital stay;
- increase abdominal pain;
- decrease pulmonary function;
- falsely reassure the clinician that there is no intra-abdominal collection, when in fact the drain is blocked.

In reality, the use of drains depends on the surgeon's individual preference and surgical philosophy. However, there is reasonable consensus regarding the role of drains in certain surgical procedures, as elucidated in *Summary boxes 7.10 and 7.11*.

Summary box 7.10

Current role of drain placement in non-gastrointestinal surgery

Avoid routine drain placement

- Thyroid surgery
- Breast lumpectomy
- Inguinal hernia repair

Consider routine drain placement

- Radical and modified radical neck dissection
- Parotid surgery
- Axillary dissection with or without mastectomy
- Inguinal lymphadenectomy
- Ventral hernia repair in obese patients

Charles Bingham Penrose, 1862–1925, Professor of Gynecology, The University of Pennsylvania, Philadelphia, PA, USA.

Summary box 7.11

Current role of drain placement in gastrointestinal surgery

Avoid routine drain placement following

- Colonic surgery
- Small bowel resections
- Hepatic resections
- Cholecystectomy

Consider routine drain placement following

- Oesophageal surgery
- Major pancreatic resection

Selective use of drains following

- Rectal surgery
- Gastric resections

Emergency gastrointestinal surgery and drains

While there seems to be some anecdotal evidence advising against drainage following appendicular perforation, duodenal perforation and bowel pathology leading to localised or generalised peritonitis, a less dogmatic approach is more realistic. Patients with four-quadrant peritoneal contamination usually benefit from routine drainage, whereas a more selective approach can be tailored in patients with localised peritoneal contamination.

The decision to avoid drain placement in emergency surgery needs to be contextualised, taking into account the patient's clinical state and comorbid illnesses as well as the healthcare and hospital setting, including access to round-the-clock interventional radiologists.

Specialist use of drains

Nasogastric drainage

The role of nasogastric tube placement in the surgical patient has been steeped in dogma. There is no doubt that selective use of nasogastric tubes have a vital place in the perioperative management of patients; however, there is a trend to move away from routine placement of nasogastric tubes and from keeping them in place for protracted lengths of time when inserted. Most enhanced recovery after surgery (ERAS) pathways forbid the prophylactic use of nasogastric tubes in the elective setting, except following procedures in the upper aerodigestive tract. The indications and potential problems associated with nasogastric drainage have been detailed in *Summary boxes 7.12 and 7.13*.

Summary box 7.12

Indications for placement of the nasogastric tube

Drainage purposes

- Conservative management of postoperative paralytic ileus
- Conservative management of bowel obstruction (adhesional or partial)
- Decompression of the stomach before an emergency operation
- Prophylactically, when postoperative ileus is anticipated following extensive bowel handling

Feeding purposes

- Following procedures in the upper aerodigestive tract (nasogastric or nasoenteral)
- In patient with motor neurone disease or stroke

Summary box 7.13

Placement of nasogastric tubes

Contraindications

- Suspected or proven base of skull fracture as this may result in inadvertent cranial injury
- Oesophageal stricture or recent oesophageal surgery (unless under vision)

Complications

- Upper airway damage – pressure necrosis of the nasal ala owing to the placement of an oversized tube or following prolonged placement
- Reflux oesophagitis
- Pulmonary aspiration due to impaired function of the lower gastro-oesophageal sphincter
- Inadvertent placement into the lungs
- Traumatic placement causing bleeding and perforation

T-tube drains

A T-tube (*Figure 7.21*) may be inserted after exploration of the common bile duct and stone retrieval or following repair of a damaged common bile duct. The principle is to allow bile to

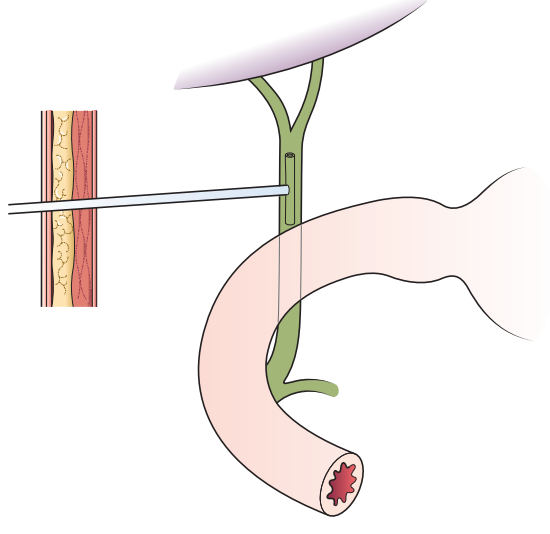

Figure 7.21 T-tube.

drain while the sphincter of Oddi is in spasm postoperatively and to act as a safety valve if there are any stones retained in the distal common bile duct. Despite its perceived uses, the T-tube is not without problems; a recent Cochrane analysis concluded that it is associated with increased bile leakage and increased hospital stay and cost with minimal benefits.

Once inserted, a T-tube should remain in place for at least 2–3 weeks to encourage fistulous tract formation, thereby minimising the risk of biliary peritonitis after removal of the T-tube. Before removal, a T-tube cholangiogram should demonstrate the free flow of bile into the duodenum with no retained stones or bile leak. The T-tube is then clamped for 24 hours and removed. The T-tube is clamped to allow preferential drainage of bile to the duodenum; if there is no distal obstruction the patient will be asymptomatic. Once the T-tube is removed, there will be minimal bile leakage through the fistulous tract for a few days. This should stop as a fistula will close if there is no distal obstruction.

Removal of drains

A drain should be removed as soon as it has served its purpose. It is important to define the objective of each drain and to ensure that, once that objective has been met, the drain is removed rather than waiting for an arbitrary drain volume amount.

- Drains placed to signal perioperative bleeding may usually be removed after 24 hours.
- Drains put in because of infection should be left until the infection is subsiding or the drainage is minimal.
- Drains placed following routine bowel anastomoses should be removed at 3–5 days. However, it should be stressed that in no way does a drain prevent an intestinal anastomotic leak, but merely may assist any such leakage to drain externally rather than producing life-threatening peritonitis.
- A suction drain should have the suction taken off before removal of the drain.
- During removal of a chest drain, the patient should be asked to breathe in and hold their breath, thus doing a Valsalva manoeuvre. In this way, no air is sucked into the pleural cavity as the tube is removed. Once the drain is out, a previously inserted purse-string suture should be tied.

PART 1 | Basic principles

CHAPTER 8

Diagnostic imaging

Learning objectives

To understand:

- The advantages of good working relationships and close collaboration with the imaging department in planning appropriate investigations
- The basic principles of radiation protection and know the law in relation to the use of ionising radiation
- The principles of different imaging techniques and their advantages and disadvantages in different clinical scenarios
- The role of imaging in directing treatment in various surgical scenarios

INTRODUCTION

Appropriate surgical management of the patient relies on correct diagnosis. While clinical symptoms and signs may provide a firm diagnosis in some cases, other conditions will require the use of supplementary investigations including imaging techniques. The number and scope of imaging techniques available to the surgeon have dramatically increased within a generation, from a time when radiographs alone were the mainstay of investigation. The development of ultrasound and colour Doppler, computed tomography (CT) and magnetic resonance imaging (MRI) has enabled the surgeon to make increasingly confident diagnoses and has reduced the need for diagnostic surgical techniques such as explorative laparotomy.

As a basic principle, the simplest, cheapest test should be chosen hoping that it will answer the clinical question. This necessitates knowledge of the potential complications and diagnostic limitations of the various methods. For example, in a patient presenting with the clinical features of biliary colic, an ultrasound examination alone may give enough information to enable appropriate surgical management. In more complex cases, it may be more efficient to opt for a single, more expensive investigation, such as CT, rather than embarking on multiple simpler and cheaper investigations that may not yield the answer. The choice of technique is often dictated by equipment availability, expertise and cost, as well as the clinical presentation. However, it must be emphasised that, not infrequently, the most valuable investigation is prior imaging; this not only reduces the cost and the amount of radiation a patient receives but very often improves patient care.

REQUESTING IMAGING

Best practice depends on close collaboration between the radiologist and the referrer and must take into account local expertise and access to facilities. When requesting imaging, consider what it is that you want to know from the investigation. Give a provisional diagnosis or state the clinical problem. If there is uncertainty over the best method to answer the clinical problem, then discussion with a radiologist is always worthwhile, informally or within the context of a clinic–radiological meeting or a multidisciplinary team (MDT) meeting.

As well as the basic demographic information stored on the radiology information system, it is important to provide relevant past medical history, e.g. diabetes, epilepsy, renal failure, allergies and anticoagulation, all of which can affect which contrast agent can be given safely, and the date of the last menses in women of childbearing potential.

INTERPRETING IMAGES

While the role of the imaging department is to provide radiological reports for imaging examinations performed, it is nevertheless good clinical practice to be able to evaluate your patients' examinations, and a systematic approach is encouraged.

The systematic approach to examining a radiograph varies according to the part of the body being imaged. For instance, for a radiograph of an extremity, the alignment, the cortices and the medullary cavity of the individual bones, the joints and the soft tissues all need to be assessed on each view.

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.

Summary box 8.1

A simple system for checking radiographs

Label	Name of patient
Site	Date of examination
Side (check marker)	
	What part is the film centred on?
	Does the film cover the whole area required?
	Is there more than one view?
Quality	Is the penetration appropriate?
Compare	How have the appearances changed from previous images?
Conclude	Is the diagnosis clear?
	Is further imaging needed?

HAZARDS OF IMAGING

Contrast media

There has been a dramatic increase in the use of contrast agents in recent years, mainly related to the increasing use of CT. Potential problems include allergic reaction and nephrotoxicity. Reactions are rare: serious reactions occur in about 1:2500 cases and life-threatening reactions in fewer than 1:100 000 cases. The risk of sudden death, however, has not changed with the new agents. Local policies for dealing with patients at increased risk vary between departments and, indeed, between countries. Premedication with steroids given at least 6 hours before the contrast can reduce the incidence and severity of anaphylactoid reactions but there is no evidence it reduces the risk of death. Low-osmolality contrast media (LOCMs) or iso-osmolar media are up to 10 times safer than the older ionic media. Most serious reactions occur shortly after injection, so observation of the patient for 30 minutes after injection with the intravenous cannula still *in situ* is recommended for higher risk individuals.

In patients with diabetes or renal impairment, a recent creatinine level should be available. The risks of contrast-induced acute kidney injury are highest in patients with severe renal impairment (estimated glomerular filtration rate [eGFR] <30 mL/min/1.73 m^2), whereas in patients with normal renal function (eGFR >60 mL/min/1.73 m^2) or even moderately impaired stable renal function (eGFR 45 mL/min/1.73 m^2) the risk is zero to minimal.

Contrast should never be withheld if the benefits to the patient of making the diagnosis are felt to be justified by the referring surgeon and radiologist. But in patients with severe renal impairment the risks and benefits of contrast administration need to be carefully assessed and, if contrast is given, the patient should be well hydrated and the lowest dose of an LOCM should be given. The evidence for the use of *N*-acetylcysteine or sodium bicarbonate for renal protection is mixed, and their use is not recommended.

Concerns have been raised about giving contrast to patients taking metformin. Latest recommendations are that it appears safe to continue the metformin if the eGFR is above 30 mL/min/1.73 m^2 for intravenous administration or above 45 mL/min/1.73m^2 for intra-arterial injections. Any decision to stop metformin should be made with the radiologist and the physician managing the patient's diabetes.

Gadolinium-containing contrast agents are used in MRI examinations. Allergic reactions to these agents are very rare, occurring in less than 0.1% of administrations. However, they can be nephrotoxic in patients with renal failure. In addition, they are associated with a risk of nephrogenic systemic fibrosis (NSF), an extremely rare but serious life-threatening condition whereby connective tissue forms in the skin causing it to become coarse and hard. NSF may also affect other organs, including joints, muscle, liver and heart. High-risk gadolinium-containing contrast agents are contraindicated in severe renal failure, in neonates and in the perioperative period of liver transplantation, and are not recommended in pregnancy. However, lower risk gadolinium preparations are available that may be used with caution.

Liver-specific contrast agents for MRI, selectively taken up by hepatocytes, are increasingly used to characterise liver lesions and in cancer staging.

HAZARDS OF IONISING RADIATION

The majority of ionising radiation comes from natural sources on Earth and cosmic rays, and this makes up the background radiation. However, medical exposure accounts for around 15% of the total received by humans. The effects of ionising radiation can be broadly divided into two groups. The first group comprises predictable, dose-dependent tissue effects and includes, for example, the development of cataracts in the lens of the eye. These effects are important for those chronically exposed to radiation, including those using image intensifiers regularly. The second group comprises the all-or-nothing effects such as the development of cancer (termed stochastic). These effects are not dose dependent, but increase in likelihood with increased radiation dose.

The risk of radiation-induced cancer for plain films of the chest or extremities is very small, of the order of 1:1 000 000. However, that risk rises considerably for high-dose examinations such as CT of the abdomen or pelvis, where the estimated lifetime excess risk of cancer increases to the order of 1:1000. Use of CT has increased dramatically in the last 20 years, with a 12-fold increase in the UK, and it has been estimated that up to 30% of these examinations may be unnecessary. Obviously, the risk of such examinations has to be balanced against the benefit to the patient in terms of increased diagnostic yield, and must also be viewed in the context that the lifetime risk of cancer for people generally is about 1:3. Nevertheless, the increased risk is important since it is iatrogenic and applied to a large population. Therefore, techniques that do not use ionising radiation, such as ultrasound and MRI, should be carefully considered as alternatives, particularly in children and young people.

CURRENT LEGISLATION

In the UK, the Ionising Radiation (Medical Exposure) Regulations (IR(ME)R) introduced in 2000, and amended in 2006, impose on the radiologist the duty to the patient to make sure that all studies involving radiation (plain radiographs, CT and nuclear medicine) are performed appropriately and to the highest standards. Inappropriate use of radiation is a criminal offence, so investigations involving radiation need careful consideration in order to prevent wasteful use of radiology.

Summary box 8.2

Criteria for useful investigations

A useful investigation is one in which the result – positive or negative – will inform clinical management and/or add confidence to the clinician's diagnosis. A significant number of radiological investigations do not fulfil these aims and may add unnecessarily to irradiation of patients. To avoid the wasteful use of radiology, the important questions to be asked are as follows.

1. **Has it been done already**? Repeating investigations that have already been done: such as at another hospital, in an outpatient department or in an emergency department. Every attempt should be made to obtain previous images and reports. Transfer of digital data through electronic links will assist in this respect. Although guidelines may not directly address this question, there are other initiatives that do
2. **Is it needed**? Undertaking investigations when results are unlikely to affect patient management or over-investigating: because the anticipated positive finding is usually irrelevant – for example, degenerative spinal disease – or because a positive finding is unlikely. Some clinicians and patients tend to rely on investigations more than others for reassurance
3. **Is it needed now**? Investigating too early: for example, before the disease could have progressed or resolved, or before the results could influence treatment. The need for investigation and treatment should be reviewed at a more appropriate time
4. **Is this the best investigation**? Doing the wrong investigation: imaging techniques undergo rapid change. It is often helpful to discuss an investigation with a specialist in clinical radiology or nuclear medicine before it is requested
5. **Has the problem been properly explained**? Failing to provide appropriate clinical information and questions that the imaging investigation should answer: deficiencies here may lead to the use of the wrong technique, or the report being poorly focused on the clinical problem. In some clinical situations firm guidelines have been established

There are special considerations for portable and fluoroscopy units. The longer an operator keeps the fluoroscopy unit running, the higher the dose of radiation to all in the vicinity. Portable x-ray machines and fluoroscopic imaging equipment use much more radiation to achieve the same result. The staff, and patients in the next bed, are at risk when portable equipment is used. The result is also of lower quality, so portable x-ray machines should not be used unless absolutely necessary. When using the image intensifier, lead aprons, thyroid shields, lead glasses and radiation badges should always be worn. Pregnancy in the female patient or staff must be excluded.

Summary box 8.3

Responsibilities of the radiologist and referrer

- Radiologists have a legal responsibility to keep imaging as safe as possible
- The referrer has a duty to balance risk against benefit
- The referrer must provide adequate clinical details to allow justification of the examination
- Avoid using portable (mobile) x-ray machines whenever practical
- Take all precautions when using an image intensifier
- The gonads, eyes and thyroid are especially vulnerable to radiation and should be protected

The UK's Royal College of Radiologists produces an evidence-based guidance tool, called iRefer, which is widely available on line and shows radiation doses for common procedures (*Table 8.1*).

TABLE 8.1 Band classification of the typical doses of ionising radiation from common imaging procedures.

Symbol	Typical effective dose (mSv)	Examples	Lifetime additional risk of cancer induction /exam
None	0	US; MRI	0
☢	<1	CXR; XR limb, pelvis, lumbar spine; mammography	<1:20 000
☢☢	1–5	IVU; NM (e.g. bone); CT head and neck	1:20 000–1:4000
☢☢☢	5.1–10	CT KUB; NM (e.g. cardiac)	1:4000–1:2000
☢☢☢☢	>10	Extensive CT studies, some NM studies (e.g. some PET/CT)	>1:2000

CT, computed tomography; CXR, chest x-ray; IVU, intravenous urography; KUB, kidneys, ureters and bladder; MRI, magnetic resonance imaging; NM, nuclear medicine; PET, positron emission tomography; US, ultrasound; XR, x-ray.

DIAGNOSTIC IMAGING

Basic principles of imaging methods

Conventional radiography

Although it is over 120 years since the discovery of x-rays by Roentgen in 1895, conventional radiography continues to play a central role in the diagnostic pathway of many acute

Wilhelm Conrad Roentgen, 1845–1923, Professor of Physics, Würzburg (1888–1900), and then at Munich, Germany. He was awarded the Nobel Prize in Physics in 1901 for his work on x-rays.

surgical problems and particularly in chest disease, trauma and orthopaedics.

X-rays emitted from an x-ray source are absorbed to varying degrees by different materials and tissues and therefore cause different degrees of blackening of radiographic film, resulting in a radiographic image. This differential absorption is dependent partly on the density and the atomic number of different substances. In general, higher density tissues result in a greater reduction in the number of x-ray photons and reduce the amount of blackening caused by those photons. In terms of conventional radiographs, a large difference in tissue structure and density is required before an appreciable difference is manifested radiographically. The different densities visible consist of air, fat, soft tissue, bone and mineralisation, and metal. Different soft tissues cannot be reliably distinguished as, in broad terms, they possess similar quantities of water (*Figure 8.1*). Manipulation of x-ray systems and x-ray energies, as used in circumstances such as mammography, may allow better differentiation between some soft-tissue structures. Despite this inherent lack of soft-tissue contrast, conventional radiography has many advantages. It is cheap, universally available, easily reproducible and comparable with prior examinations and, in many instances, has a relatively low dose of ionising radiation in contrast to more complex examinations. However, injudicious repeat radiography, particularly of the abdomen, pelvis and spine, can easily result in doses similar to CT.

The lack of soft-tissue contrast allows little assessment of the internal architecture of many abdominal organs. To obviate this problem, techniques employing the administration of contrast material combined with radiography have long been used. These techniques include intravenous urography (IVU) and barium examinations (*Figure 8.2*). IVU involves a series of radiographs taken before and after contrast injection, but has been largely superseded by CT urography, which is more accurate in detecting and defining pathology (*Figure 8.3*). A further modification of conventional x-rays uses fluorescent screens to allow real-time monitoring of organs and structures as opposed to the 'snapshot' images obtained with radiographs. This is used to follow the passage of barium through the bowel, obtaining dedicated images at specific points of interest only. Motility of the bowel can also be assessed in this way. Fluoroscopy is used extensively in interventional radiology, allowing the operator to guide catheters and wires into the patient while monitoring their position in real time.

Naturally, with the more sustained use of ionising radiation, the cumulative doses tend to be greater than when obtaining a conventional radiograph.

Ultrasound

Ultrasound is the second most commonly used method of imaging. It relies on high-frequency sound waves generated by a transducer containing piezoelectric material. The generated sound waves are reflected by tissue interfaces and, by ascertaining the time taken for a pulse to return and the magnitude and direction of a pulse, it is possible to form an image. Medical ultrasound uses frequencies in the range 3–20 MHz. The higher the frequency of the ultrasound wave, the greater the resolution of the image, but the less depth of view from the skin. Consequently, abdominal imaging uses transducers with

Figure 8.1 Supine abdominal radiograph of a patient with small bowel obstruction demonstrates multiple dilated small bowel loops. The different densities visible are air (within the bowel), bones, soft tissues and fat. The different soft tissues, subcutaneous and intra-abdominal, cannot be differentiated.

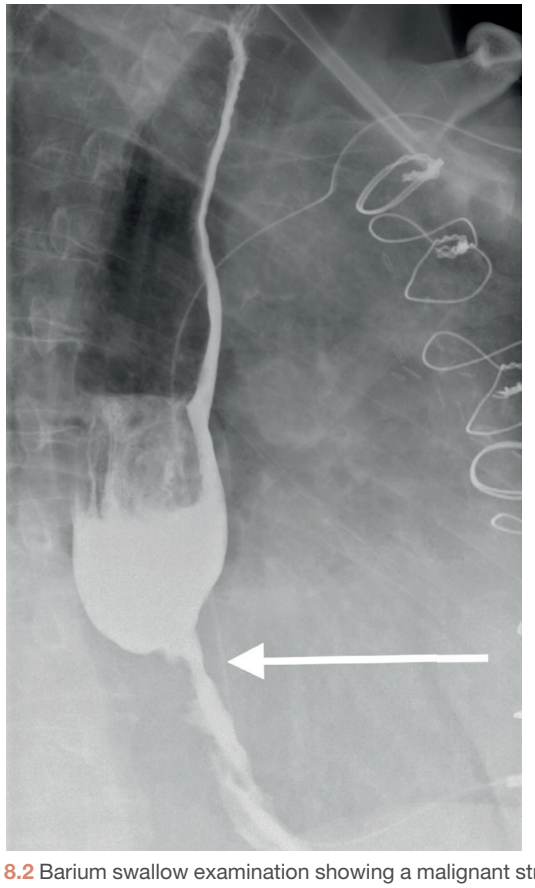

Figure 8.2 Barium swallow examination showing a malignant stricture (arrow) due to an oesophageal carcinoma.

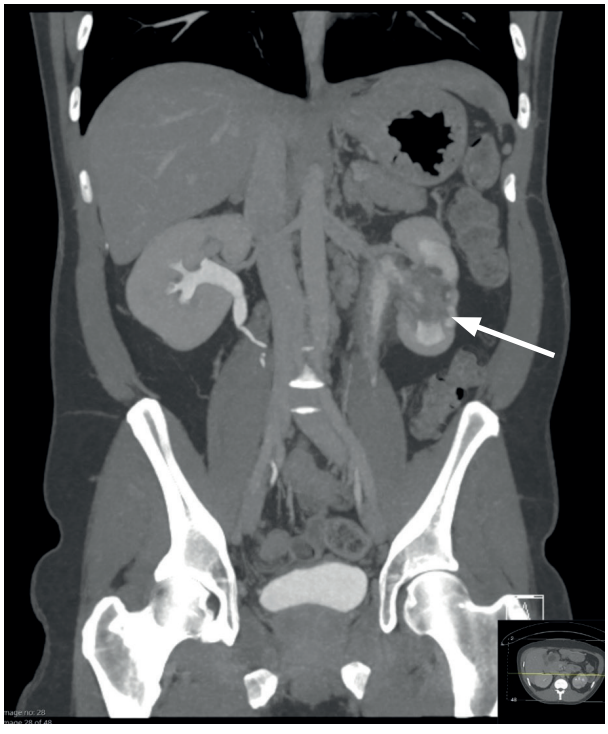

Figure 8.3 Coronal maximum intensity projection image from a computed tomography intravenous urogram shows a transitional cell carcinoma in the left renal pelvis (arrow) with normal excretion of contrast on the right.

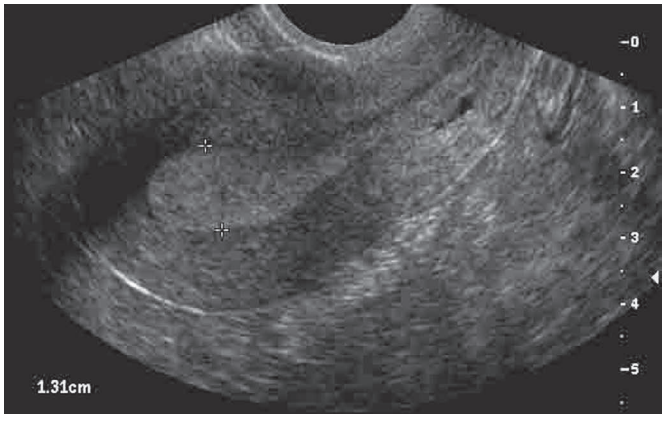

Figure 8.4 Longitudinal transvaginal ultrasound scan of the uterus demonstrates thickening of the endometrium in a patient during the secretory phase of the menstrual cycle.

a frequency of 3–7 MHz, while higher frequency transducers are used for superficial structures, such as musculoskeletal and breast ultrasound. Dedicated transducers have also been developed for endocavity ultrasound, such as transvaginal scanning and transrectal ultrasound of the prostate, allowing high-frequency scanning of organs by reducing the distance between the probe and the organ of interest (***Figure 8.4***). A further application of dedicated probes has been in the field of endoscopic ultrasound, allowing exquisite imaging of the wall of a hollow viscus and the adjacent organs such as the biliary tree and pancreas.

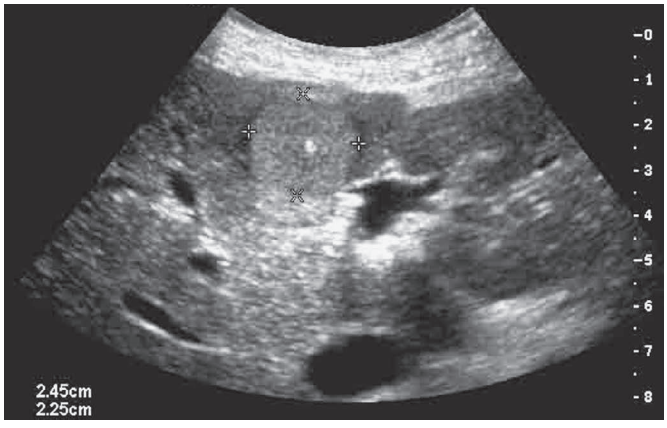

Figure 8.5 Transverse ultrasound image of the liver in a patient with colorectal cancer shows a solitary liver metastasis.

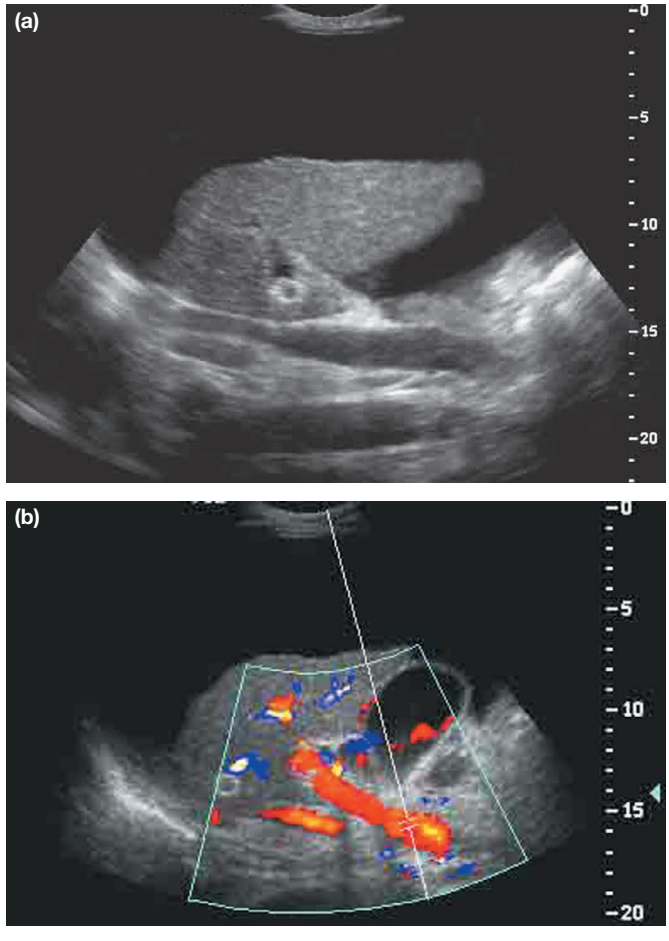

Figure 8.6 Sagittal ultrasound image of the liver **(a)** in a patient with cirrhosis demonstrates nodularity of the liver surface and extensive ascites. Doppler ultrasound **(b)** illustrates portal vein flow with a normal direction.

Reflection of an ultrasound wave from moving objects such as red blood cells causes a change in the frequency of the ultrasound wave. By measuring this frequency change, it is possible to calculate the speed and direction of the movement. This principle forms the basis of Doppler ultrasound, whereby velocities within major vessels, as well as smaller vessels in organs such as the liver and the kidneys, can be measured.

Doppler imaging is widely used in the assessment of arterial and venous disease, in which stenotic lesions cause an alteration in the normal velocity. Furthermore, diffuse parenchymal diseases, such as cirrhosis, may cause an alteration in the normal Doppler signal of the blood vessels of the affected organ.

The advantages of ultrasound are that it is cheap and easily available. It is the first-line investigation of choice for assessment of the liver, the biliary tree and the renal tract (*Figures 8.5 and 8.6*). Ultrasound is also the imaging method of choice in obstetric assessment and gynaecological disease. High-frequency transducers have made ultrasound the best imaging technique for the evaluation of thyroid and testicular disorders, in terms of both diffuse disease and focal mass lesions. It is also an invaluable tool for guiding needle placement in interventional procedures such as biopsies and drainages, allowing direct real-time visualisation of the needle during the procedure. Ligament, tendon and muscle injuries are also probably best imaged in the first instance by ultrasound (*Figure 8.7*). The ability to stress ligaments and to allow tendons to move during the investigation gives an extra dimension, which greatly improves its diagnostic value. The use of 'panoramic' or 'extended field of view' ultrasound (*Figure 8.8*) provides images that are more easily interpreted by an observer not performing the examination, and are of particular assistance to surgeons planning a procedure. Ultrasound will demonstrate most foreign bodies in soft tissues, including those that are not radio-opaque.

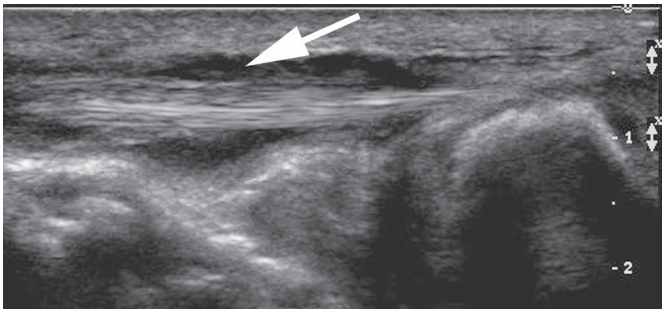

Figure 8.7 Ultrasound of the dorsal surface of the wrist shows the normal fibrillar pattern of the extensor tendons. There is increased fluid (arrow) within the tendon sheath in this patient with extensor tenosynovitis.

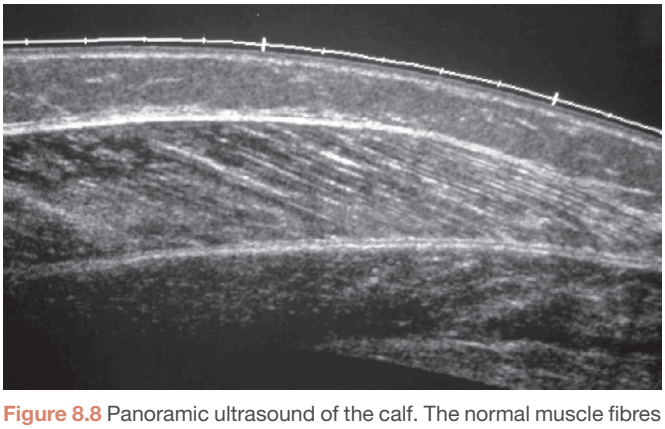

Figure 8.8 Panoramic ultrasound of the calf. The normal muscle fibres and the fascia can be identified over an area measuring approximately 12 cm.

The disadvantages of ultrasound are that it is highly operator dependent, and most of the information is obtained during the actual process of scanning as opposed to reviewing the static images. Another drawback is that the ultrasound wave is highly attenuated by air and bone and, thus, little information is gained with regard to tissues beyond bony or air-filled structures; alternative techniques may be required to image these areas.

Summary box 8.4

Ultrasound

Strengths

- No radiation
- Inexpensive
- Allows interaction with patients
- Superb soft-tissue resolution in the near field
- Dynamic studies can be performed
- First-line investigation for hepatic, biliary and renal disease
- Endocavity ultrasound for gynaecological and prostate disorders
- Excellent resolution for breast, thyroid and testis imaging
- Good for soft tissue, including tendons and ligaments
- Excellent for cysts and foreign bodies
- Doppler studies allow assessment of blood flow
- Good real-time imaging to guide interventional biopsies and drainages

Weaknesses

- Interpretation only possible during the examination
- Visualisation of structures can be hampered by overlying gas and bone, and body habitus may also impact on the scan
- Long learning curve for some areas of expertise
- Resolution dependent on the machine available
- Images cannot be reliably reviewed away from the patient

Computed tomography

There has been a great deal of development in CT technology over the last 30 years from the initial conventional CT scanners through to helical or spiral scanners and the current multidetector machines. CT scanners consist of a gantry containing the x-ray tube, filters and detectors, which revolve around the patient, acquiring information at different angles and projections. This information is then mathematically reconstructed to produce a two-dimensional grey-scale image of a slice through the body. This technique overcomes the problem of superimposition of different structures, which is inherent in conventional radiography. Improvements in gantry design, development of more sensitive detectors and an increase in the number of detectors have resulted in an increase in spatial resolution, as well as the speed at which the images are acquired. In early CT scanners, the table on which the patient was positioned moved in between the gantry revolution to allow imaging of an adjacent slice. Modern scanners allow for continuous movement of the table and the patient during the gantry revolution, thus greatly reducing the scan time. With

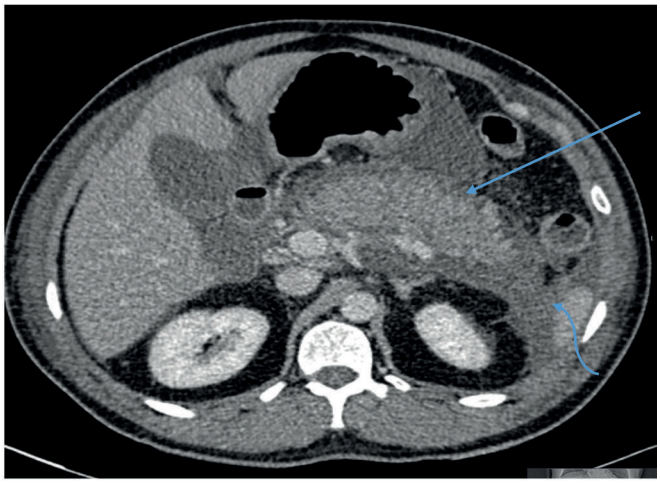

Figure 8.9 Axial computed tomography scan of a patient with acute pancreatitis demonstrates a swollen oedematous pancreas (arrow) with extensive peripancreatic free fluid (curly arrow).

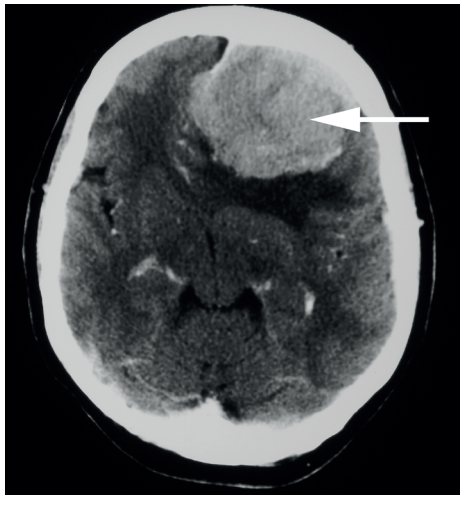

Figure 8.10 Axial computed tomography scan of the head following intravenous contrast demonstrates a large mass lesion in the left frontal region (arrow) in a patient with a large left frontal meningioma.

modern equipment, it is now not only possible to obtain images of the chest, abdomen and pelvis in under 10 seconds but these axial images can also be reformatted in multiple planes with practically no degradation in image quality.

In addition, CT has a far higher contrast resolution than plain radiographs, allowing the assessment of tissues with similar attenuation characteristics. As with radiographs, the natural contrast of tissues is further augmented by the use of intravenous iodinated contrast medium. Rapid scanning of a volume of tissue also allows the scans to be performed at different phases of enhancement, which is advantageous in identifying different diseases. For instance, very early scanning during the arterial phase is ideally suited to the examination of the arterial tree and hypervascular liver lesions, whereas scanning performed after a delay may be better suited to the identification of other solid organ pathology such as renal masses. More delayed scans, for example at 5–10 minutes post contrast injection, can be used to assess the ureters and bladder (***Figure 8.3***). Furthermore, it is possible to obtain scans during several phases including the arterial and venous phases in the same patient, which may aid in the identification and characterisation of lesions.

CT is widely used in thoracic, abdominal (***Figure 8.9***), neurological (***Figure 8.10***), musculoskeletal (***Figure 8.11***) and trauma imaging. The thinner collimation and improved spatial resolution have also resulted in the development of newer techniques such as CT angiography, virtual colonoscopy and virtual bronchoscopy. Furthermore, three-dimensional images can be reconstructed from the raw data to aid in surgical planning and to provide virtual endoluminal views in virtual colonoscopy for example. The disadvantage of CT compared with ultrasound and conventional radiography lies largely in the increased costs and the far higher doses of ionising radiation. For instance, a CT scan of the abdomen and pelvis has a radiation dose equivalent to approximately 500 chest radiographs.

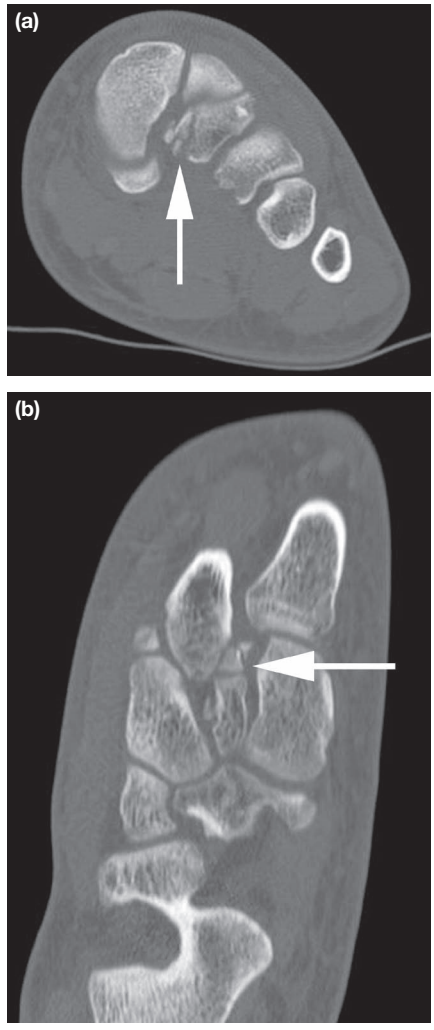

Figure 8.11 Coronal computed tomography **(a)** and axial reformats **(b)** of the foot in a patient involved in a road traffic accident demonstrates Lisfranc fracture dislocation with a comminuted fracture of the base of the second metatarsal (arrows).

Jacques Lisfranc de St. Martin, 1790–1847, Professor of Surgery and Operative Medicine, Paris, France.

Summary box 8.5

Computed tomography

Strengths

- High spatial and contrast resolution
- Contrast resolution enhanced by ability to image in multiple phases, including arterial, venous and delayed
- Rapid acquisition of images in one breath-hold
- Imaging of choice for the detection of pulmonary masses
- Allows global assessment of the abdomen and pelvis
- Excellent for liver, pancreatic, renal and bowel pathology
- Three-dimensional reconstruction allows complex fracture imaging
- Multiplanar reconstruction and three-dimensional imaging, e.g. CT angiography and colonoscopy
- Ability to guide intervention such as percutaneous biopsy and drainage

Weaknesses

- High radiation dose
- Poor soft-tissue resolution of the peripheries and superficial structures
- Patient needs to be able to lie flat and still
- Less readily available than plain films and ultrasound

Magnetic resonance imaging

Over the last 20 years, MRI has become an integral part of the imaging arsenal with ever-expanding indications. MRI relies on the fact that nuclei containing an odd number of protons have a characteristic motion in a magnetic field (precession) and produce a magnetic moment as a result of this motion. In a strong uniform magnetic field such as an MRI scanner, these nuclei align themselves with the main magnetic field and result in a net magnetic moment. A brief radiofrequency pulse is then applied to alter the motion of the nuclei. Once the radiofrequency pulse is removed, the nuclei realign themselves with the main magnetic field (relaxation) and in the process emit a radiofrequency signal that can be recorded, spatially encoded and used to construct a grey-scale image. The specific tissue characteristics define the manner and rate at which the nuclei relax. This relaxation is measured in two ways, referred to as the T1 and T2 relaxation times. The relaxation times and the proton density determine the signal from a specific tissue.

There are a large number of imaging sequences that can be used by applying radiofrequency pulses of different strengths and durations. The image characteristic and signal intensity from different tissues are governed by the pulse sequence employed and whether it is T1 weighted or T2 weighted. For instance, fat, methaemoglobin and mucinous fluid are bright on T1-weighted images, whereas water and thus most pathological processes, which tend to increase tissue water content, are bright on T2-weighted images. Cortical bone, air, haemosiderin and ferromagnetic materials are of very low signal on all pulse sequences. In general, T1-weighted images are superior in the delineation of anatomy, while T2-weighted images tend to highlight pathology better. For added tissue contrast, intravenous gadolinium may be administered. Other more specific contrast media are also available for liver, bowel and lymph node imaging.

MRI's exquisite contrast resolution, coupled with a lack of ionising radiation, is very attractive in imaging, particularly of tissues that have relatively little natural contrast. MRI also has the advantage of multiplanar imaging, as images can be acquired in any plane prescribed. It has traditionally been used extensively in the assessment of intracranial, spinal and musculoskeletal disorders (***Figures 8.12, 8.13 and 8.14***), allowing a global assessment of bony and soft-tissue structures. More recent developments have resulted in new indications and applications. Today, MRI is commonly used in oncological imaging, such as staging of rectal carcinoma and gynaecological malignancies, identification and characterisation of hepatic

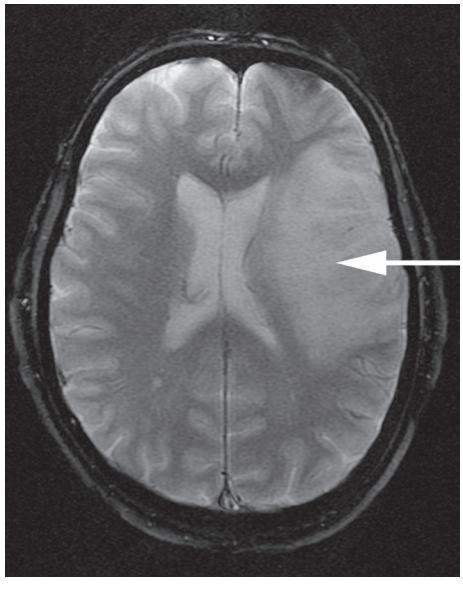

Figure 8.12 T2-weighted axial magnetic resonance imaging scan of the head in a patient with a large left-sided oligodendroglioma (arrow).

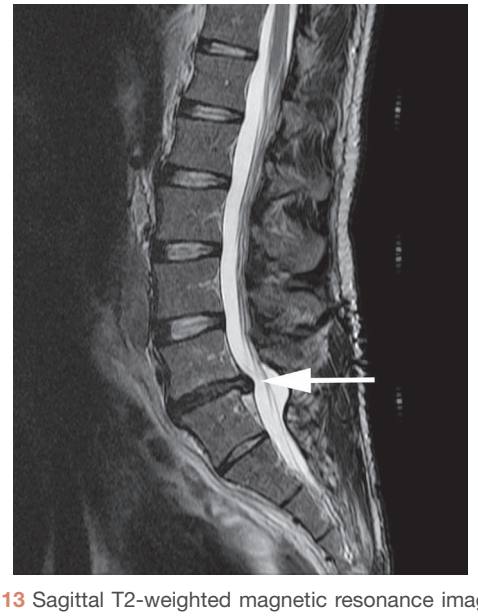

Figure 8.13 Sagittal T2-weighted magnetic resonance imaging scan of the lumbar spine demonstrates disc herniation (arrow) in a patient with acute back pain.

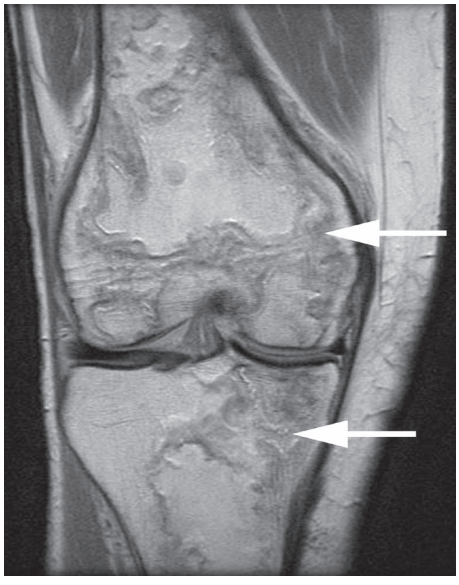

Figure 8.14 Coronal magnetic resonance imaging scan of the knee demonstrates extensive serpiginous areas of altered signal intensity in the distal femur and proximal tibia (arrows) in a patient with bone infarcts secondary to oral corticosteroids.

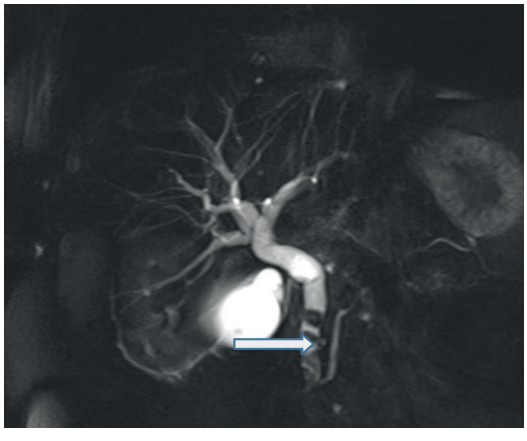

Figure 8.15 Magnetic resonance cholangiopancreatography image demonstrates dilated intrahepatic ducts and proximal common bile duct (CBD) secondary to multiple calculi in the distal CBD (arrow). This type of imaging has the potential to alter cholecystectomy surgical planning.

masses and assessment of the biliary tree (magnetic resonance cholangiopancreatography [MRCP]; ***Figure 8.15***). MRI has become increasingly important in imaging of the small bowel, for example in Crohn's disease, where repeated imaging with ionising radiation can incur a significant radiation dose over time. Magnetic resonance (MR) angiographic techniques allow non-invasive angiographic assessment of the cranial and peripheral circulation (***Figure 8.16***) and cardiac imaging.

Diffusion-weighted imaging is a relatively new type of MRI sequence that exploits the different rates of Brownian motion between different tissues. Tissues with greater cellular density have lower rates of diffusion of water molecules, and this difference can be exploited to distinguish benign and malignant or inflammatory lesions in a variety of organs as malignant or inflammatory lesions tend to have greater density of cells.

However, the availability of MRI is still relatively limited in comparison with other imaging techniques, and it is time-consuming with respect to image acquisition and interpretation. Images are easily degraded by motion, including respiratory and cardiac motion. The use of respiratory and cardiac gating can minimise this, although bowel peristalsis can still be a problem. The long acquisition times require a cooperative patient who can lie very still, which can be difficult especially in claustrophobic individuals or those in pain. Furthermore, because of the use of high-strength magnetic fields, patients with some metallic implants, such as some aneurysm clips and prosthetic heart valves, and those with implanted electronic devices, such as pacemakers and defibrillators, cannot be examined. Some newer implants may, however, be MRI compatible, and patients with joint replacements can be studied safely.

Summary box 8.6

Magnetic resonance (MR) imaging

Strengths

- No ionising radiation
- Excellent soft-tissue contrast
- Best imaging technique for
  - Intracranial lesions
  - Spine
  - Bone marrow and joint lesions

Other uses

- Staging
- MRCP
- MR angiography
- Breast malignancy
- Pelvic malignancy
- Cardiac imaging
- MR enterography
- Diffusion-weighted imaging

Weaknesses

- Absolute contraindications
  - Ocular metallic foreign bodies
  - Cochlear implants
  - Cranial aneurysm clips
- Relative contraindications
  - Pacemakers
  - First trimester of pregnancy
  - Claustrophobia
- Long scan times so patients may not be able to keep still, especially if in pain
- Limited availability
- Expensive

Nuclear medicine

In other imaging techniques using ionising radiation such as CT and conventional radiography, the individual is exposed to ionising radiation from an external source and the radiation transmitted through the patient is recorded. In nuclear medicine, however, a radioactive element or radionuclide such

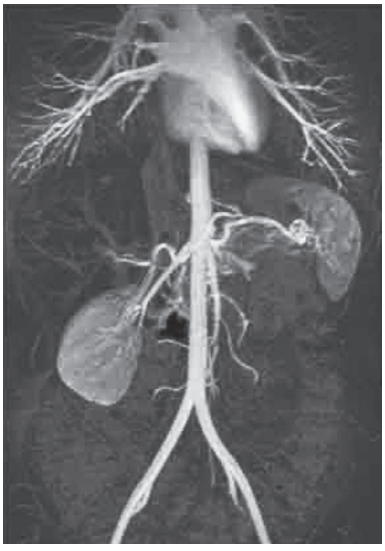

Figure 8.16 Maximum intensity projection image from a magnetic resonance angiogram demonstrates the abdominal aorta, common and external iliac arteries as well as parts of the pulmonary, mesenteric and renal vasculature.

as technetium, gallium, thallium or iodine is administered to the patient as part of a radiopharmaceutical agent, and a detector such as a gamma camera is then used to record and localise the emission from the patient, thus forming the image. The radionuclide is chosen and coupled with other compounds such that it is distributed and taken up in the tissues of interest. Therefore, a variety of radionuclides are required for imaging of different tissues. Nuclear medicine also differs from other means of imaging, which are largely anatomically based, as it also provides functional information.

Radionuclide imaging is widely used in bone imaging with very high sensitivity for assessing metastatic disease, metabolic bone disease, established arthropathies and occult infection and traumatic injuries (*Figure 8.17*), although many of these applications are being replaced by MRI. In genitourinary disease, dynamic imaging can be performed to assess renal perfusion and function including obstruction, to investigate renovascular hypertension and to evaluate renal transplants. Radionuclide imaging is also commonly used in thyroid and parathyroid disorders, ischaemic cardiac disease, detection of pulmonary emboli and assessment of occult infection and inflammatory bowel disease.

Positron emission tomography (PET) is an extension of nuclear medicine, in which a positron-emitting substance such as ^{18}F is tagged and used to assess tissue metabolic characteristics. The most commonly used radiolabelled tracer is ^{18}F-2-fluoro-2-deoxy-D-glucose (FDG), although other tracers can also be used in order to assess metabolic functions such as oxygen and glucose consumption and blood flow. Radioisotope decay causes the emission of a positron, which subsequently, within a few millimetres, collides with and annihilates an electron to produce a pair of annihilation photons. The drawbacks have been high cost, very limited availability and relatively low spatial resolution. The last of these has been addressed by PET/CT systems combining simultaneous PET imaging and CT, allowing the two sets of images to be registered so that the anatomical location of the abnormality can be localised more precisely. This modality has significantly improved the accuracy of cancer staging for a range of malignancies and is also useful in inflammatory conditions and imaging pyrexia of unknown origin.

Summary box 8.7

Radionuclide imaging

Strengths

- Allows functional imaging
- Allows imaging of the whole body
- Bone scan has a high sensitivity for metastatic bone disease, fractures and infection
- PET scanning is valuable in the detection of metastatic cancer

Weaknesses

- Specific agents are required for specific indications
- Often non-specific and an abnormal result may require further imaging
- Generally poor spatial resolution

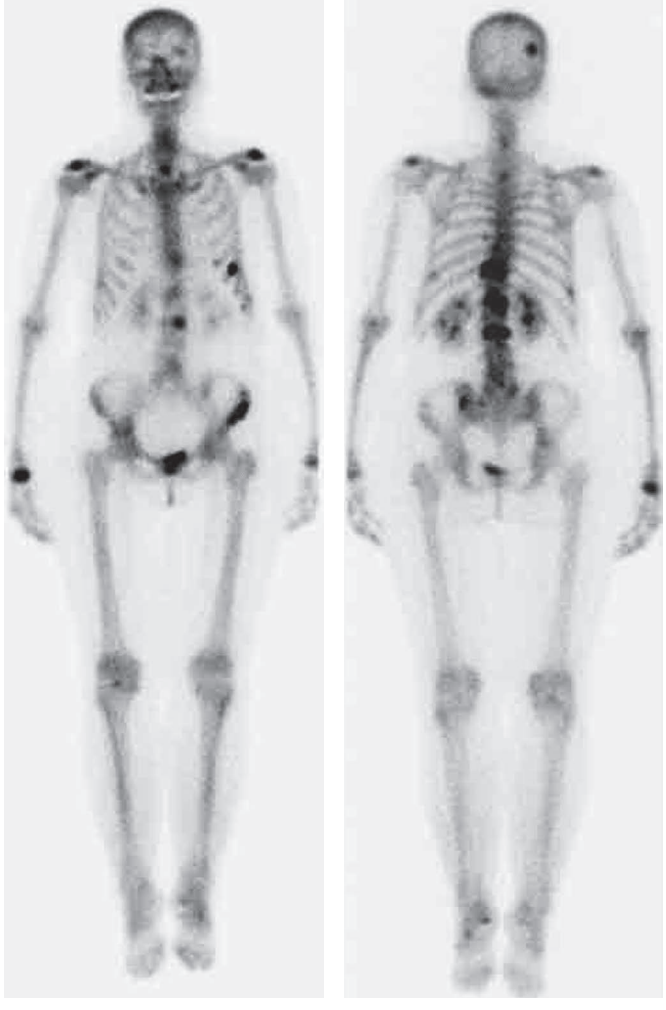

Figure 8.17 Bone scintigraphy in a patient with carcinoma of the breast illustrates bony metastatic deposits involving multiple vertebrae, the skull, pelvis and ribs.

IMAGING IN ORTHOPAEDIC SURGERY

Introduction

Imaging is an integral part of musculoskeletal diagnosis. Image-guided, minimally invasive techniques also play a major role in treatment. In broad terms, radiographs are the best method of looking for bony lesions or injuries, MRI shows bone marrow disease, muscle, tendon and soft-tissue disorders and ultrasound has better resolution than MRI for small structures, with the added advantage of showing dynamic changes. CT enables visualisation of the fine detail of bony structures, clarifying abnormalities seen on plain radiographs.

There are occasions when a combination of techniques will be important, and due consideration should be given to reducing the ionising radiation burden to the patient, using ultrasound and MRI as primary investigations whenever appropriate.

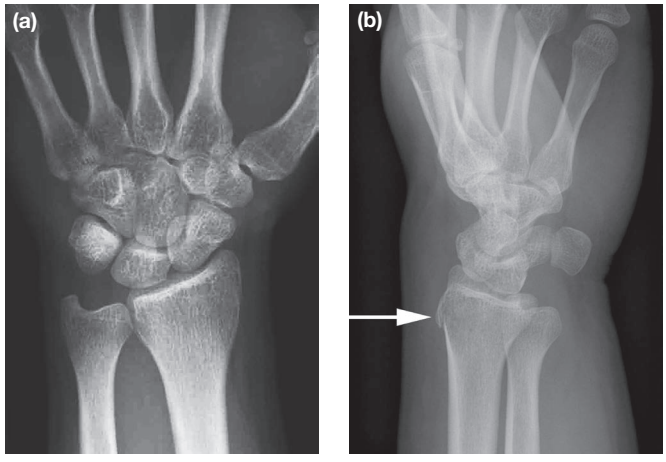

Figure 8.18 Anteroposterior radiograph of the wrist **(a)** in a patient following a fall does not show an acute bony injury. It is only on the second view **(b)** that a fracture of the dorsal cortex of the distal radius is visualised (arrow).

Summary box 8.8

Imaging in musculoskeletal conditions

- Radiographs are the best first-line test for bone lesions and fractures
- MRI is good for diagnosing bone marrow disease, occult fractures and tendon and soft-tissue disorders
- CT enables visualisation of the fine detail of bony structures
- CT gives the best three-dimensional information on fractures
- Ultrasound has better resolution in accessible soft tissues and can be used dynamically
- Ultrasound is the best method of distinguishing solid from cystic lesions
- Ultrasound is the only method for locating non-metallic foreign bodies
- Ultrasound is the best method for detecting muscle hernias

Skeletal trauma

Musculoskeletal trauma is best imaged by an initial plain radiograph. All skeletal radiographs should be taken from two different angles, usually at right angles to each other. This is important in trauma because a fracture or dislocation may not be visible on a single view (***Figure 8.18***). Occasionally, and in specific locations such as the scaphoid, more than two views are routinely performed. If this fails to make a clear diagnosis, or if there is suspicion of soft-tissue injuries, then cross-sectional studies are indicated.

Increasingly in the assessment of spinal trauma, CT is replacing radiographs as the first-line investigation for two main reasons: the first is that the sensitivity of CT is superior, the second is that it is quicker, enabling treatment to commence sooner.

Axial CT images alone may fail to diagnose some fractures, so three-dimensional reformatting is important to prevent errors. Sections should be thin, but care must be taken not to cover too wide an area, as the radiation burden may be excessive, particularly with multislice CT.

Summary box 8.9

Trauma imaging

- Initial imaging is either radiography or CT
- At least two views are needed for radiographs
- Use CT for spine, intra-articular or occult fractures

Degenerative disease

Synovitis

Radiographs are usually the first-line imaging investigation performed for the examination of joints. Typical changes of a degenerative or an erosive arthropathy are well known and understood. However, early arthropathy will be missed on radiographs and, with the advent of disease-modifying drugs, it is important to detect early synovitis before it is even apparent on clinical examination. Gadolinium diethyl triamine penta-acetic (DTPA)-enhanced MRI is the most sensitive method for detecting synovial thickening of numerous joints, but ultrasound is also sensitive, albeit more laborious to perform. Ultrasound shows effusions and synovial thickening clearly, and shows the increased blood flow around the affected joints without the use of contrast agents (***Figures 8.19 and 8.20***).

Articular cartilage damage

Articular surface disease is difficult to detect using non-invasive techniques. MRI is probably the best method, although it is not sensitive to early chondral changes (***Figure 8.21***). Higher field strength magnets (3 tesla and above) with dedicated surface coils provide more precise assessment; however, MR arthrography is currently the imaging 'gold standard'. A dilute quantity of

Nikola Tesla, 1856–1943, American physicist and electrical engineer who worked for the Westinghouse Electric and Manufacturing Company. A tesla is the SI unit of magnetic flux density.

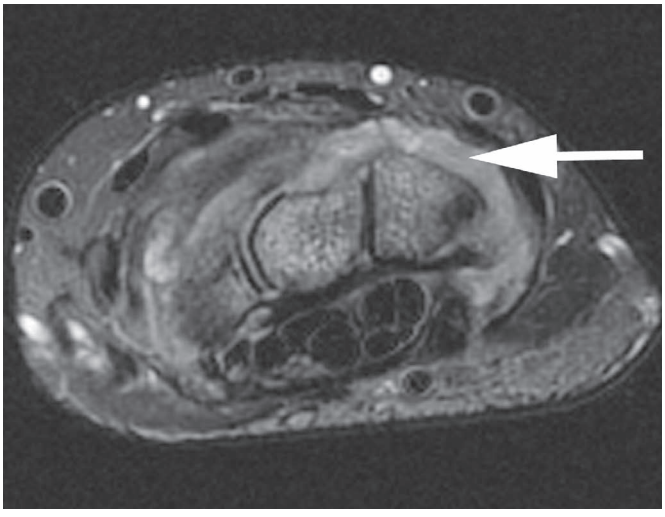

Figure 8.19 Axial T2-weighted fat-suppressed image of the wrist in a patient with rheumatoid arthritis demonstrates synovitis manifested as increased signal dorsal to the carpal bones (arrow).

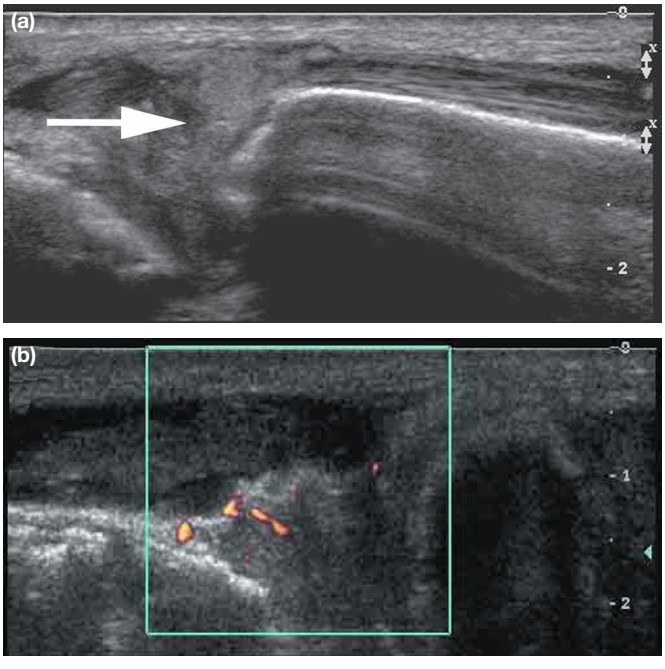

Figure 8.20 Ultrasound of the wrist (a) shows thickening of tissues on the dorsal aspect of the radiocarpal joint (arrow). (b) There is increased flow on power Doppler ultrasound in this patient with wrist synovitis and rheumatoid arthritis.

Figure 8.21 Coronal magnetic resonance imaging of the knee demonstrates a focal osteochondral abnormality of the medial femoral condyle, with full-thickness loss of the articular cartilage and abnormality of the subchondral bone (arrow).

Figure 8.22 Coronal computed tomography arthrogram of the wrist showing a central perforation of the triangular fibrocartilage with contrast extending into the distal radioulnar joint (arrow) and radiocarpal articulation.

gadolinium DTPA is introduced into the joint by needle puncture under fluoroscopic, CT or ultrasound guidance, which is followed by an MRI examination. Using this technique, more subtle changes in the articular surface can be seen, including thinning, fissuring and ulceration. However, early softening of articular cartilage will not be visible. MR arthrography is also useful for detecting labral tears in the shoulder or hip, and in the assessment of patients who have undergone a previous meniscectomy. The triangular fibrocartilage of the wrist is also difficult to assess fully without MR or CT arthrography (*Figure 8.22*).

In the shoulder, rotator cuff trauma and degenerative changes can be studied using ultrasound or MRI. In experienced hands, ultrasound has a higher accuracy rate because image resolution is better and because the mechanical integrity of the cuff can be tested by dynamically stressing it (*Figure 8.23*). MRI has the advantage of being able to show abnormalities in the subcortical bone.

In the majority of arthropathies and degenerative disorders, serial imaging is useful. Changes in films taken weeks or months apart are far easier to see and interpret than a single snapshot study.

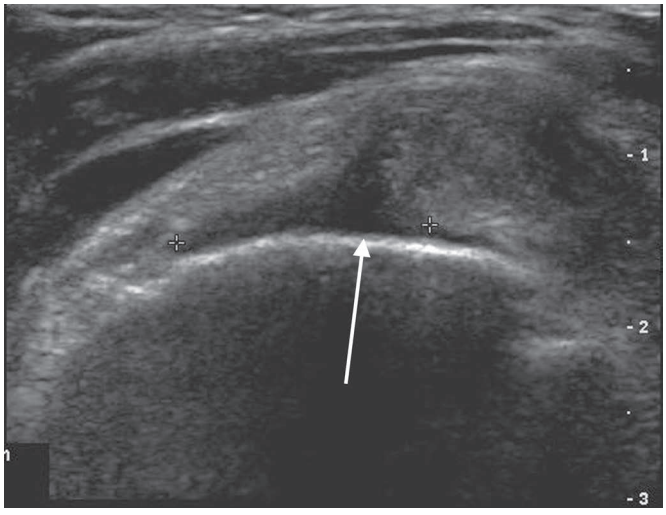

Figure 8.23 Ultrasound of the supraspinatus tendon identifies a partial tear of the tendon (arrow), which is predominantly articular sided but with a component that is nearly full thickness.

Summary box 8.10

Imaging techniques for joint disease

- Radiographs are good for assessing established articular disease
- Synovitis can be detected using ultrasound or contrast-enhanced MRI
- Early damage to articular cartilage is difficult to image by conventional methods
- Rotator cuff lesions are best studied using ultrasound or MRI
- Destructive lesions are best studied first on plain radiographs
- MRI is best for staging tumours
- Biopsy can be guided by fluoroscopy, CT or ultrasound

Aggressive bone disease

The radiograph is the first imaging technique for destructive lesions in bones. There is considerable experience required in the interpretation of these films, especially with regard to whether the lesion is benign or malignant (***Figure 8.24***).

Radiographs are also vital in the assessment of soft-tissue calcification in tumours of muscle, tendon and subcutaneous fat. When a lesion is detected, there needs to be an early decision as to whether this is benign or malignant. If there is a suspicion of malignancy on the radiograph, or any uncertainty, then local staging is indicated. This is best performed by MRI for both bone and soft-tissue lesions (***Figure 8.25***). At this stage, it is likely that a biopsy will be indicated, and preferably under image guidance. Soft-tissue and bone biopsy needles may be guided by CT, ultrasound or interventional MRI systems. The route of puncture should avoid vital structures and must be agreed with the surgeon, who will perform local excision if the lesion proves to be malignant. Care should be taken to avoid contaminating other compartments. In all circumstances, samples are best sent for both histopathological and microbiological examination. It may be difficult to tell on imaging whether or not a lesion is infected, and histology often provides a clear diagnosis in inflammatory conditions. Bone scintigraphy is useful in detecting whether a lesion is solitary or multiple, although whole-body MRI is becoming available.

Summary box 8.11

Imaging of aggressive lesions in bone

- Plain radiographs are important as a first investigation
- MRI is best for local staging
- Bone scintigraphy or whole-body MRI for solitary or multiple lesion determination
- CT detects lung metastases
- Fluoroscopy, CT, MRI or ultrasound can be used to guide the biopsy

Mass lesions

Mass lesions in muscle and soft tissue are examined by ultrasound, which can be diagnostic in the majority of cases, thereby avoiding the need for further imaging. This is most often the case when a lesion is purely cystic and, as most soft-tissue masses are cysts, ultrasound is a very effective screening test. There are occasions when no mass lesion is found at the site of

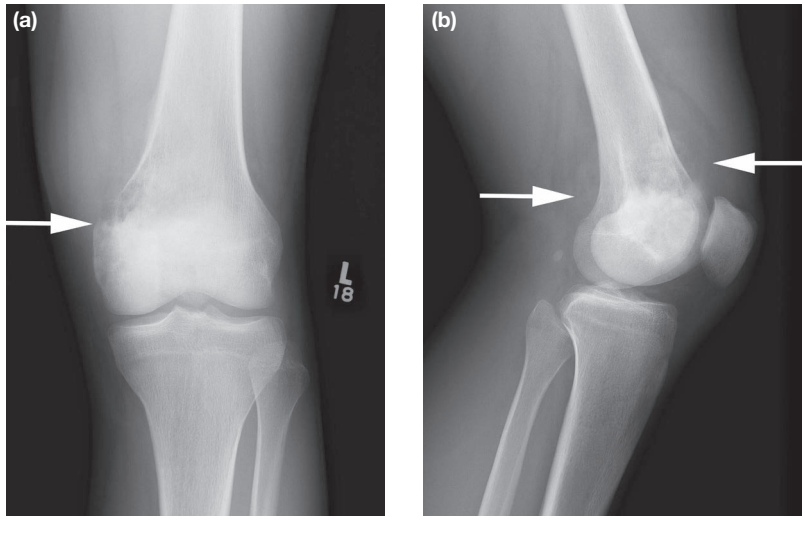

Figure 8.24 Anteroposterior **(a)** and lateral **(b)** radiographs of the left knee in a young patient with knee pain. There is a mixed lucent and sclerotic lesion of the distal femur with breach of the cortex medially and soft-tissue extension seen anteriorly and posteriorly (arrows). The location and appearances are consistent with osteosarcoma.

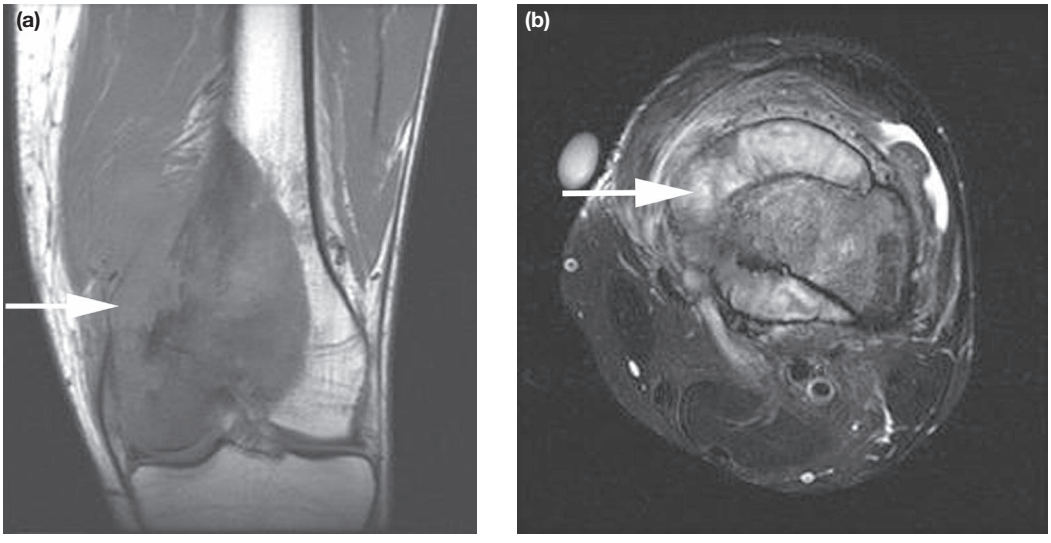

Figure 8.25 Coronal T1- **(a)** and axial T2-weighted fat-suppressed **(b)** images through the distal femur of the patient in **Figure 8.24** illustrates the bony area involved, the soft-tissue extent of the tumour and the relationship of the neurovascular structures to the mass (arrows).

concern, and then reassurance can be offered. If the ultrasound examination is normal, this effectively excludes soft-tissue neoplasia. A reasonable protocol is to perform ultrasound on all palpable 'lesions' to exclude cysts, and on patients without any identifiable mass, and to proceed to MRI only when there is a solid or partly solid element to an unidentifiable lesion. Tumour vascularity is best assessed by Doppler ultrasound. It can be studied by intravenous gadolinium DTPA-enhanced MRI; however, this is a more expensive and invasive technique, providing no more information than Doppler ultrasound.

Summary box 8.12

Imaging of soft-tissue lesions

- Ultrasound is the best for screening; it is often the only imaging required
- MRI is best for local staging and follow-up
- Doppler ultrasound can assess vascularity cheaply and effectively
- Ultrasound is useful for biopsy

Infection

In the early stages of joint infection, the plain films may be normal, but they should still be performed to exclude bony erosions in case a painful joint is the first sign of an arthropathy. Ultrasound examination is the easiest and most accurate method of assessing joint effusions, although, when an effusion is identified, it is not possible to discriminate between blood and pus. Aspiration guided by ultrasound is the best method of making this distinction. MRI may be required to assess early articular cartilage and bone involvement.

Radiographs should also be used to examine patients with suspected osteomyelitis. Although they may not detect early infection, they will demonstrate or exclude bony destruction, calcification and sequestrum formation. CT may be needed to give a cross-sectional view, in order to assess the extent of bony sequestrum.

MRI is perhaps the most sensitive method for detecting early disease and is the preferred technique to define the activity and extent of infection, as it shows not only the bony involvement but also the extent of oedema and soft-tissue involvement (*Figure 8.26*). Abscesses may be detected or excluded, and subperiosteal oedema is readily visible. MRI can be used as a staging procedure to plan treatment, including surgical intervention. Serial examinations can be used to follow the response to intravenous antibiotics and are very useful in the management of complex osteomyelitis. In cases of negative or equivocal MRI, nuclear medicine techniques such as bone scintigraphy can be very sensitive, and specialised studies using tracers such as gallium citrate or indium-labelled white cells increase specificity.

Summary box 8.13

Imaging of potentially infected bone and joint

- Plain radiographs may be needed to exclude bone erosion
- Ultrasound is sensitive for an effusion, periosteal collections and superficial abscesses and can be used for guided aspiration
- CT is useful in established infection to look for sequestrum
- MRI is useful to define the activity of osteomyelitis, early infection and soft-tissue collections
- Bone scans are sensitive but of low specificity
- Complex nuclear medicine studies are useful in negative MR examinations or equivocal cases

Metabolic bone disease

Plain radiographs should be the first images of patients with metabolic bone disease. They may detect the subperiosteal erosions in hyperparathyroidism or, more commonly, the osteopenia in osteoporosis, but they cannot be used to quantify osteoporosis. The apparent density of the bone on the film is linked to the penetration of the rays, among other variables, as well as to the bone density. If a quantitative method is needed,

however, bone mineral density using dual x-ray absorptiometry (DEXA) is the most accurate and practical. However, fractures will cause erroneously high readings, and they tend to occur in the vertebrae used for DEXA measurements. Quantitative CT is an alternative technique, although this is less readily available. Ultrasound transmission measurement in the extremities has its advocates, as it arguably measures factors that better represent the strength of bone rather than its density. Its limitations are that it cannot be used to study the vertebrae or hip, and these are the sites where osteoporotic fractures occur most frequently. MRI may be useful in detecting fractures and is an essential prerequisite to percutaneous vertebroplasty.

IMAGING IN MAJOR TRAUMA

Introduction

Trauma remains a major cause of mortality and morbidity in all age groups. Presented with a multiply injured patient, rapid and effective investigation and treatment are required to maximise the chances of survival and to reduce morbidity. Imaging plays a major role in this assessment and in guiding treatment. As with the clinical assessment, imaging is carried out according to the principles of primary and secondary surveys, identifying major life-threatening injuries of the airway, respiratory system

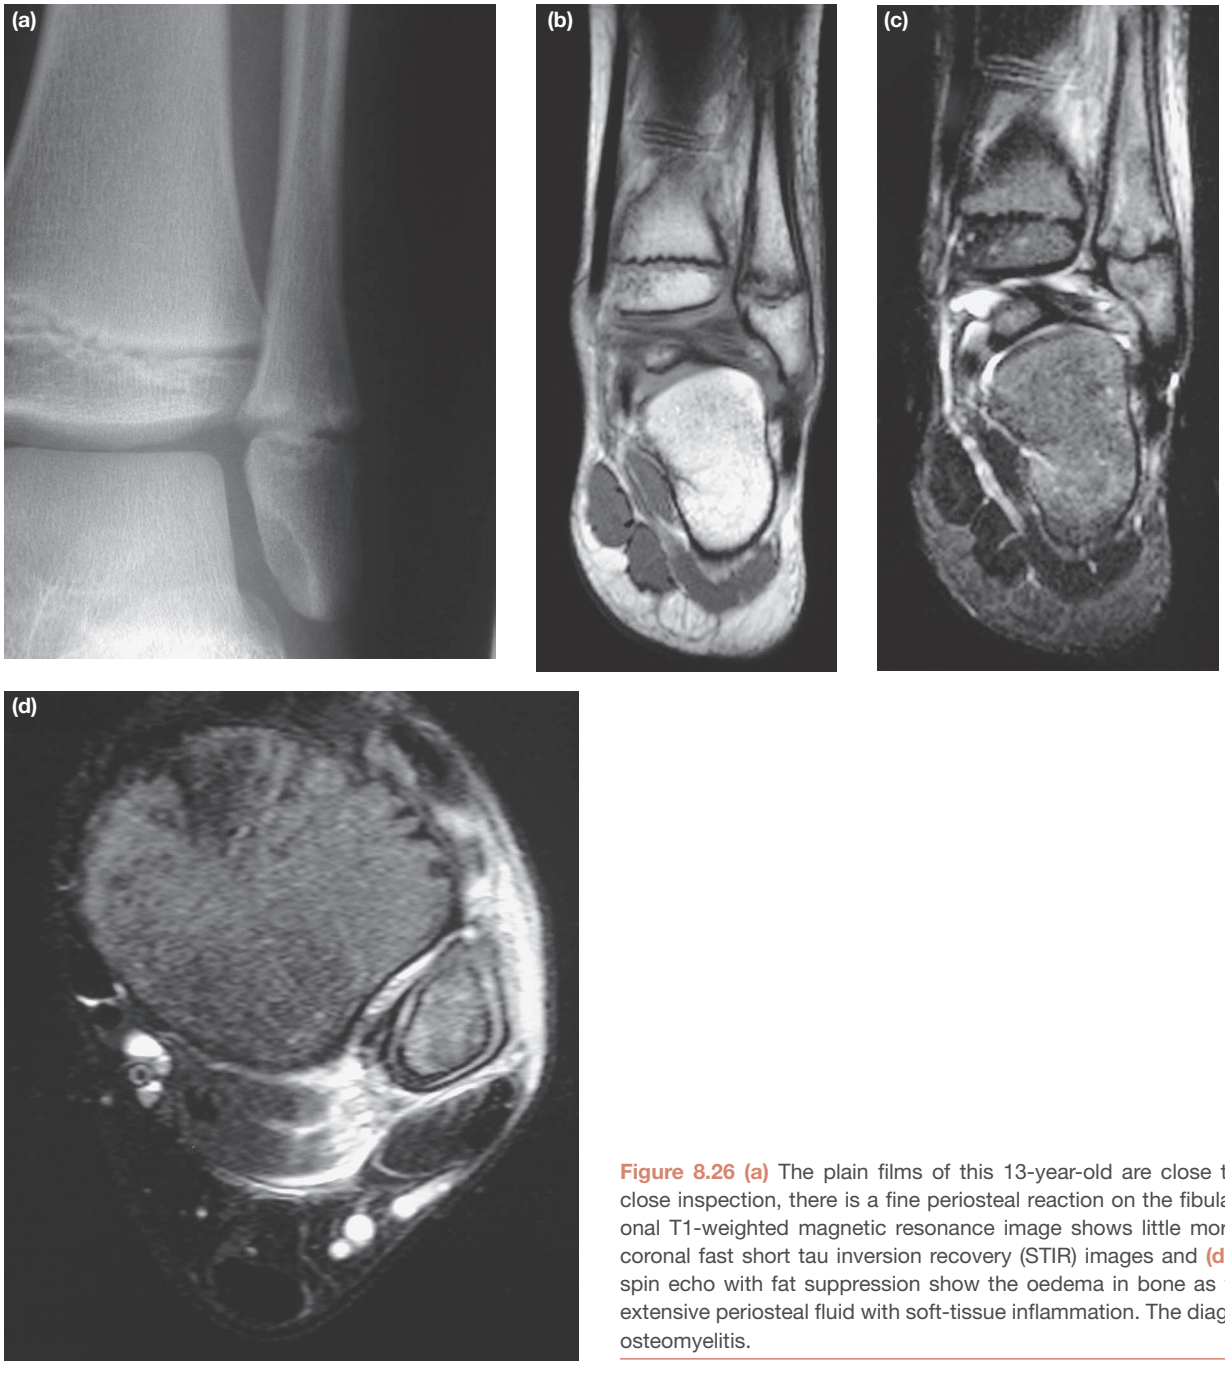

Figure 8.26 (a) The plain films of this 13-year-old are close to normal. On close inspection, there is a fine periosteal reaction on the fibula. **(b)** The coronal T1-weighted magnetic resonance image shows little more, but **(c)** the coronal fast short tau inversion recovery (STIR) images and **(d)** axial T2 fast spin echo with fat suppression show the oedema in bone as white and the extensive periosteal fluid with soft-tissue inflammation. The diagnosis is acute osteomyelitis.

and circulation before a more detailed and typically time-consuming assessment of other injures. At no point should imaging delay the treatment of immediately life-threatening injuries. As in other settings, the quickest and least invasive examinations should be performed first. A radiologist present in the trauma room at the time of patient assessment is able to evaluate the radiographs rapidly, relay this information back to the team and guide further imaging, which may include further plain films, CT, ultrasound and MRI.

Plain radiographs

Conventional radiography allows rapid assessment of the major injuries and can be carried out in the trauma room while the patient is clinically assessed and treated. Despite the time constraints, the number of staff involved and the restricted mobility of the patient, high-quality images can be routinely obtained with due care and attention. Increasingly plain films are being replaced by whole-body CT. In many centres CT scanners are immediately available in the emergency department and indeed in some departments patients are assessed and treated on the scanning table.

There is no routine set of radiographs to be obtained, and the decision is based on the mechanism of injury, the stability of the patient's condition and whether the patient is intubated. The most commonly performed initial radiographs are a chest radiograph, a single anteroposterior view of the pelvis and a cervical spine series.

The supine chest radiograph should encompass an area from the lung apices to the costophrenic recesses and include the ribs laterally. Chest radiographs give valuable information in both blunt and penetrating trauma. Evaluation of the radiograph should be undertaken in a systematic manner to minimise the chances of missing an injury. In the first instance, the position of lines and tubes, including the endotracheal tube, should be assessed, followed by assessment of the central airways. Following this, the lungs should be evaluated for abnormal focal areas of opacification, which may represent aspiration, haemorrhage, haematoma or oedema, as well as more diffuse opacification reflecting a pleural collection. Alternatively, relative focal or unilateral lucency may reflect a pneumothorax in the supine position. Evaluation of the mediastinum should include its position, which may be altered by tension pneumothoraces or large collections, as well as its contour, an alteration of which may reflect a mediastinal haematoma due to aortic or spinal injury. Finally, the skeleton and the soft tissue should be carefully examined for rib, vertebral, scapular and limb fractures, as well as evidence of surgical emphysema and paraspinal haematomas (***Figure 8.27***).

Pelvic radiographs are also commonly performed to screen for, and assess, fractures of the bony pelvis. The image should include the iliac crests in their totality and extend inferiorly to below the lesser trochanters. When assessing the film, the alignment of the sacroiliac joints and the symphysis pubis should be carefully examined, as some fractures, especially those of the sacral arcades, can be very subtle on the pelvic radiograph. The presence of pubic fractures raises the possibility of urethral injury and should alert clinicians to exercise caution with bladder catheterisation (***Figure 8.28***).

The utility of cervical spine x-rays depends on the consciousness level of the patient and the presence of distracting injuries. In fully conscious patients with an isolated neck injury, clinical assessment can be used to guide the need for x-rays. In patients with distracting injuries and/or altered consciousness, including intubated patients, CT is preferred (***Figure 8.29***).

Further radiographs of the thoracic and lumbar spine and the peripheral skeleton may be required, depending on the clinical setting. As with all skeletal radiographs, two

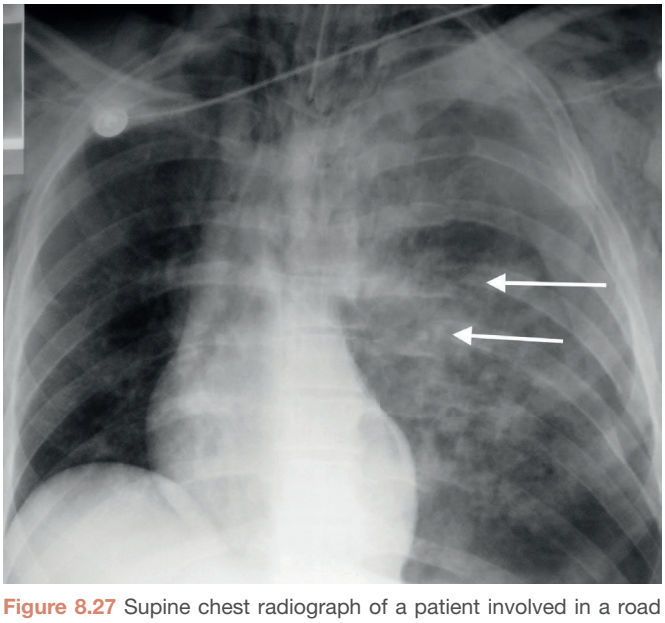

Figure 8.27 Supine chest radiograph of a patient involved in a road traffic accident. The patient is intubated. There are multiple left-sided rib fractures (arrows) and extensive surgical emphysema. Depression of the left hemidiaphragm and mediastinal shift to the right suggest that there is a tension pneumothorax present.

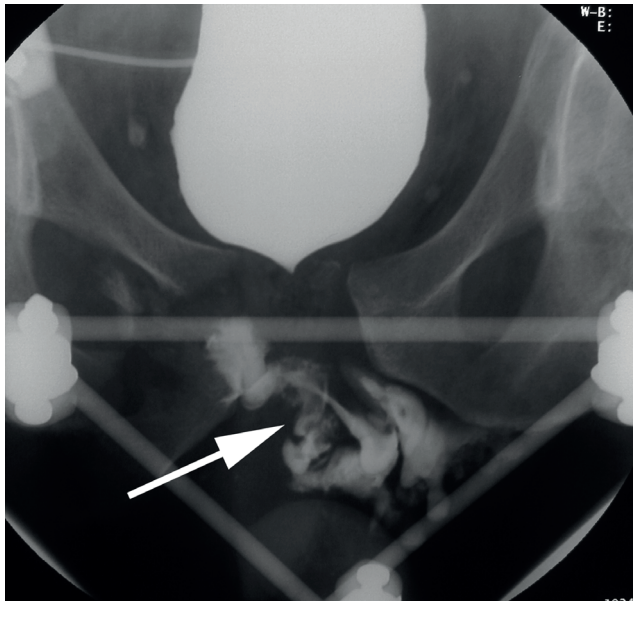

Figure 8.28 Retrograde urethrogram in a patient who sustained extensive pelvic fractures following a fall. The pelvic injuries have been stabilised using an external fixation device. The urethrogram identifies extensive injury to the urethra with extravasation of contrast (arrow).

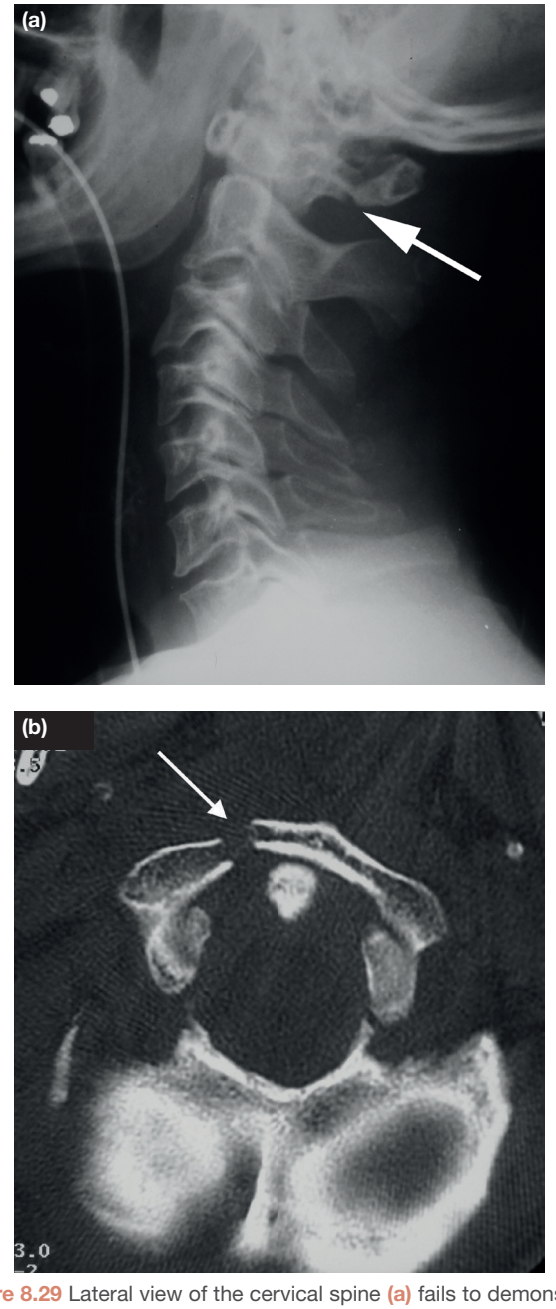

Figure 8.29 Lateral view of the cervical spine **(a)** fails to demonstrate the cervicothoracic junction. In addition, there appears to be a break in the posterior arch of C1 (arrow). Computed tomography of the cervical spine **(b)** demonstrates a fracture of the anterior arch as well as the posterior arch of C1 (arrow).

perpendicular views are required for adequate assessment. However, with the increasing use of CT in assessment of the torso the need for plain films is diminishing.

Radiographs of the skull or facial bones have no role in the immediate assessment of the multitrauma individual, except for immediate localisation of a penetrating object.

Ultrasound

Ultrasound has an evolving role in the assessment of acutely traumatised patients. The main current roles of ultrasound include the assessment of intraperitoneal fluid and haemopericardium (focused assessment with sonography for trauma [FAST]), the evaluation of pneumothoraces in supine patients and in guiding intervention.

FAST ultrasound is a limited examination directed to look for intraperitoneal fluid or pericardial injury as a marker of underlying injury. This avoids the invasiveness of diagnostic peritoneal lavage. In the presence of free intraperitoneal fluid and an unstable patient, the ultrasound allows the trauma surgeon to explore the abdomen as a cause of blood loss. In the presence of fluid and a haemodynamically stable individual, further assessment by way of CT can be performed. However, it is important to realise that ultrasound has limitations in the identification of free fluid. This includes obscuration of fluid by bowel gas or extensive surgical emphysema. More organised haematoma may be more difficult to visualise. It must also be emphasised that the principal role of ultrasound is not to identify the primary solid organ injury, although this may be visualised. Occasionally, a second ultrasound scan may show free fluid in the presence of an initially negative FAST scan.

The detection of a pneumothorax on a supine radiograph can be very difficult. Ultrasound examination may be used to identify a radiographically occult pneumothorax. With a high-resolution linear probe, the pleura can be visualised as an echogenic stripe, and its motion with respiration can also be assessed. In the presence of a pneumothorax, the sliding motion of the pleura is lost. Ultrasound may also be used to detect a haemothorax or haemopericardium.

Finally, ultrasound may be of value in guiding the placement of an intravascular line by direct visualisation of the vessels. This can be especially advantageous in shocked patients.

Computed tomography

CT is the main imaging method for the investigation of intracranial and intra-abdominal injuries and vertebral fractures. With current multidetector scanners a comprehensive examination of the head, spine, chest, abdomen and pelvis can be completed in less than 5 minutes. Traditionally the CT scanner was referred to as 'the doughnut of death', as imaging could lead to delays in emergency treatment. However, as the availability of scanners and the speed of scanning has dramatically increased, it has become standard practice to use CT early in the assessment of trauma patients. Emergency departments have CT scanners co-located to the resuscitation or trauma bays or patients can be assessed and treated while on the CT table.

CT examination of the head is accurate in identifying treatable intracranial injuries (***Figures 8.30 and 8.31***) and should not be delayed by radiography of peripheral injuries, as there is declining success in cases of intracranial collection when treated after the initial 3–4 hours. In comparison, identification of more widespread injuries, such as diffuse axonal injury, is relatively poor. Examination of facial injuries and cervical spine fractures can also be carried out at the same time as this only adds seconds to the examination. There is evidence that CT of the abdomen and pelvis is of benefit in multiple trauma when there is a head injury, as it often shows unexpected abnormalities; this may affect the immediate management, especially if the patient deteriorates.

Figure 8.30 Computed tomography of the head in a patient with head injury shows bilateral large frontal extradural collections (arrow).

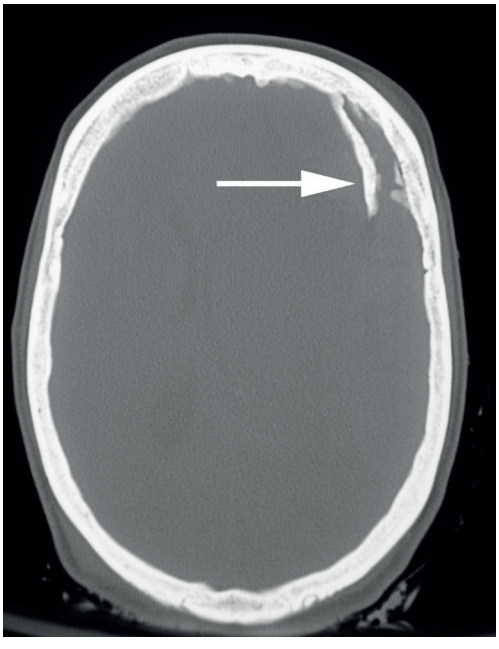

Figure 8.31 Computed tomography of the head following head trauma shows a skull fracture with a large depressed component (arrow).

Chest CT with intravenous contrast agent is valuable in identifying vascular and lung injuries and is the most accurate way of demonstrating haemothorax and pneumothorax. The position of chest drains can be identified, allowing adjustment of position if necessary. Abdominal and pelvic CT is usually undertaken as an extension to the chest CT. If an abdominal examination is performed, the pelvis should be included to avoid missing pelvic injuries and free pelvic fluid. CT is an excellent means of identifying hepatic, splenic (*Figure 8.32*) and renal injuries. Delayed examination after the administration of intravenous contrast agents allows assessment of the pelvicalyceal system in cases of renal trauma. Pancreatic and duodenal injuries may also be identified, but detection of these injuries may be more problematic. Using CT, the accuracy of detection of bowel or mesenteric injuries is less than it is for solid organ injury, and these injuries should be suspected when there is free intraperitoneal fluid without an identifiable cause (*Figure 8.33*). Close clinical follow-up and early repeat scanning with oral contrast can often reveal the bowel or mesenteric injury in patients with free fluid with no other cause identified.

The image data may be reconstructed into thinner slices for the diagnosis of injuries to the thoracic and lumbar spine and for the better delineation of pelvic and acetabular fractures. Complex intra-articular fractures of the peripheral skeleton, such as calcaneal and tibial plateau fractures, may be usefully examined by dedicated thin-section studies provided this does not delay the treatment of other more serious injuries (*Figure 8.34*). CT angiography may be used to demonstrate vascular injuries in the limbs in those with penetrating injuries or complex displaced fractures.

Magnetic resonance imaging

The value of immediate MRI in trauma is relatively limited and is largely confined to the imaging of spinal injuries (*Figure 8.35*).

Access to urgent MRI is not widely available, and there are major practical problems in imaging patients who require ventilation or monitoring. MRI is therefore only practical in stable patients. All monitoring equipment must be MRI compatible, and ventilation support should be undertaken by staff skilled and experienced in these techniques as applied to the MRI environment. MRI may be used to diagnose injuries of the spinal cord and associated perispinal haematomas in patients with neurological signs or symptoms. MRI can supplement CT in spinal injuries by imaging soft-tissue injuries to the longitudinal and interspinous ligaments. MRI is mandatory in patients in whom there is facetal dislocation if surgical reduction is being considered, to minimise the risk of displacing soft-tissue or disc material into the spinal canal during reduction procedures. Subtle fractures may be difficult to identify, particularly if they are old, but an acute injury is normally identified by the surrounding oedema. Bony abnormalities should be reviewed using CT as fracture lines are hard to identify with MRI and unstable injuries may be overlooked. In the less acute setting, MRI may also be used to assess diffuse axonal injuries, with an accuracy exceeding CT.

Vascular interventional radiology

With the development and refinement of CT angiography techniques, the diagnostic role of formal angiography has become limited. CT angiography is the first-line investigation for aortic trauma and for penetrating and non-penetrating peripheral vascular trauma.

Endovascular techniques play an important role in the treatment of acute solid organ injuries, and the interventional radiologist should be consulted early in the decision-making

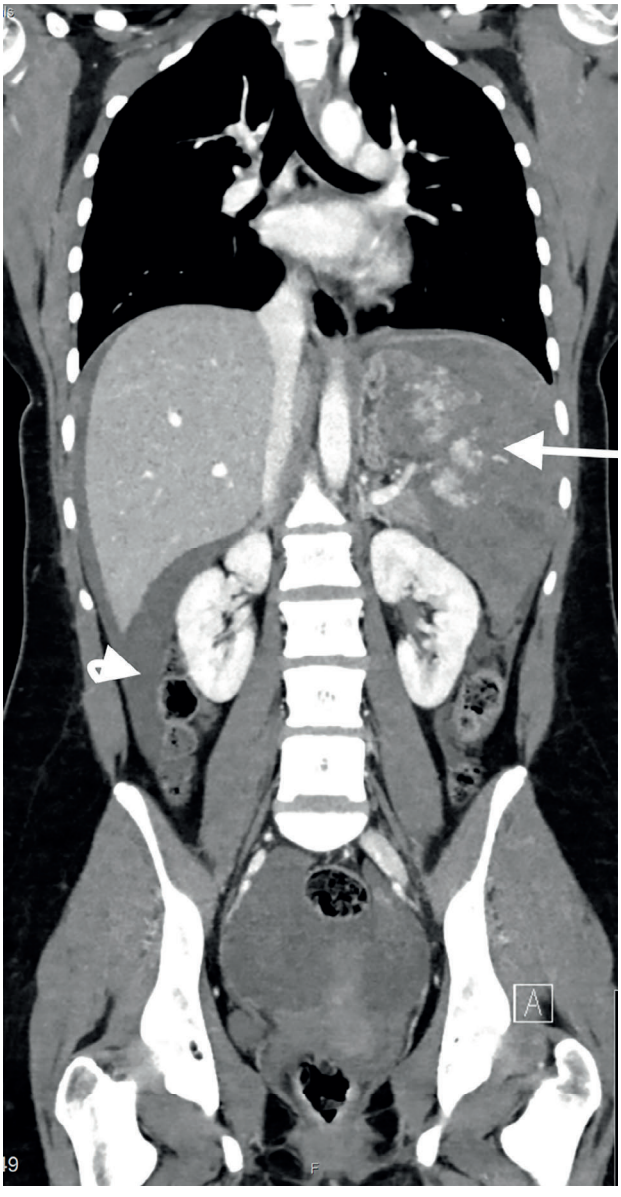

Figure 8.32 Coronal computed tomography image of the body shows a grade V splenic injury ('shattered spleen'; arrow) with vascular injury at the hilum and free fluid around the spleen and liver (arrowhead).

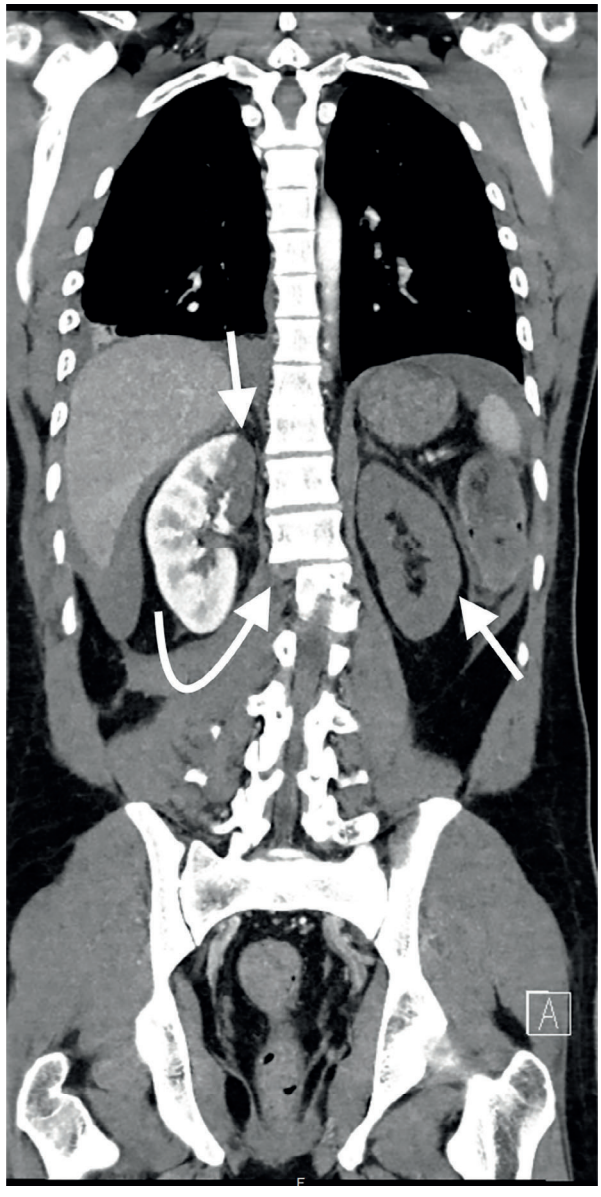

Figure 8.33 Coronal computed tomography demonstrating free fluid around the liver. The upper pole of the right kidney and whole left kidney demonstrate no contrast uptake in keeping with acute vascular injury (arrows). In addition there is a distraction injury with lateral dislocation of the T11–T12 intervertebral junction (curved arrow).

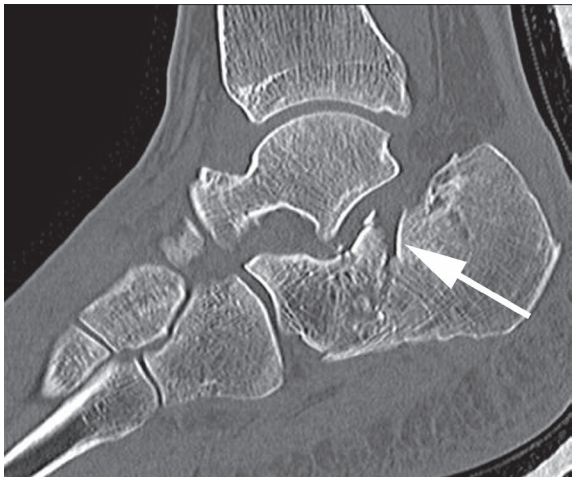

Figure 8.34 Sagittal reformats of computed tomography of the calcaneus in a patient following a fall illustrate a comminuted calcaneal fracture with intra-articular extension into the posterior facet of the subtalar joint (arrow).

process. Using coaxial catheter systems and a variety of available embolic agents such as soluble gelatin sponge and microcoils, selective embolisation and reduction of blood flow to the injured segment can be achieved without causing infarction. Selective embolisation techniques are also suitable for the treatment of patients with pelvic fractures with ongoing blood loss and volume issues. With penetrating and non-penetrating extremity trauma, balloon occlusion and embolisation may be employed to control haemorrhage, while the application of stent grafts can aid in re-establishing the circulation to the affected extremity.

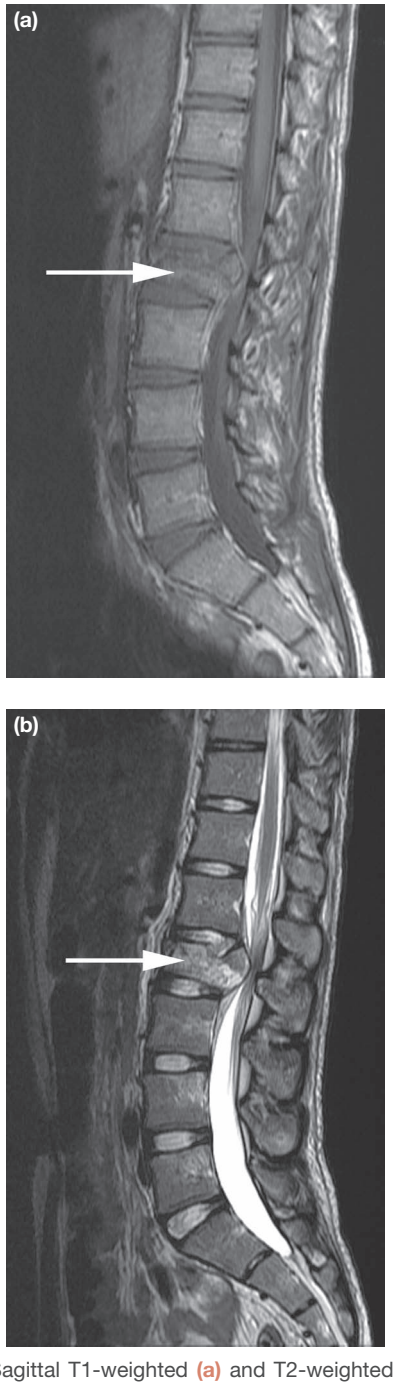

Figure 8.35 Sagittal T1-weighted (a) and T2-weighted (b) magnetic resonance imaging of the spine demonstrate a burst fracture of L2 causing neural compression (arrows).

IMAGING IN ABDOMINAL SURGERY

The acute abdomen

The term 'acute abdomen' encompasses many diverse entities.

IMAGING IN COMMON SURGICAL CLINICAL SCENARIOS

In this section the roles of different radiological modalities in common surgical scenarios are discussed, with a brief rationale behind their use and typical appearances of various pathological processes.

Bowel obstruction

The plain abdominal radiograph is a useful tool in diagnosing bowel obstruction. Small bowel obstruction can generally be distinguished from large bowel obstruction by virtue of the following: the small bowel lies centrally in the abdomen while the large bowel lies peripherally; the valvulae conniventes (folds) of the small bowel traverse the entire width of the lumen while the haustra of the large bowel do not; and the calibre of the small bowel is typically less than the large, even when obstructed (typical measurements in obstruction: small bowel 3.5–5 cm, large bowel 5–8 cm).

However, it must be stressed that a normal plain radiograph does not exclude an obstruction – if there is persistent concern, further imaging is indicated; CT is the modality of choice, having largely superseded the contrast follow-through or enema, particularly in the acute setting. The key to diagnosis of a mechanical obstruction of either small or large bowel on CT, and differentiation from paralytic ileus, is identification of a transition zone from dilated proximal bowel to collapsed distal bowel. In small bowel obstruction if no obvious cause such as a mass, volvulus or intussusception is identified, then the most likely aetiology is adhesional. There is no need to give oral contrast for a suspected bowel obstruction CT as fluid in the lumen is a natural contrast agent and, in any case, oral contrast may well not reach the point of obstruction by the time of the scan. CT is also invaluable to diagnose complications of bowel obstruction such as perforation and ischaemia. If there is ongoing uncertainty after CT as to whether the diagnosis is mechanical obstruction or a paralytic ileus, delayed plain abdominal radiographs obtained 1 and 4 hours after ingestion of dilute Gastrografin (typically 75 mL Gastrografin mixed with 75 mL water) can be useful to assess if contrast reaches the colon. Gastrografin also has an osmotic effect that can, on occasion, be therapeutic.

Closed loop obstruction, where the bowel is obstructed at two points, often in close proximity to each other and frequently related to an internal hernia or adhesional band, is a particular type of small bowel obstruction prone to developing ischaemia. It should be suspected at CT if the bowel is dilated distal to a transition point with a further transition point more distally (*Figure 8.36*).

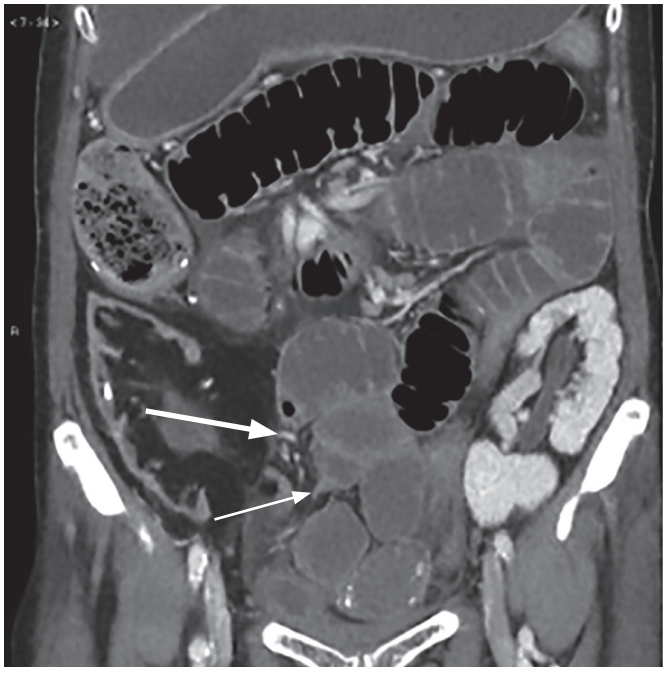

Figure 8.36 Coronal computed tomography showing a failed renal transplant in the right iliac fossa and second transplant in the left iliac fossa. There has also been a right hemicolectomy. There is proximal small bowel obstruction with dilated fluid-filled small bowel loops. Distal to the first point of obstruction (large arrow) there are dilated thick-walled fluid-filled loops in the pelvis with some adjacent free fluid, which could be followed to a second point of obstruction (small arrow). Laparotomy confirmed a closed loop obstruction secondary to an adhesive band with ischaemia in the segment of small bowel between the points of obstruction.

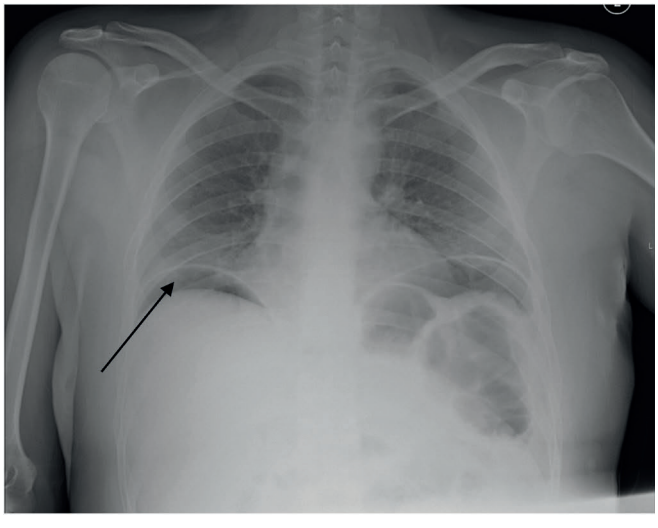

Figure 8.37 Erect chest radiograph showing subdiaphragmatic free gas (arrow) consistent with hollow organ perforation.

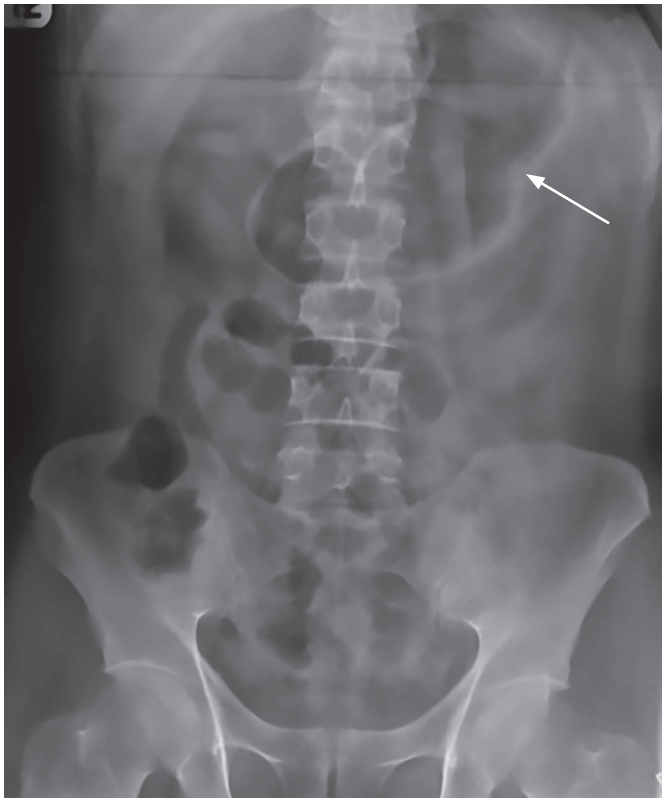

Figure 8.38 Plain abdominal radiograph showing an abnormal appearance to the gastric wall, which is very clearly visualised owing to the presence of gas both inside the lumen and outside the lumen (arrow). This is Rigler's sign of hollow organ perforation, in this case due to a duodenal ulcer.

Perforation

The erect chest x-ray (CXR) is the ideal first test for hollow organ perforation and as little as 10–20 mL of free air can be detected under the diaphragm (***Figures 8.37 and 8.38***). About 10 minutes should be left between sitting the patient upright and taking the film to allow time for air to rise; the free air must be sought under the right hemidiaphragm to prevent misinterpretation of the gastric air bubble; and the reviewer must be able to recognise Chilaiditi's syndrome, the harmless and asymptomatic interposition of large bowel between the liver and diaphragm. Caution must also be exercised in interpreting any free air in the context of recent abdominal surgery, as postoperative air can persist for up to 5–7 days in the peritoneal cavity.

If the erect CXR is equivocal or a possible walled-off perforation is suspected, a CT is the optimal modality, which may show tiny quantities of free air but may also show the cause, e.g. peptic ulcer, diverticulitis or a neoplastic lesion. As with suspected obstruction, oral or rectal contrast is unnecessary if perforation is suspected as making the diagnosis should prompt appropriate management even if the precise site of perforation is not identified. Also, it cannot be overstressed that if there is any possibility of a leak from the gastrointestinal tract (GIT)

Leo George Rigler, 1896–1979, American radiologist, described the double-wall sign in pneumoperitoneum.
Demetrius Chilaiditi, 1883–1975, Greek radiologist.

(including an anastomotic leak after surgery), then the use of barium is absolutely contraindicated as it can induce a serious and potentially fatal peritonitis.

Ischaemia/infarction

The most useful test when bowel ischaemia or infarction is suspected is a CT scan. Intravenous contrast administration is essential to look for thrombus/embolus in the mesenteric vessels, though ischaemia due to low-flow states can still occur in their absence. Ischaemia can be a difficult diagnosis to make radiologically but is suspected, in the appropriate clinical context, by bowel wall thickening, submucosal oedema and free fluid between the folds of the mesentery (particularly if haemorrhagic). Ischaemia must be strongly suspected if these findings are seen in association with a closed loop obstruction or strangulated hernia. Ischaemic colitis typically affects the 'watershed area', which is the junction of the areas supplied by the superior and inferior mesenteric arteries, typically in the region of the splenic flexure.

When bowel wall ischaemia proceeds to transmural infarction, the diagnosis is usually more straightforward with evidence of pneumatosis (air in the bowel wall) typically identified. The air in the bowel wall can then track into mesenteric veins and thence to the portal vein, a CT sign of grave prognostic significance in an adult as it implies widespread and relatively longstanding bowel infarction.

Gastrointestinal haemorrhage

The aetiology of acute gastrointestinal (GI) haemorrhage varies between the upper GIT (common causes including peptic ulcer disease, varices and Mallory–Weiss tears) and the lower GIT (common causes including angiodysplasia, diverticular haemorrhage and neoplastic lesions). While endoscopy is a useful first-line investigation for both, in refractory or occult GI haemorrhage radiology can also contribute to diagnosis and management. Nuclear medicine scans using radioisotope-labelled red blood cells are useful when bleeding is intermittent, but for patients suspected of active bleeding the best investigation is a CT mesenteric angiogram. Non-contrast scans to look for bright blood in the bowel lumen should be supplemented with scans in the arterial phase to assess for a blush due to active extravasation and the portal venous phase to optimise detection of wall thickening and masses and to look for sites of venous bleeding. If non-invasive imaging is effective, catheter angiography can be used to embolise a bleeding point.

Inflammatory processes

Appendicitis

Historically, a straightforward clinical diagnosis of appendicitis obviated any need for imaging, but with the proven accuracy of available modalities imaging has become increasingly popular to reduce negative appendicectomy rates and to make alternative diagnoses. While a plain radiograph may demonstrate a calcified appendicolith in the right iliac fossa, it is insufficiently sensitive or specific to be reliable. In children, who typically have a favourable body habitus, ultrasound is the best test as it reduces radiation exposure. This also applies to females of childbearing age, again to reduce radiation exposure, but also because the symptoms may be mimicked by gynaecological pathology, such as ectopic pregnancy, haemorrhagic ovarian cyst and tubo-ovarian abscess, all diagnoses that are best made with ultrasound. The definitive exclusion of appendicitis, however, hinges on the identification of a normal appendix, measuring less than 6 mm in diameter. Retrocaecal appendicitis can readily escape detection with ultrasound, and thus CT is the next modality of choice; indeed, frequently it is the first requested in most adults (***Figure 8.39***). The diagnosis of appendicitis on CT requires the identification of a thickened appendix (>7 mm), with periappendiceal inflammatory change as evidenced by stranding in the surrounding fat. Other signs that may be sought include free fluid, thickening of the caecal pole, possible localised small bowel ileus and right iliac fossa lymphadenopathy. Both CT and ultrasound can also identify collections if an inflamed appendix ruptures, and can be used to guide percutaneous drainage as a bridge to definitive surgery.

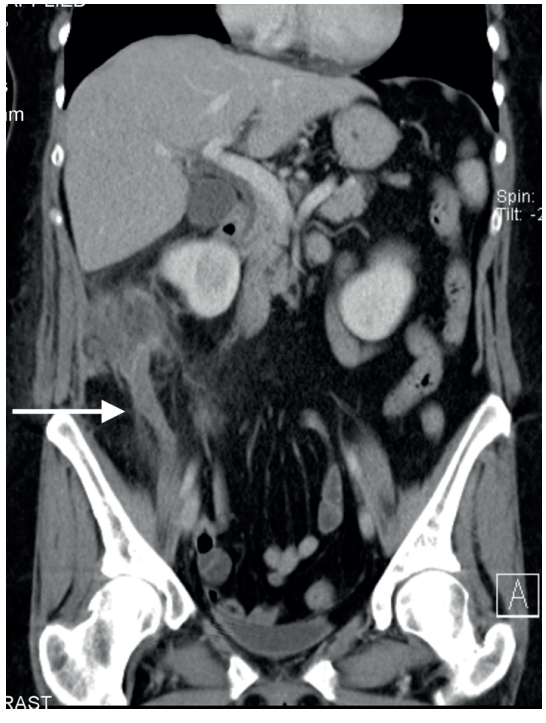

Figure 8.39 Acute appendicitis. Contrast-enhanced computed tomography scan reconstructed in the coronal plane demonstrates a thickened appendix in the right iliac fossa (arrow) with inflammatory changes in the surrounding fat and reactive thickening of the caecal pole.

George Kenneth Mallory, 1900–1986, Professor of Pathology, Boston University, Boston, MA, USA.
Soma Weiss, 1898–1942, Professor of Medicine, Harvard University Medical School, Boston, MA, USA.

Diverticulitis

Inflammation of an obstructed diverticulum typically presents with left iliac fossa pain and pyrexia (***Figure 8.40***). While some authors have promoted the use of focused ultrasound for this indication, in general it is best diagnosed with a CT scan. The typical CT appearance is of pericolic inflammatory change around a diverticulum, most commonly in the sigmoid colon. Complications of diverticulitis include perforation, abscess formation, fistulation to adjacent structures and strictures in the bowel. CT is also the modality of choice to identify these; as with appendicitis, it can be used to guide percutaneous abscess drainage as a bridge to definitive surgery.

Inflammatory bowel disease

The diagnosis of inflammatory bowel disease is made histologically. Radiologically, the diagnosis and monitoring of inflammatory bowel disease has changed significantly in recent years. Previously a barium study of the small bowel, either a follow-through (where barium is ingested orally) or enteroclysis (where dilute barium is infused via a nasojejunal tube) was used as a screening tool if symptoms are vague. If the diagnosis of Crohn's disease is established, barium studies can still be useful to demonstrate the extent of disease, particularly to demonstrate the length and number of strictures if surgery is planned. Increasingly, however, the role of barium studies has been superseded by cross-sectional imaging, particularly MRI enterography, which entails an abdominopelvic MRI scan after ingestion of an agent such as lactulose or mannitol to distend the small bowel. The other obvious advantage of MRI is the lack of radiation, which is particularly relevant in young patients with Crohn's disease, who often undergo multiple imaging studies over their lifetime; for this reason it is gaining in popularity for inflammatory bowel disease follow-up.

An acute flare-up may also require imaging, and an ultrasound is usually a good first test to look for dilated bowel loops and any abscess, though CT may ultimately be required as gas-filled bowel loops can obscure visualisation of an abscess on ultrasound. MRI is the imaging modality of choice to assess perianal fistulae and abscesses.

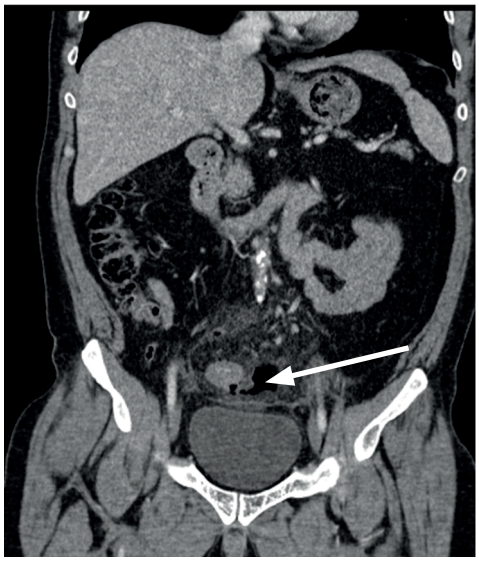

Figure 8.40 Coronal computed tomography reformatted images showing a diverticular perforation. There is stranding around the sigmoid colon with an extraluminal track of gas (arrow). Because of surrounding inflammatory changes diverticular perforation usually leads to pericolic localised gas collections rather than generalised pneumoperitoneum.

Acute pancreatitis

As with acute appendicitis, when the diagnosis is straightforward clinically there may be no need for imaging, though increasingly it is used to confirm the diagnosis, to assess the severity of the process and to look for complications. While ultrasound may show gallstones and can demonstrate an enlarged pancreas with peripancreatic fluid and inflammatory changes, the optimal modality is CT. CT performed too early in the course of the attack, e.g. in the first 12 hours, can be equivocal and the optimal timing of imaging is 48–72 hours.

In mild acute pancreatitis, CT may be normal or may show an enlarged oedematous gland, but in more severe attacks other findings which should be sought include peripancreatic fluid collections, vascular complications such as arterial pseudoaneurysm formation or venous thrombosis and necrosis, either of the gland itself or of the surrounding fat. Necrosis typically develops 48–72 hours after the onset of symptoms and is manifest on CT as lack of enhancement of the necrotic areas. CT with intravenous contrast is therefore essential to look for necrosis, which is potentially catastrophic, particularly if it becomes infected. While CT is not always reliable to diagnose infected necrosis, it is suggested by bubbles of air in the necrotic segment. As with other intra-abdominal inflammatory processes, either ultrasound or more usually CT can be used to guide percutaneous drainage of inflammatory fluid collections.

Acute cholecystitis/biliary colic/jaundice

While acute cholecystitis is usually due to mechanical obstruction of the cystic duct or gallbladder neck by a gallstone, acute acalculous cholecystitis can occur in critically ill patients from a number of causes. In any case ultrasound is the modality of choice should this diagnosis be suspected, and the classic diagnostic features are of gallbladder distension with wall thickening (>3 mm). A gallstone obstructing the gallbladder neck or cystic duct may be visualised; alternatively, in acalculous cholecystitis sludge may be seen layering in the gallbladder lumen. Associated signs include pericholecystic fluid and hyperaemia on Doppler examination. Ultrasonographic Murphy's sign refers to tenderness over the gallbladder when

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932 along with Leon Ginzburg and Gordon Oppenheimer.

John Benjamin Murphy, 1857–1916, Professor of Surgery, Northwestern University, Chicago, IL, USA, described his sign in 1903. He was the son of Irish immigrants fleeing the potato famine in Ireland, and was known as the 'Stormy Petrel' of American surgery, demonstrating the benefit of appendicectomy over conservative treatment among many things.

pressure is applied while scanning and is a supportive finding in making the diagnosis. As a second-line investigation CT is also accurate for this condition, demonstrating similar signs of gallbladder distension and wall thickening with surrounding inflammatory changes. CT is also useful to diagnose complications such as gangrenous cholecystitis, gallbladder perforation and emphysematous cholecystitis, which may necessitate emergency cholecystectomy. If cross-sectional studies are equivocal, hepatobiliary scintigraphy can be useful, with the diagnosis of acute cholecystitis suggested by non-visualisation of the gallbladder 3 hours after radioisotope administration.

A frequent limitation of ultrasound is failure to visualise the common bile duct throughout its length owing to overlying bowel gas, and elective cholecystectomy was typically accompanied by bile duct imaging or exploration to look for duct calculi. Increasingly, however, MRCP has been shown to be highly accurate in excluding bile duct calculi before surgery.

Ultrasound is also a useful first-line investigation for jaundice of unknown cause as it can demonstrate duct dilatation and gallstones. If a definitive cause is not shown with ultrasound, or a mass is identified but its precise nature and extent is uncertain, CT is indicated to look for common causes, including stones, cholangiocarcinoma and pancreatic carcinoma. CT can not only identify malignant lesions but also demonstrate the extent of local infiltration, including the very important assessment of vascular involvement if surgery is considered, and the presence of metastases to determine potential resectability. If the ducts are of normal calibre in a jaundiced patient, liver biopsy should be considered.

Renal colic

The historical methods of imaging for renal colic all have their limitations. Plain film radiography may not demonstrate all calculi, will not show renal tract obstruction and is unreliable for alternative diagnoses. IVU necessitates the administration of intravenous contrast and, if a level of obstruction is sought, delayed films up to 8 hours after injection may be required; it also will not provide alternative diagnoses. Ultrasound will demonstrate hydronephrosis and hydroureter, and calculi in the kidneys and either the proximal or distal ureters can usually be identified as echogenic foci with posterior acoustic shadowing; however, the ureter from just below the kidneys to the pelvis is usually obscured by bowel gas, which significantly impairs stone detection.

For these reasons the optimal investigation is now CT of the kidneys, ureters and bladder, a non-contrast, low-dose (2–3 MSv if a low mA scan is performed, equivalent to the dose from a limited IVU series) scan from the upper poles of the kidneys to the pubic symphysis. Contrast administration, either orally or intravenously, is not employed as it does not aid stone detection and may even impair it. Stones are readily identified as high-attenuation (typically calcific) foci, and the secondary signs of acute ureteric obstruction may also be seen, including hydronephrosis and hydroureter, renal enlargement and perinephric fat stranding. The most common sites for stones to be seen are at the areas of ureteric narrowing, namely the pelviureteric junction, the pelvic brim and vesicoureteric junction. CT also offers unrivalled capability for making alternative diagnoses when compared with other modalities.

Abdominal aortic aneurysm

If a pulsatile mass is felt in the abdomen and the diagnosis of a possible abdominal aortic aneurysm (AAA) is suspected, ultrasound is a useful modality; provided the aorta is not obscured by bowel gas, an aneurysm can usually reliably be excluded. If, however, ultrasound visualisation is suboptimal and the diagnosis is as a result equivocal, or if an aneurysm is identified and information regarding the extent and exact size is required, for example for surgical or endovascular repair planning, CT angiography is indicated, with the aorta typically scanned from the arch to the pubic symphysis in the arterial phase after intravenous contrast. MR angiography is a useful alternative if iodinated contrast is contraindicated.

In the case of suspected aneurysm rupture, provided the patient is sufficiently haemodynamically stable to undergo CT, CT angiography should be urgently performed; a supplementary non-enhanced initial scan is useful to look for retroperitoneal haematoma, which is typically of relatively high attenuation compared with the blood in the lumen on a non-contrast scan.

IMAGING IN ONCOLOGY

Modern surgical treatment of cancer requires an understanding of tumour staging systems, as in many instances the tumour stage will define appropriate management. The development of stage-dependent treatment protocols involving neoadjuvant chemotherapy and preoperative radiotherapy relies on the ability of imaging to determine stage accurately before surgical and pathological staging. The importance of accurate cancer staging is reflected in the central role of the radiologist in most MDT meetings.

Once a diagnosis of cancer has been established, often by percutaneous or endoscopic biopsy, new imaging techniques can considerably improve the ability to define the extent of tumour, although the pathological specimen remains the 'gold standard'. Many staging systems are based on the tumour–node–metastasis (TNM) classification.

Tumour

In most published studies, cross-sectional imaging techniques (CT, ultrasound, MRI) are more accurate in staging advanced (T3, T4) than early (T1, T2) diseases, and the staging of early disease remains a challenge. In gut tumours, endoscopic ultrasound is more accurate than CT or MRI in the local staging of early disease (T1, T2) by virtue of its ability to demonstrate the layered structure of the bowel wall and the depth of tumour penetration (***Figure 8.41***). Developments in MRI may also improve the staging accuracy of early disease. MRI is extremely valuable in bone and soft-tissue tumour staging and in intracranial and spinal disease.

Nodes

Accurate assessment of nodal involvement remains a challenge for imaging. Most imaging techniques rely purely on size criteria to demonstrate lymph node involvement, with

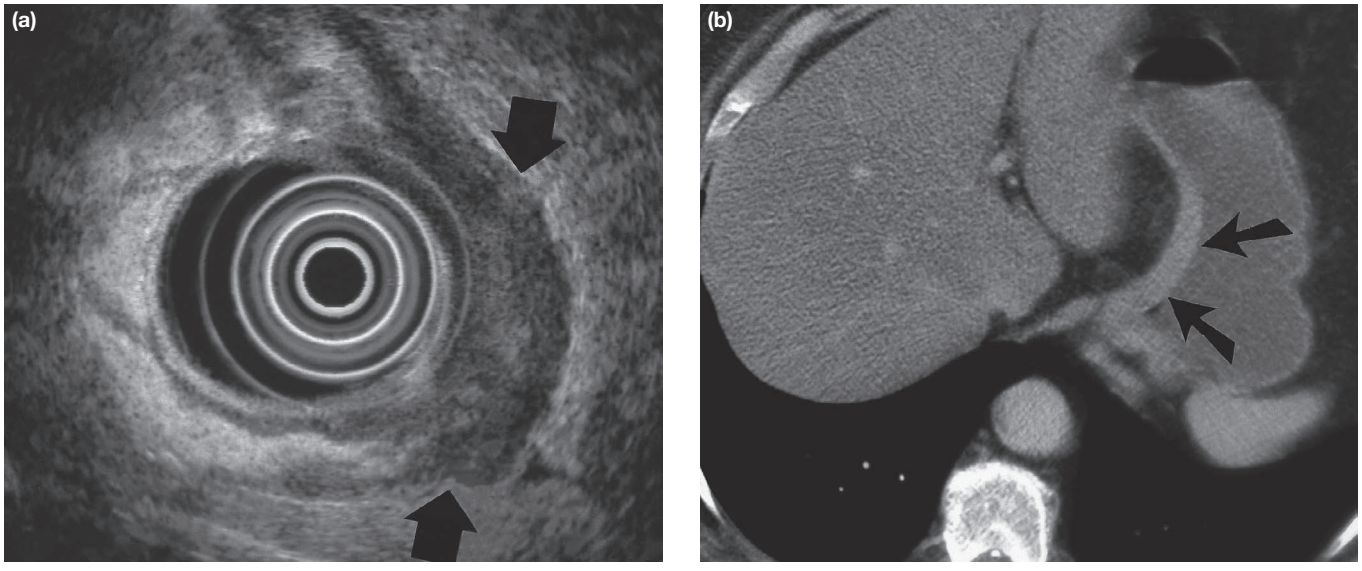

Figure 8.41 (a) Endoscopic ultrasound in gastric cancer. The hypoechoic tumour (arrows) is infiltrating the layered structure of the gastric wall and extending out beyond the serosa. **(b)** Computed tomography scan demonstrates thickening and enhancement of the gastric wall in the same area (arrows). The stomach is distended with water to provide low-density contrast.

no possibility of identifying micrometastases in normal-sized nodes. A size criterion of 8–10 mm is often adopted, but it is not usually possible to distinguish benign reactive nodes from infiltrated nodes. This is a particular problem in patients with intrathoracic neoplasms, in whom enlarged benign reactive mediastinal nodes are common. The echo characteristics of nodes at endoscopic ultrasound have been used in many centres to increase the accuracy of nodal staging, and nodal sampling is possible via either mediastinoscopy or transoesophageal biopsy under endoscopic ultrasound control. PET/CT is of increasing use in detecting nodal metastases from a wide range of malignancies, with the capacity to co-register the area of increased FDG uptake with a precise anatomical location. Novel MRI contrast agents may help in the identification of non-enlarged tumour-infiltrated nodes.

Metastases

The demonstration of metastatic disease will usually significantly affect surgical management. Modern cross-sectional imaging has greatly improved the detection of metastases, but occult lesions will be overlooked in between 10% and 30% of patients. CT is the most sensitive technique for the detection of lung deposits, although the decision to perform CT will depend on the site of the primary tumour, its likelihood of intrapulmonary spread and the effect on staging and subsequent therapy of the demonstration of intrapulmonary deposits.

Ultrasound and CT are most frequently used to detect liver metastases. Contrast-enhanced CT can detect most lesions greater than 1 cm, although accuracy rates vary with the technique used and range from 70% to 90%. Recent studies suggest that MRI may be more accurate than CT in demonstrating metastatic disease. Preoperative identification of the segment of the liver involved can be determined by translation of the segmental surgical anatomy, as defined by Couinaud, to the cross-sectional CT images (***Figure 8.42***).

The technique of PET/CT with FDG, an analogue of glucose, is becoming a powerful tool in oncological imaging. This functional and anatomical imaging technique reflects tumour metabolism and allows the detection of otherwise occult metastases. The most common indications for PET/CT have been staging of lymphoma, lung cancer, particularly non-small cell lung cancer, and preoperative assessment of potentially resectable liver metastases, such as colorectal carcinoma metastases (***Figure 8.43***).

Intraoperative ultrasound is an additional method of staging that provides superb high-resolution imaging of subcentimetre liver nodules that may not be palpable at surgery. This is often used immediately prior to resection of liver metastases.

Claude Couinaud, 1922–2008, French surgeon and anatomist, described the segmental anatomy of the liver in his seminal book *Le Foie: Études anatomiques et chirurgicales.*

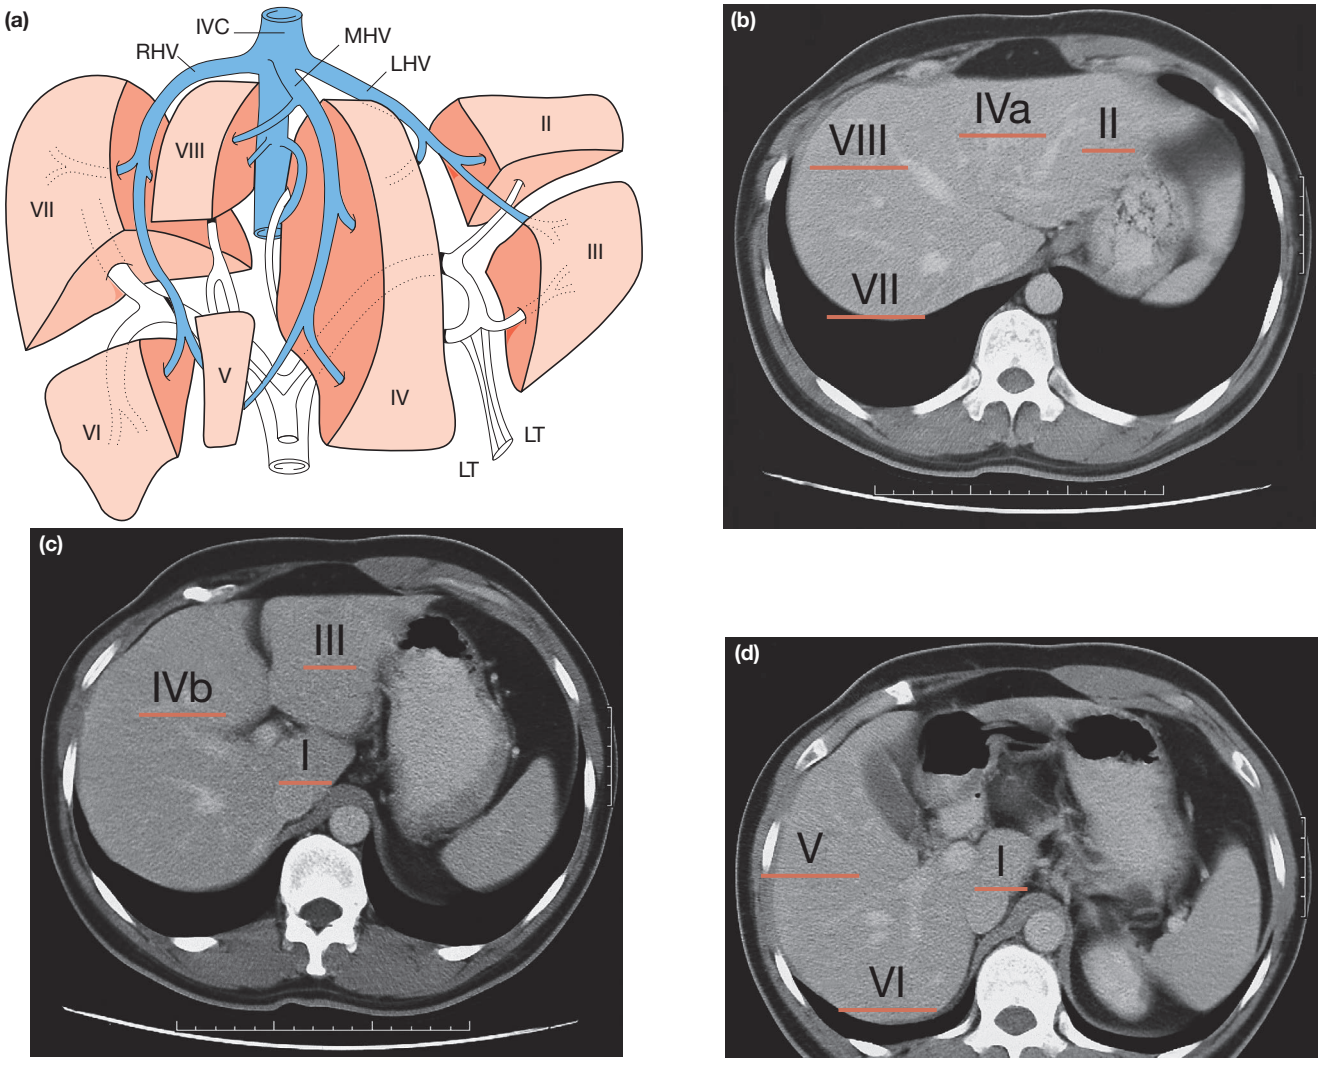

Figure 8.42 (a) Surgical lobes of the liver (after Couinaud). PART 1 | Basic principles

CHAPTER 9

Gastrointestinal endoscopy

Learning objectives

To gain an understanding of:

- The role of endoscopy as a diagnostic and therapeutic tool
- The basic organisation of an endoscopy unit and its equipment
- Consent and safe sedation
- Special situations: the key points in managing endoscopy in at-risk patients
- The indications for diagnostic and therapeutic endoscopic procedures including endoscopic ultrasound
- The recognition and management of complications
- Novel techniques for endoscoping the small bowel
- Advances in diagnostic ability

INTRODUCTION

The gastrointestinal tract has a myriad of functions, such as digestion, absorption and excretion, as well as the synthesis of an array of hormones, growth factors and cytokines. In addition, a complex enteric nervous system has evolved to control its function and communicate with the central and peripheral nervous systems. Finally, as the gastrointestinal tract contains the largest sources of foreign antigens to which the body is exposed, it houses well-developed arms of both the innate and acquired immune systems. Therefore, it is not surprising that malfunction or infection of this complex organ results in a wide spectrum of pathology. However, its importance in disease pathogenesis is matched only by its inaccessibility to traditional examination.

Few discoveries in medicine have contributed more to the practice of gastroenterology than the development of diagnostic and therapeutic endoscopy. Although spectacular advances in radiology have occurred recently with the introduction of multislice spiral computed tomography (CT) and magnetic resonance imaging (MRI), the ability to take targeted mucosal biopsies remains a unique strength of endoscopy. Historically, radiological techniques were required to image areas of jejunum and ileum inaccessible to the standard endoscope; however, the introduction of both capsule endoscopy and single-/double-balloon enteroscopy allows both diagnostic and therapeutic access to the entire gastrointestinal tract. Image enhancement with techniques such as chromoendoscopy, magnification endoscopy and narrow band imaging allows increased resolution at the mucosal level and increases diagnostic yield. Endoscopic ultrasound (EUS) can examine all layers of the intestinal wall as well as extraintestinal structures. Finally, experimental techniques such as confocal laser endomicroscopy give resolution at a level compatible with standard histology. The advances in the diagnostic accuracy of endoscopy lend themselves to disease surveillance for specific patient groups as well as population screening for gastrointestinal malignancy. Likewise, there has been a rapid expansion in the therapeutic capability of endoscopy with both luminal and extraintestinal surgery being performed via endoscopic access.

As in all areas of interventional practice, competent endoscopists must match a thorough grounding in anatomy and physiology with a clear understanding of the capabilities and limitations of the rapidly advancing techniques available. Perhaps most importantly they must appreciate all aspects of patient care, including preprocedural management, communication before and during the procedure and the management of endoscopic complications. This chapter aims to guide the reader through these areas in addition to introducing the breadth of procedures that are currently performed.

HISTORY OF ENDOSCOPY

Over the last 50 years, endoscopy has become a powerful diagnostic and therapeutic tool. However, its development required two obvious but formidable barriers to be overcome. First, the gastrointestinal tract is rather long and tortuous and, second, no natural light shines through the available orifices! Therefore, successful visualisation of anything beyond the distal extremities requires a flexible instrument with an intrinsic light source that can transmit images to the operator.

The breakthrough was the discovery that images could be transmitted using flexible quartz fibres. Although this was first described in the late 1920s, it was not until 1954 that Hopkins built a model of a flexible fibre imaging device. The

availability of highly transparent optical quality glass led to the development in 1958 of the first flexible fibreoptic gastroscope by Larry Curtiss, a graduate student in physics, and Basil Hirschowitz, a trainee in gastroenterology.

Over the next 30 years, the fibrescope evolved to allow examination of the upper gastrointestinal tract, the biliary system and the colon. In parallel with advances in diagnostic ability, a range of therapeutic procedures was developed (***Table 9.1***). Although the fibreoptic endoscope has been the workhorse of many endoscopy units over the last three decades, its obsolescence was guaranteed by the invention of the charge-coupled device (CCD) in the 1960s, which allowed the creation of a digital electronic image, permitting endoscopic images to be processed by a computer and transmitted to television screens. Thus, the modern endoscope was born (***Figure 9.1***).

Figure 9.1 Photograph of a standard gastroscope and colonoscope.

History does not sit still, and endoscopic evolution will continue with the replacement of much diagnostic endoscopy with capsule endoscopy and virtual imaging. Enhanced resolution with high-definition operating systems, dye and digital chromoendoscopy and even histological-grade images have increased the diagnostic yield of surveillance procedures. EUS allows diagnosis and therapy to extend beyond the mucosal surface of the intestine. Endoscopy has become increasingly therapeutic and historical divisions between medicine, radiology and surgery will become progressively blurred. As the complexity of the procedures increases, the distinction between specialist and general endoscopists will become more definite. This reinforces the need for all endoscopic practitioners to have a detailed understanding of the units in which they work and the instruments that they use.

THE MODERN ENDOSCOPY UNIT

Organisation

A well-designed endoscopy unit staffed by trained endoscopy nurses and dedicated administrative staff is essential to support good endoscopic practice and training. Clinical governance with regular appraisal and assessment of performance should be embedded within the unit's philosophy. Endoscopist training demands particular attention, with a transparent process of skills- and theory-based education centred on practical experience and dedicated training courses. Experienced supervision of all trainees is essential until competency has been obtained and assessed by an appropriately validated technique, such as direct observation of practical skills (DOPS) and review of procedure logbooks. All endoscopists should record diagnostic and therapeutic procedure numbers and markers of competency such as colonoscopy completion rates, polyp detection rates, mean sedation use and complication rates. Central to this is an efficient data management system that provides outcome analysis for all aspects of endoscopy, including adherence to guidelines, near misses, patient satisfaction, decontamination processes and scope tracking, as well as the more obvious completion and complication rates.

In the UK the Joint Advisory Group (JAG) provides guidance for endoscopist competence assessment and operates a certification system of individual endoscopic competencies, based on procedure numbers, key performance indicators (e.g. caecal intubation rate, adenoma detection, sedation levels, complications), course attendance and peer assessment.

Equipment

A full description of all available endoscopic equipment is beyond the scope of this chapter. However, each unit should have a sufficient range of endoscopes, processors and accessories as dictated by the local case mix and sufficient endoscope numbers to ensure smooth service provision. These should include both forward- and lateral-viewing gastroscopes, an enteroscope for proximal small bowel visualisation and a

Larry E Curtiss, physicist, University of Michigan, Ann Arbour, MI, USA.
Basil I Hirschowitz, 1925–2013, Professor of Medicine, University of Alabama, Birmingham, AL, USA.

range of adult and paediatric colonoscopes to aid examination of both redundant and fixed colons. Dedicated small bowel centres require capsule endoscopy and a single-/double-balloon enteroscope for ileojejunal visualisation and therapeutics. Larger centres will require linear and radial EUS, particularly if they specialise in gastrointestinal and hepatobiliary malignancy. An electrosurgical unit is the cornerstone of many therapeutic procedures, and this may be supplemented by argon plasma coagulation (APC), laser units and radiofrequency ablation for advanced therapeutics.

Instrument decontamination

Endoscopes will not withstand steam-based autoclaving and therefore require high-level disinfection between cases to prevent transmission of infection. Although accessories may be autoclaved, best practice requires the use of disposable single-use items whenever possible. All equipment should be decontaminated to an identical standard whether for use on immunocompromised/infected patients or not. This process involves two equally important stages: first, removal of physical debris from the internal and external surfaces of the instrument and, second, chemical neutralisation of all microbiological agents. A variety of agents are available and endoscopists should familiarise themselves with the agent in use in their department. In 2020 the British Society of Gastroenterology updated its guidelines for decontamination of endoscopes (see Further reading). Care should be applied to the decontamination of duodenoscopes because of reports of transmission of multiresistant bacteria (*Summary box 9.1*).

Summary box 9.1

Disinfection of endoscopes

- All channels must be brushed and irrigated throughout the disinfection process
- All instruments and accessories should be traceable to each use, patient and cleaning cycle
- All staff should be trained and protected (particularly if glutaraldehyde is used in view of its immune-sensitising properties)
- Regular monitoring of disinfectant power and microbiological contamination should be performed

There are currently no reliable means of decontaminating scopes from contact with prion-associated conditions such as variant Creutzfeldt–Jakob disease (vCJD), although risk of transmission of this is considered very low. If an 'invasive' procedure (where gut mucosa is breached and an unsheathed accessory withdrawn through the endoscope working channel) is conducted in a patient with known or possible vCJD, the endoscope needs to be quarantined after use. The performance of an invasive procedure in a patient at risk of vCJD owing to receipt of pooled plasma concentrates is no longer deemed to confer a high risk of endoscope contamination. A single quality assured decontamination cycle is considered sufficient, but the endoscope should be decontaminated separately from others with a single-use disinfectant. There is no longer a requirement to quarantine the endoscope provided that routine traceability data can be demonstrated.

CONSENT IN ENDOSCOPY

Approximately 1% of medical negligence claims in the USA relate to the practice of endoscopy. Many of these could have been avoided by a careful explanation of the procedure, including an honest discussion of the risks and benefits. Therefore, obtaining informed consent is a cornerstone of good endoscopic practice. It preserves a patient's autonomy, facilitates communication and acts as a shield against future complaints and claims of malpractice.

The most important aspect of the consent procedure is that a patient understands the nature, purpose and risk of a particular procedure, in addition to potential alternatives. Current guidelines would suggest that a patient should be informed of minor adverse events with a risk of more than 10% and serious events with an incidence of more than 0.5%. The key risks of endoscopy are summarised in *Summary box 9.2*. British Society of Gastroenterology Guidelines for Consent have been published (see Further reading).

Summary box 9.2

The risks of endoscopy

- Sedation-related cardiorespiratory complications
- Damage to dentition
- Aspiration
- Perforation or haemorrhage after endoscopic dilatation/therapeutic EUS
- Perforation, infection and aspiration after percutaneous endoscopic gastrostomy insertion
- Perforation or haemorrhage after flexible sigmoidoscopy/colonoscopy with polypectomy
- Pancreatitis, cholangitis, perforation or bleeding after endoscopic retrograde cholangiopancreatography

SAFE SEDATION

If performed competently the majority of diagnostic endoscopies and colonoscopies can be performed without sedation or with pharyngeal anaesthesia alone. However, therapeutic procedures may cause pain and patients are often anxious; thus, in most countries sedation and analgesia are offered to achieve a state of conscious sedation (not anaesthesia). Medication-induced respiratory depression in elderly patients or those with comorbidities is the greatest cause of endoscopy-

Hans Gerhard Creutzfeldt, 1885–1964, neurologist, Kiel, Germany.
Alfons Marie Jakob, 1884–1931, neurologist, Hamburg, Germany.

related mortality and, therefore, safe sedation practices are essential. The involvement of anaesthetists to advise on appropriate protocols is recommended. Endoscopy in certain situations (particularly paediatric endoscopy) requires a general anaesthetic – this should only be undertaken by appropriately trained staff with adequate equipment available.

Summary box 9.3

Sedation in endoscopy

- Pharyngeal anaesthesia may increase the risk of aspiration in more heavily sedated patients
- Comorbidities must be identified so that sedation can be individualised
- All sedated patients require secure intravenous access
- Benzodiazepines reach their maximum effect 9–20 minutes after administration – doses should be titrated carefully, particularly in the elderly or those with comorbidities
- Coadministration of opiates and benzodiazepines has a synergistic effect; opiates should be given first and doses need to be reduced
- The use of supplementary oxygen is essential in all sedated patients
- Sedated patients require pulse oximetry to monitor oxygen saturation; high-risk patients or those undergoing high-risk procedures also require blood pressure and electrocardiogram monitoring
- A trained assistant should be responsible for patient monitoring throughout the procedure
- Resuscitation equipment and sedation reversal agents must be readily available
- The use of anaesthetic agents such as propofol for complex procedures requires specialist training
- The half-life of benzodiazepines is 4–24 hours – appropriate recovery and monitoring is essential. Postprocedural consultations may not be remembered, and patients must be advised not to drink alcohol or drive for 24 hours

ENDOSCOPY IN PATIENTS WITH DIABETES

As approximately 2% of the population has diabetes, managing glycaemic control before and after endoscopy is an essential aspect of endoscopic practice. Each unit should develop a policy for managing diabetic control during endoscopy. Factors influencing management include the type of diabetes, the procedure that is planned, the preparation/recovery time and the history of diabetes control in the individual patient. Thus, a patient with poorly controlled insulin-dependent diabetes undergoing colonoscopy will require more input than a patient with type 2 diabetes on oral hypoglycaemic medication undergoing upper gastrointestinal endoscopy. All patients should bring their own medication to the unit and should be advised not to drive in case there is an alteration in their glycaemic control. Most patients can be managed using clear protocols on an outpatient basis; however, elderly patients and those with brittle control should be admitted. In general, patients with diabetes should be endoscoped first on the morning list. In complex cases the diabetes team should be involved.

ANTIBIOTIC PROPHYLAXIS

The majority of endoscopies can be performed safely without the need for routine antibiotic prophylaxis. However, given that certain endoscopic procedures are associated with a significant bacteraemia (*Table 9.2*), there are several specific situations where antibiotic cover is required to prevent either bacterial endocarditis, infection of surgical prostheses or systemic sepsis. In general, the risk of infection relates to the level of bacteraemia and the risk of the underlying medical condition. Traditionally, patients with a previous history of endocarditis or a metallic heart valve received antibiotic prophylaxis for all endoscopic procedures, and some national guidelines still reflect this. However, in 2009 UK guidelines changed in response to the low reported incidence of infective endocarditis in this patient group undergoing endoscopy. Patients with severe neutropenia may also require antibiotic prophylaxis for endoscopy. The antibiotic regime used will depend on local guidelines.

TABLE 9.2 Approximate incidence of bacteraemia in immunocompetent individuals following various procedures involving the gastrointestinal tract.

Procedure	Incidence of bacteraemia (%)[a]
Rectal digital examination	4
Proctoscopy	5
Barium enema	11
Tooth brushing	25
Dental extraction	30–60
Colonoscopy	2–4
Diagnostic upper gastrointestinal endoscopy	4
Sigmoidoscopy	6–9
ERCP (no duct occlusion)	6
ERCP (duct occluded)	11
Oesophageal varices band ligation	6
Oesophageal varices sclerotherapy	10–50[b]
Oesophageal dilatation/prosthesis	34–54
Oesophageal laser therapy	35
EUS +/– fine-needle aspirate	0–6

ERCP, endoscopic retrograde cholangiopancreatography; EUS, endoscopic ultrasound.
[a] Summary of published data.
[b] Higher after emergency than after elective management.

Procedures such as endoscopic percutaneous gastrostomy are associated with a significant incidence of wound or stoma infection, particularly if inserted for malignancy. Antibiotic prophylaxis reduces this complication and a single intravenous injection of co-amoxiclav should be administered before the procedure. Antibiotics are routinely used during endoscopic manipulation of an obstructed biliary tree in which it is unlikely that complete drainage will be achieved or there is significant comorbidity. When cystic cavities are aspirated at EUS, a one-off dose of a broad-spectrum antibiotic (e.g. co-amoxiclav) is recommended to prevent cyst infection.

ANTICOAGULATION IN PATIENTS UNDERGOING ENDOSCOPY

Many patients undergoing endoscopy may be taking a medication that interferes with normal haemostasis, such as warfarin, heparin, direct oral anticoagulants, clopidogrel or aspirin. The key points to remember when managing anticoagulants in patients undergoing endoscopy are given in *Summary box 9.4*.

Summary box 9.4

Managing anticoagulants in patients undergoing endoscopy

It is important to recognise and understand:

- The risk of complications related to the underlying gastrointestinal disease from anticoagulant therapy
- The risk of haemorrhage related to an endoscopic procedure in the setting of anticoagulant therapy
- The risk of a thromboembolic/ischaemic event related to interruption of anticoagulant therapy

Urgent endoscopy for gastrointestinal bleeding in the anticoagulated patient

The risk of clinically significant gastrointestinal bleeding in patients on warfarin is increased, particularly in patients with a past history of similar events, if the international normalised ratio (INR) is above the therapeutic range or if the patient is taking concomitant aspirin/non-steroidal anti-inflammatory drugs (NSAIDs). In these situations, the risk of reversing the anticoagulation must be weighed against the risk of ongoing haemorrhage. If complete reversal is not appropriate, correction of the INR to approximately 1.5 is usually sufficient to allow endoscopic diagnosis and therapy. Anticoagulation can often be resumed 24 hours after successful endoscopic therapy (*Figure 9.2*).

Elective endoscopy in patients on anticoagulants and antiplatelet agents

Endoscopic procedures vary in their potential to produce significant or uncontrolled bleeding. Diagnostic oesophagogastroduodenoscopy (OGD), colonoscopy, enteroscopy, diagnostic EUS and endoscopic retrograde cholangiopancreatography (ERCP) without sphincterotomy are considered low risk, as is mucosal biopsy. High-risk procedures include polypectomy, endoscopic sphincterotomy, stent placement and procedures with the potential to produce bleeding that is inaccessible or uncontrollable by endoscopic means, such as dilatation of benign or malignant strictures, percutaneous gastrostomy insertion and EUS-guided fine-needle aspiration. Likewise, the probability of a thromboembolic complication during temporary cessation of anticoagulant or antiplatelet therapy depends on the underlying medical condition (*Table 9.3*).

TABLE 9.3 The risk of a thromboembolic event varies according to the underlying medical condition.

Condition	Risk
Atrial fibrillation with valvular heart disease	High
Mechanical mitral valve	High
Mechanical valve and previous thromboembolic event	High
Deep vein thrombosis	Low
Uncomplicated atrial fibrillation	Low
Bioprosthetic valve	Low
Mechanical aortic valve	Low

Aspirin

Aspirin and NSAIDs inhibit platelet cyclo-oxygenase, resulting in suppression of thromboxane A_2-induced platelet aggregation. Limited published data do not suggest an increased bleeding risk in patients taking standard doses and, therefore, there is no need to discontinue therapy before endoscopic procedures.

UPPER GASTROINTESTINAL ENDOSCOPY

OGD is the most commonly performed endoscopic procedure. Excellent visualisation of the oesophagus, gastro-oesophageal junction, stomach, duodenal bulb and second part of the duodenum can be obtained. Retroversion of the gastroscope in the stomach is essential to obtain complete views of the gastric cardia and fundus (*Figure 9.3*). Traditional forward-viewing endoscopes do not adequately visualise the ampulla, and a side-viewing scope should be used if this is essential. Likewise, although it is possible to reach the third part of the duodenum with a standard 120-cm instrument, a longer enteroscope is required if views beyond the ligament of Treitz are required. In addition to clear mucosal views, diagnostic endoscopy allows mucosal biopsies to be taken, which may either undergo processing for histological examination or be used for near-patient detection of *Helicobacter pylori* infection using a commercial urease-based kit. In addition, brushings may be taken for cytology and aspirates for microbiological culture.

Indications for oesophagogastroduodenoscopy

A full assessment of the role of OGD is outside the scope of this chapter. It will vary with local circumstances and the availability of alternative diagnostic techniques. OGD is usually appropriate when a patient's symptoms are persistent despite appropriate empirical therapy or are associated with warning signs such as intractable vomiting, anaemia, weight loss, dysphagia or bleeding. It is also part of the diagnostic work-up for patients with anaemia, symptoms of

malabsorption and chronic diarrhoea. However, increasing ease of access to OGD with the availability of 'open access' endoscopy has resulted in a significant number of unnecessary procedures being performed in young patients with dyspepsia or gastro-oesophageal reflux disease (GORD). This has led to a number of international gastroenterology societies proposing guidelines for the management of dyspepsia and GORD, including the empirical use of acid suppression and non-invasive *H. pylori* tests, such as urease breath tests and stool antigen assay (e.g. the National Institute for Health and Care Excellence guidelines on dyspepsia: https://www.nice.org.uk/guidance/cg184/chapter/1-recommendations). In addition

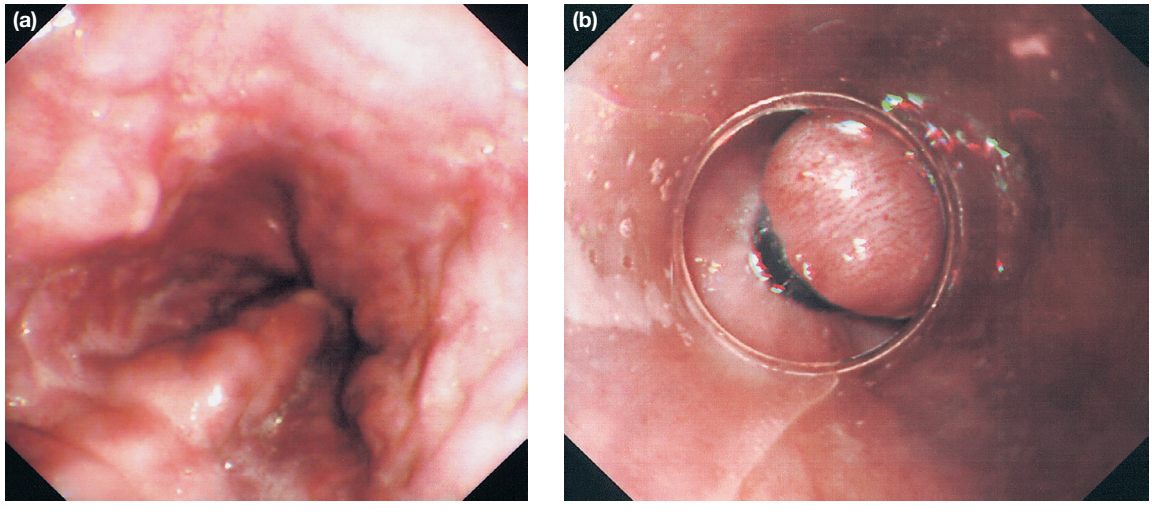

Figure 9.4 Grade 2 oesophageal varices **(a)**, which can be treated by the application of bands to ligate the vessel and reduce blood flow **(b)**.

to the role of OGD in diagnosis, it is also commonly used in the surveillance of neoplasia development in high-risk patient groups, such as those with genetic conditions such as familial adenomatous polyposis and premalignant conditions such as Barrett's oesophagus (see *Chapter 66*).

Therapeutic oesophagogastroduodenoscopy

Appropriate patient selection and monitoring are essential to minimise complications. The most common therapeutic endoscopic procedure performed as an emergency is the control of upper gastrointestinal haemorrhage of any aetiology. Band ligation has replaced sclerotherapy in the management of oesophageal varices (*Figure 9.4*), whereas sclerotherapy using thrombin-based glues can be used to control blood loss from gastric and duodenal varices. Injection therapy with adrenaline (epinephrine) coupled with a second haemostatic technique such as thermal coagulation or endoclip application is the technique of choice for a peptic ulcer with active bleeding or high-risk stigmata of haemorrhage (*Figure 9.5*). Such high-risk bleeds should be followed by 72 hours of intravenous proton pump inhibition. Chronic blood loss from angioectasia is most safely treated with APC because of the controlled depth of burn compared with alternative thermal techniques (*Figure 9.6*). Haemostatic powders provide a further way to arrest bleeding; these work best for diffuse bleeding or as salvage therapy.

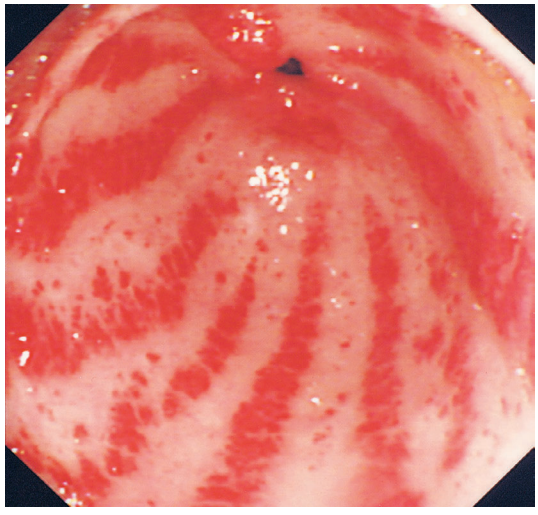

Figure 9.6 The classic appearance of gastric antral vascular ectasia, which is often treated with argon plasma coagulation.

Benign oesophageal and pyloric strictures may be dilated under direct vision with through-the-scope (TTS) balloon dilators or the more traditional guidewire-based systems such as Savary–Gilliard bougie dilators (*Figure 9.7*). On occasion, more difficult benign strictures can be treated by the insertion of a fully covered removable stent, or with a biodegradable stent. Likewise, the non-relaxing lower oesophageal sphincter associated with achalasia can be treated by pneumatic balloon

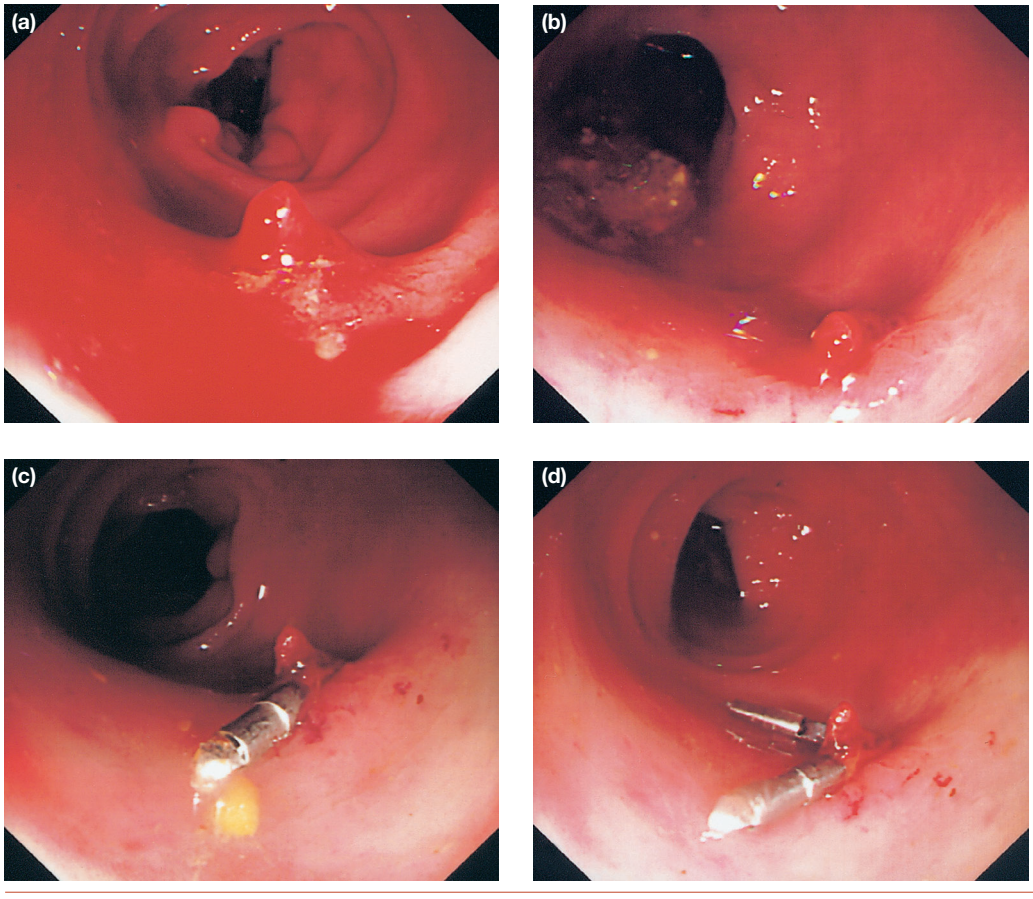

Figure 9.5 A gastric ulcer with active bleeding **(a)** is initially treated with adrenaline injection to achieve haemostasis **(b)**. Two haemoclips are then applied to prevent rebleeding **(c and d)**.

Norman Rupert Barrett, 1903–1979, surgeon, St Thomas's Hospital, London, UK.

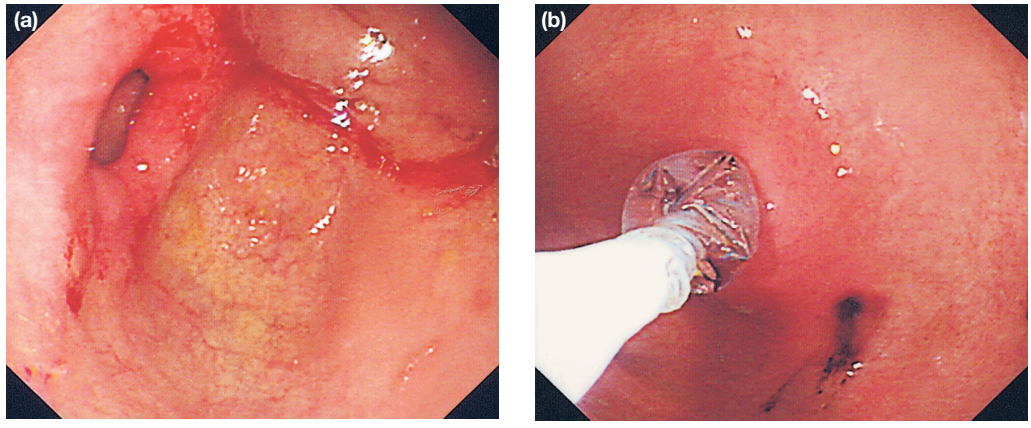

Figure 9.7 A pyloric stricture **(a)** can be dilated using a through-the-scope balloon under direct vision to minimise complications **(b)**.

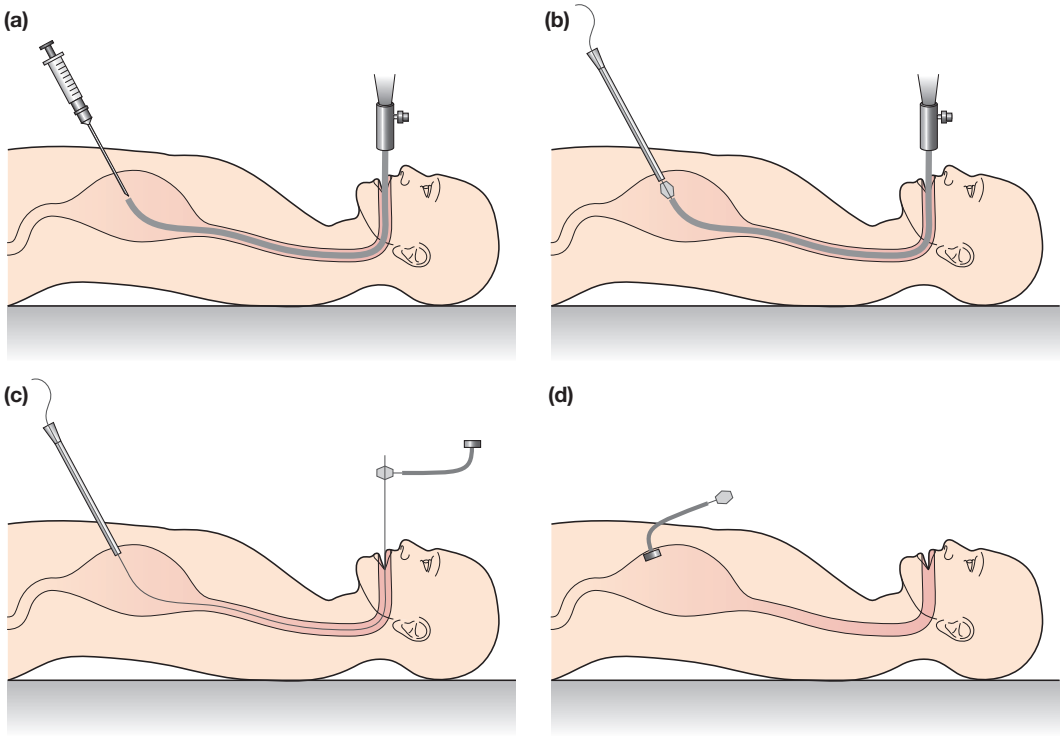

Figure 9.8 A schematic diagram of percutaneous endoscopic gastrostomy insertion. A standard endoscopy is performed to ensure that there are no contraindications to gastrostomy insertion. The stomach is insufflated with air and a direct percutaneous needle puncture made at a point where the stomach abuts the abdominal wall. Lignocaine is infused on withdrawal **(a)**. A trocar is inserted and a wire passed into the stomach, which can be caught with a snare **(b)**. The scope is withdrawn, pulling the wire out through the mouth, at which point it is attached to the gastrostomy tube **(c)**. The gastrostomy is pulled through into the stomach and out through the track created by the trocar insertion **(d)**.

dilatation with a 30- to 40-mm balloon. Endoscopic dissection techniques (see ***Therapeutic colonoscopy***) are now being employed to treat achalasia by natural orifice myotomy (peroral endoscopic myotomy; POEM) with good follow-up results. An alternative in unfit patients is injection of botulinum toxin into the lower oesophageal sphincter, although this has a limited (3–6 months) duration of benefit.

There are a limited number of endoscopic techniques available to reduce gastro-oesophageal reflux, which rely on tightening the loose gastro-oesophageal junction by plication, by the application of radiofrequency ablation or by mucosal resection techniques. These may have a role in some patients but are yet to demonstrate benefit over surgical fundoplication.

Endoscopic bariatric therapies, such as intragastric balloons, sleeve gastroplasty and duodenal resurfacing, may all provide alternatives to more established surgical options. In contrast, there is clear evidence that the insertion of a percutaneous endoscopic gastrostomy (PEG) tube enhances nutritional and functional outcome in patients unable to maintain oral nutritional intake (***Figure 9.8***). PEG insertion is often a prelude to treatment of complex orofacial malignancy and may be used to support nutrition in patients with alternative malignant, degenerative or inflammatory diseases.

The deployment of self-expanding metal stents with or without a covering sheath inserted over a stiff guidewire leads to a significant improvement in symptomatic dysphagia and quality of life in patients with malignant oesophageal and gastric outlet obstruction (***Figure 9.9***). Covered stents are the mainstay of treatment for benign or malignant tracheo-oesophageal fistulae.

It is now possible to endoscopically manage early oesophageal and gastric neoplasia with endoscopic mucosal resection (EMR) or endoscopic submucosal dissection (ESD). These techniques require specialist training but have allowed

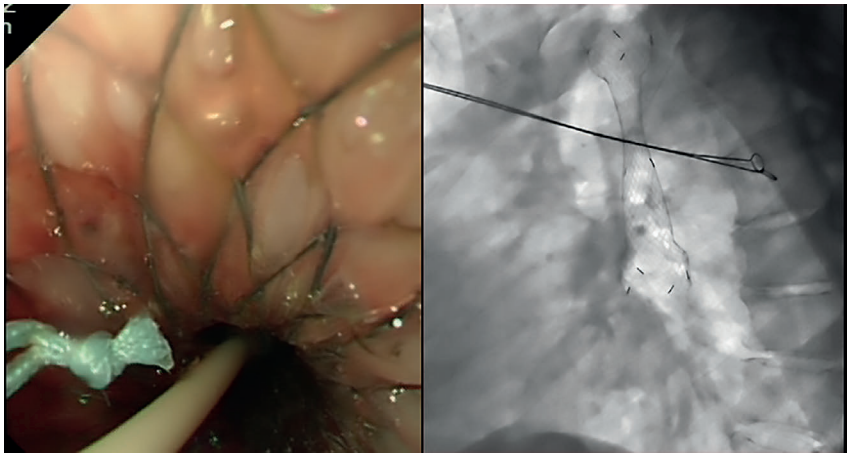

Figure 9.9 A self-expanding metal stent may alleviate symptoms relating to malignant oesophageal strictures. (Left) An endoscopic view of a deployed stent, and (right) the radiographic image.

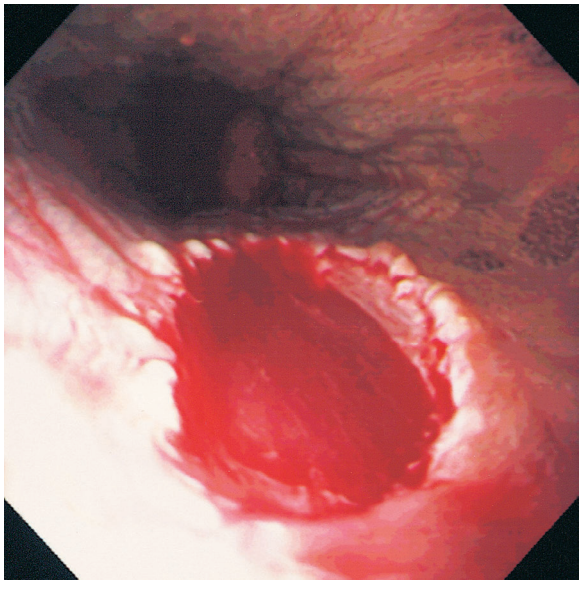

Figure 9.10 Novel upper gastrointestinal therapeutic uses of oesophagogastroduodenoscopy include the use of endoscopic mucosal resection to remove early gastric cancer leaving a clean base.

endoscopic management of mucosal lesions that were previously subject to surgical intervention (*Figure 9.10*). A prime example has been improved endoscopic treatment of Barrett's high-grade dysplasia and early oesophageal adenocarcinoma. Destruction of residual Barrett's epithelium in cases of low- or high-grade dysplasia is possible with endoscopic ablation, and has been shown to reduce risk of progression to cancer. The most commonly used technique for this purpose is radiofrequency ablation, where 360° ablation can be achieved with a balloon catheter, or more focused ablation with smaller probes. Cryotherapy and APC can also be used for ablation, but photodynamic therapy is now used much less often.

Complications of diagnostic and therapeutic oesophagogastroduodenoscopy

Diagnostic upper gastrointestinal endoscopy is a safe procedure with minimal morbidity as long as appropriate patient selection and safe sedation practices are embedded in the unit's policy. The rate of serious complications is approximately 1:10 000. The majority of adverse events relate to sedation and patient comorbidity. Particular caution should be exercised in patients with recent unstable cardiac ischaemia and respiratory compromise. Perforation can occur at any point in the upper gastrointestinal tract, including the oropharynx. It is rare during diagnostic procedures and is usually associated with inexperience. Perforation is more common in therapeutic endoscopy, particularly oesophageal dilatation and EMR/ESD for early malignancy. Early diagnosis significantly improves outcome and can potentially be managed endoscopically with clips or endoscopic suturing.

Prompt management includes radiological assessment using CT/water-soluble contrast studies, strict nil by mouth, intravenous fluids and antibiotics and early review by an experienced upper gastrointestinal surgeon.

Summary box 9.5

Symptoms of endoscopic oesophageal perforation

- Neck/chest pain
- Increasing tachycardia
- Dysphagia/drooling saliva
- Hypotension
- Abdominal pain
- Surgical emphysema

ENDOSCOPIC ASSESSMENT OF THE SMALL BOWEL

Introduction and indications

The requirement to visualise, biopsy and treat the small bowel is far less than in the stomach, biliary tree or colon, resulting in a time lag in technological advances. The most frequent indication is investigation of gastrointestinal blood loss, which may present with either recurrent iron deficiency anaemia (occult haemorrhage) or recurrent overt blood loss per rectum (cryptic haemorrhage) in a patient with normal OGD (with

duodenal biopsies) and colonoscopy. Other indications include the investigation of malabsorption; the exclusion of cryptic small bowel inflammation such as Crohn's disease in patients with diarrhoea/abdominal pain and evidence of an inflammatory response; targeting lesions seen on radiological investigations; and surveillance for neoplasia in patients with inherited polyposis syndromes.

A standard enteroscope is able to reach and biopsy lesions detected in the proximal small bowel; however, even in the most experienced hands this is limited to approximately 100 cm distal to the pylorus, although the use of a stiffening overtube may increase this somewhat. The procedure takes approximately 45 minutes and may be uncomfortable, requiring high doses of sedation with the attendant increased risk of perforation and sedation-related morbidity.

Therefore, until recently, barium follow-through or enteroclysis were the most effective imaging modalities to visualise the distal duodenum, jejunum and ileum. Obviously, these techniques do not give true mucosal views, and outside specialist centres their decreasing use has led to diminished expertise and a reduced diagnostic yield. There have been rapid advances in axial radiological techniques such as MRI and CT enterography, which demonstrate excellent diagnostic accuracy in this area (see ***Chapter 8***). However, although these techniques may yield information about vascularity and bowel wall thickening, they do not allow direct mucosal views, have no biopsy capability and have limited scope in terms of therapeutics. Historically, if an area of interest was outside the reach of a standard enteroscope, direct access via enterotomy under either laparoscopic or open surgery was required. Two major clinical advances have revolutionised small bowel diagnosis and therapeutics. First, the development of the capsule endoscope allows diagnostic mucosal views of the entire small bowel to be obtained with minimal discomfort in unsedated patients. Second, the novel technique of single-/double-balloon enteroscopy allows endoscopic access to the entire small bowel for biopsy and therapeutics (***Table 9.4***).

TABLE 9.4 Comparison of the advantages and disadvantages of the currently available modalities to endoscope the small intestine.

Technique	Advantages	Disadvantages
Conventional enteroscopy	Simple technique with wide availability Full range of therapeutics available Performed under sedation	Some discomfort Can only access proximal small bowel
Capsule endoscopy	Able to visualise the entire small bowel Preferable for patients No sedation Painless	No biopsies Not controllable and no accurate localisation Variable transit Incomplete studies owing to battery life Not suitable for patients with strictures Large capsule to swallow
Double-/single-balloon enteroscopy	Able to visualise the entire small bowel Full range of therapeutics	Requires admission Specialist centres only Complications include perforation

Capsule endoscopy

The prototype capsule endoscope was developed at the Royal London Hospital in the UK by Professor Paul Swain. Several companies have developed different systems for routine clinical use, but the basic principles remain identical. The technique requires three main components: an ingestible capsule, a portable data recorder and a workstation equipped with image-processing software. The capsule consists of an optical dome and lens, two light-emitting diodes, a processor, a battery, a transmitter, and an antenna encased in a resistant coat the size of a large vitamin pill (***Figure 9.11***). It acquires video images during natural propulsion through the digestive system that it transmits via a digital radiofrequency communication channel to the recorder unit worn outside the body; this also contains sensors that allow basic localisation of the site of image capture within the abdomen. Upon completion of the examination, the physician transfers the accumulated data to the workstation for interpretation via a high-capacity digital link. The workstation is a modified personal computer required for off-line data storage, interpretation and analysis of the acquired images and report generation.

The small bowel capsule provides good visualisation from mouth to colon with a high diagnostic yield. It compares favourably with other techniques for localisation of occult gastrointestinal bleeding and the diagnosis of small bowel Crohn's disease. Use of the capsule endoscope is contraindicated in patients with known small bowel strictures in which it may impact, resulting in acute obstruction and requiring retrieval at laparotomy or via laparoscopy. Severe gastroparesis and pseudo-obstruction are also relative contraindications to its use. Some units advocate a barium follow-through or small bowel MRI to exclude stricturing disease in all patients before capsule endoscopy. However, there are well-reported episodes of capsule impaction in a stricture that was not visualised on prior imaging. Therefore, a 'dummy' patency capsule that can be tracked via a handheld device or conventional radiology as it passes through the intestine should be used in all patients in whom there is a possibility of stricturing disease. The patency capsule will dissolve after 40 hours if it becomes impacted. Technology in this field is rapidly advancing, with capsule systems now available to image the colon.

Single-/double-balloon enteroscopy

This technique allows the direct visualisation of and therapeutic intervention for the entire small bowel and may be attempted via either the oral or rectal route. Double-balloon enteroscopy involves the use of a thin enteroscope and

Christopher Paul Swain, b. 1943, gastroenterologist, The Royal London Hospital, London, UK.
Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

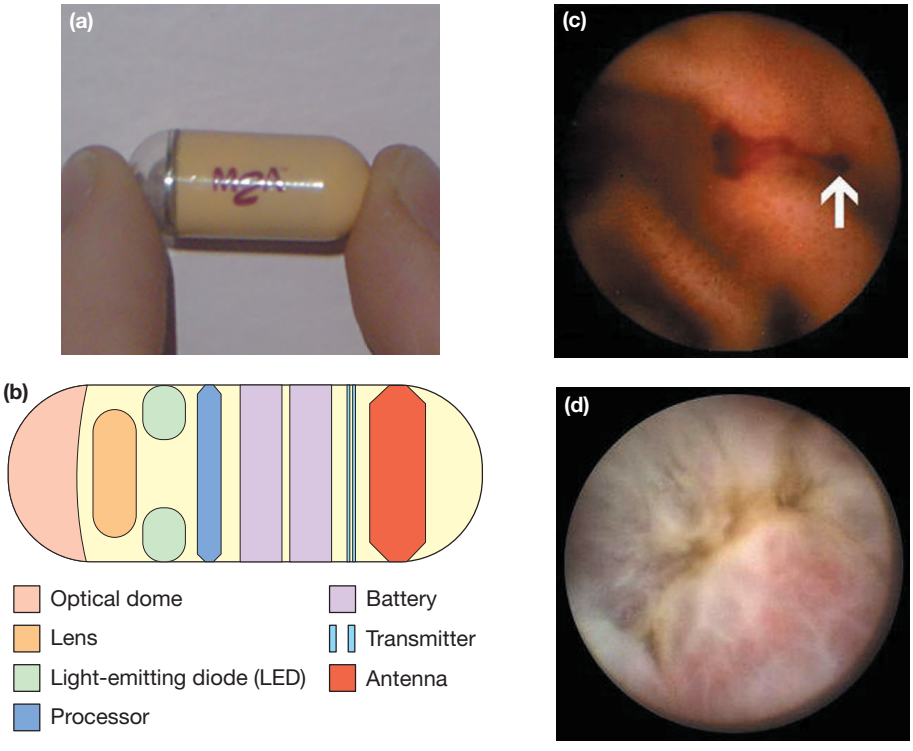

Figure 9.11 Complete diagnostic visualisation of the small bowel can be achieved with capsule endoscopy **(a)**. The structure of the capsule is shown in **(b)**. Clear mucosal pictures can be achieved, here showing angioectasias (arrow) **(c)** and small bowel Crohn's disease **(d)**.

an overtube, which are both fitted with a balloon. The procedure is usually carried out under general anaesthesia but may be undertaken with the use of conscious sedation. The enteroscope and overtube are inserted through either the mouth or anus and steered to the proximal duodenum/terminal ileum in the conventional manner. Following this the endoscope is advanced a small distance in front of the overtube and the balloon at the end is inflated. Using the assistance of friction at the interface between the enteroscope and intestinal wall, the small bowel is accordioned back to the overtube. The overtube balloon is then deployed and the enteroscope balloon is deflated.

The process is then continued until the entire small bowel is visualised (*Figure 9.12*). In single-balloon enteroscopy, developed more recently, an enteroscope and overtube are used, but only the overtube has a balloon attached. A full range of therapeutics including diagnostic biopsy, polypectomy, APC and stent insertion are available for balloon enteroscopy. Some experts advocate routine capsule endoscopy before balloon enteroscopy in an attempt to localise any lesions and plan whether oral or rectal access is more appropriate. The indications for single-/double-balloon endoscopy are given in *Summary box 9.6*.

Summary box 9.6

Current established indications for single-/double-balloon endoscopy

- Bleeding from the gastrointestinal tract of obscure cause
- Iron deficiency anaemia with normal colonoscopy and gastroscopy
- Visualisation of and therapeutic intervention for abnormalities seen on traditional small bowel imaging/capsule endoscopy

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

This procedure involves the use of a side-viewing duodenoscope, which is passed through the pylorus and into the second part of the duodenum to visualise the papilla. This is then cannulated, either directly with a catheter or with the help of a guidewire (*Figure 9.13*). Occasionally a small precut is required to gain access. By altering the angle of approach one can selectively cannulate the pancreatic duct or biliary tree, which is then visualised under fluoroscopy after contrast injection. The significant range of complications associated with this procedure and improvements in radiological imaging using magnetic resonance cholangiopancreatography (MRCP) have rendered much diagnostic ERCP obsolete, and thus most procedures are currently performed for therapeutic purposes. There is still a role for accessing cytology/biopsy specimens.

Therapeutic endoscopic retrograde cholangiopancreatography

It is essential to ensure that patients have appropriate assessment prior to therapeutic ERCP, which is associated with a significant morbidity and occasional mortality. All patients require routine blood screening including a clotting screen. Both cardiac and oxygen saturation monitoring are required during the procedure because of the high level of sedation that is often required.

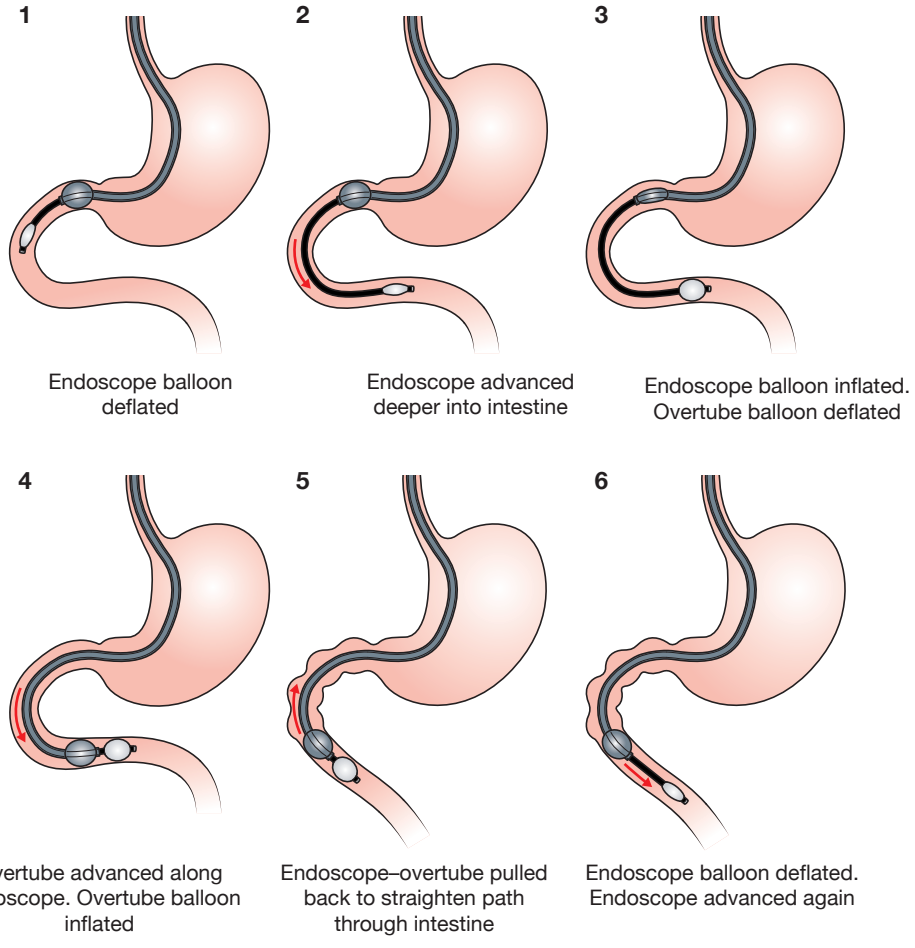

Figure 9.12 The technique of double-balloon enteroscopy is performed with an adapted enteroscope and overtube, both of which have inflatable balloons at their tip.

The most common indication for therapeutic ERCP is relief of biliary obstruction due to gallstone disease or benign or malignant biliary strictures. The preprocedural diagnosis can be confirmed by contrast injection, which will clearly differentiate the filling defects associated with gallstones and the luminal narrowing of a stricture. If there is likely to be a delay in relieving an obstructed system, percutaneous drainage may be required.

The cornerstone of gallstone retrieval is an adequate biliary sphincterotomy, which is normally performed over a well-positioned guidewire using a sphincterotome connected to an electrosurgical unit. Most gallstones <1 cm in diameter will pass spontaneously in the days and weeks following a sphincterotomy, but most endoscopists prefer to ensure duct clearance at the initial procedure to reduce the risk of impaction, cholangitis or pancreatitis. This can be achieved by trawling the duct using a balloon catheter or by extraction using a wire basket. If standard techniques fail, large or awkwardly placed stones can be crushed using mechanical lithotripsy. If adequate stone extraction cannot be achieved at the initial ERCP it is imperative to ensure biliary drainage with the placement of a removable plastic stent while alternative options are considered. These include surgery, endoscopically directed shockwaves under direct choledochoscopic vision and extracorporeal shockwave lithotripsy with subsequent ERCP to remove stone fragments.

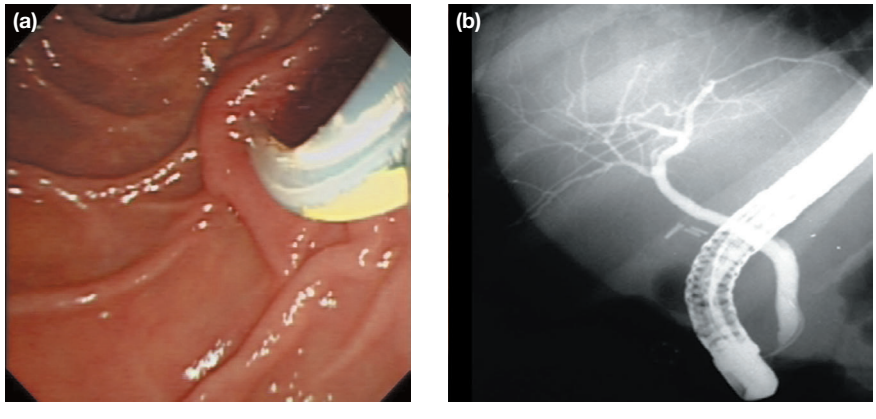

Figure 9.13 During endoscopic retrograde cholangiopancreatography a side-viewing duodenoscope is positioned opposite the papilla, which can then be cannulated using either a catheter or a guidewire **(a)**. Contrast is injected to achieve a cholangiogram **(b)**.

Dilation of benign biliary strictures uses balloon catheters similar to those used in angioplasty inserted over a guidewire under fluoroscopic control. It is traditional to insert a temporary plastic stent to maintain drainage as several attempts at dilatation may be required. Self-expanding metal stents are most commonly used for the palliation of malignant biliary obstruction and are also normally inserted after a modest sphincterotomy. Correct stent placement can normally be confirmed by a flow of bile after release and by the presence of air in the biliary tree on follow-up plain abdominal radiographs. Stent malfunction, associated with recurrent or persistent biochemical cholestasis, may be due to poor initial stent position, stent migration, blockage with blood clot or debris or tumour ingrowth. A repeat procedure is required to assess the cause, which can usually be remedied by the insertion of a second stent through the original one.

In addition to the standard techniques discussed above, ERCP is also used for pancreatic disease and the assessment of biliary dysmotility (sphincter of Oddi dysfunction) using manometry in specialist centres. Indications include pancreatic stone extraction, the dilatation of pancreatic duct strictures and the transgastric drainage of pancreatic pseudocysts. To minimise the risks of subsequent pancreatitis, pancreatic sphincterotomy is most safely performed after the placement of a temporary pancreatic stent to prevent stasis within the pancreatic duct.

Visualisation and sampling of biliary lesions is becoming easier and more effective with the development of newer through-the-duodenoscope cholangioscopes that allow direct visualisation and instrumentation of the biliary and pancreatic ducts.

Complications associated with endoscopic retrograde cholangiopancreatography

The same risks associated with other endoscopic procedures also apply to patients undergoing ERCP, but risks may be increased because of the increased patient frailty and high sedation levels required. Complications specific to ERCP include duodenal perforation (1.3%), haemorrhage (1.4%) after sphincterotomy, pancreatitis (4.3%) and sepsis (3–30%); the mortality rate approaches 1%. It is important to remember that postsphincterotomy complications may be retroperitoneal and CT scanning should be performed in patients with pain, tachycardia or hypotension post procedure.

Although normally mild, post-ERCP pancreatitis can be severe with extensive pancreatic necrosis and is associated with a significant mortality rate (***Table 9.5***). Where there is no contraindication, patients undergoing ERCP should receive per-rectal indometacin or diclofenac immediately before or after the procedure to reduce the risk of post-ERCP pancreatitis.

TABLE 9.5 Risk factors for post-ERCP pancreatitis.

Definite	Suspected SOD
	Young age
	Normal bilirubin
	Prior ERCP-related pancreatitis
	Difficult cannulation
	Pancreatic duct contrast injection
	Pancreatic sphincterotomy
	Balloon dilatation of biliary sphincter
Possible	Female sex
	Low volume of ERCPs performed
	Absent CBD stone

CBD, common bile duct; ERCP, endoscopic retrograde cholangiopancreatography; SOD, sphincter of Oddi dysfunction.

COLONSCOPY

Early attempts at colonoscopy were hindered by poor technique and limitations of available instruments. The ability to steer an endoscope around the entire colon and into the terminal ileum was made possible by the development of fully flexible colonoscopes with >90° angulation of the tip. Advances in bowel preparation have enhanced mucosal visualisation. Understanding two key technical aspects of colonoscopy allows a greater caecal intubation rate and ileal intubation with minimal discomfort using light sedation. The first is that continued inward pressure of the endoscope results in loop formation within the mobile sigmoid and transverse colon, which in turn leads to paradoxical movement and loss of fine tip control. The second is that pulling back the scope regularly with appropriate torque to ensure a straight passage through the sigmoid colon and around the splenic flexure greatly aids the completion of right-sided examination.

Endoscopic navigation systems such as Scope Guide (Olympus) and Scope Pilot (Pentax) can help to characterise the nature of the loop, allowing for more accurate loop resolution techniques. Increasing the stiffness of the colonoscope, targeted abdominal pressure and regular patient position change are also important aids to successfully reaching the caecum. It is expected that the caecum should be reached in at least 90% of colonoscopies and is confirmed by the presence of the appendiceal orifice, the triradiate fold, the ileocaecal valve and preferably terminal ileal intubation (***Figure 9.14***). Historically, air was used to insufflate the bowel, but carbon dioxide is now preferred owing to better patient tolerance and lower risk of perforation. Recent evidence has suggested that using water alone to distend the colon may reduce patient discomfort further.

The ability to take mucosal biopsies and resect polyps ensures that colonoscopy is the most appropriate investigation for the majority of patients. In selected groups, CT colonography

Ruggero Oddi, 1866–1913, anatomist and physiologist, Perugia, Italy, wrote about the structure and function of the ampullary sphincter in 1887, when still a student. He struggled in later life with drug addiction.

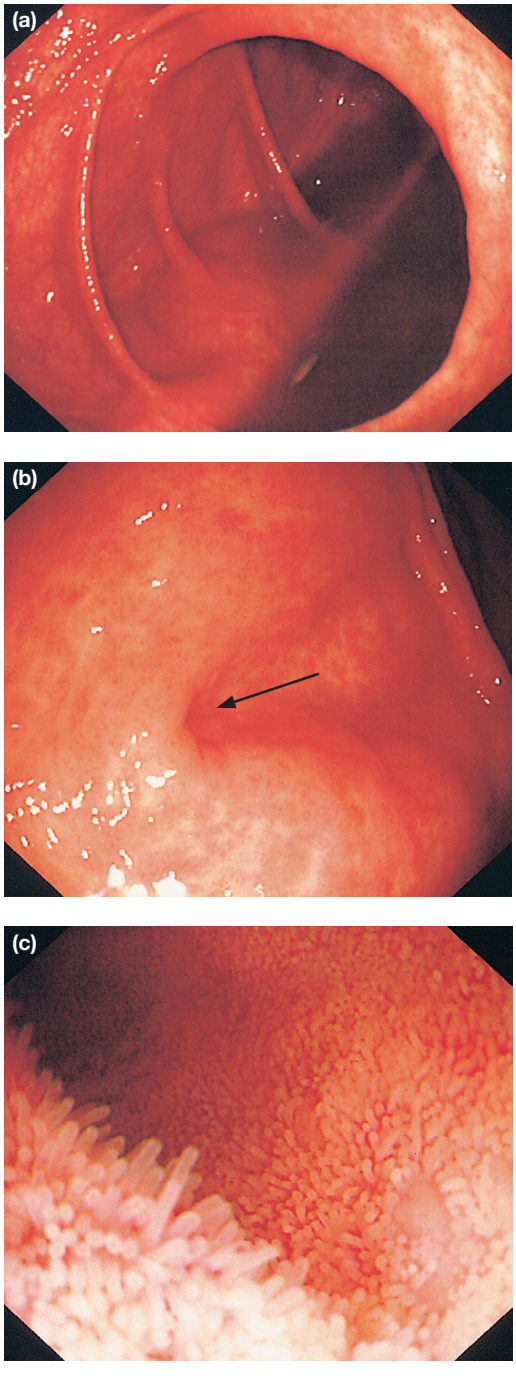

Figure 9.14 The caecal pole may not be easy to identify **(a)** and, therefore, the endoscopist should confirm complete colonoscopy by visualising the appendix orifice **(b)** (arrow) or preferably intubating the terminal ileum **(c)**, which demonstrates villi and Peyer's patches.

and colon capsule endoscopy provide an alternative route for investigating colonic pathology, though these are limited by the inability to acquire tissue. Accordingly, colonoscopy remains the cornerstone of most colorectal cancer (CRC) screening programmes globally, whether it is used as the initial screening modality or following a faecal immunochemical test (FIT).

The goal is to increase the number of early-stage CRCs detected and hence decrease mortality, as well as to identify and remove adenomatous polyps prior to the development of overt cancer. Higher adenoma detection rates (ADRs) are associated with lower rates of interval cancers and, as such, the ADR is an important indicator of colonoscopy quality. ADRs can be improved with measures such as a longer time taken on withdrawal from the caecum, optimal bowel preparation, patient position changes and a 'second look' of the right colon by changing patient position or by retroflexing the colonoscope. Distal attachments, such as a transparent cap or an Endocuff Vision™, can improve ADRs further.

Summary box 9.7

Indications for colonoscopy

- Rectal bleeding unexplained after proctoscopy/sigmoidoscopy (see *Chapter 77*)
- Abdominal pain related to bowel actions
- Iron deficiency anaemia (combined with OGD)
- Right iliac fossa mass if imaging suggestive of colonic origin
- Unexplained alteration in bowel habit
- Chronic diarrhoea (>6 weeks) after sigmoidoscopy/rectal biopsy and negative coeliac serology
- Follow-up of CRC and polyps
- Screening of patients with a family history of CRC
- Assessment/removal of a lesion seen on radiological examination
- Assessment of ulcerative colitis/Crohn's extent and activity
- Surveillance of inflammatory bowel disease
- Surveillance in patients with acromegaly or following ureterosigmoidostomy

Optical diagnosis and image enhancement

With the assistance of advanced imaging techniques, endoscopists are now able to characterise colorectal polyps with high diagnostic accuracy. This begins with a white light assessment: polyps larger than 2 cm with a large sessile component or a depressed region have the highest risk of containing cancer. Application of advanced imaging techniques can improve diagnostic accuracy further (***Figure 9.15***).

Dye-based chromoendoscopy involves topical application of stains or pigments to improve mucosal characterisation. Several agents have been described, which can broadly be categorised as absorptive (vital) stains, such as methylene blue, and contrast (reactive) stains, such as crystal violet and indigo carmine. These highlight the mucosal pits, which can aid optical diagnosis; different lesions demonstrate specific pit patterns. Dye chromoendoscopy is still widely used and remains the recommended method of dysplasia detection in inflammatory bowel disease.

Narrow band imaging (NBI; Olympus) relies on optical filter technology that radically improves the visibility of

Johann Conrad Peyer, 1653–1712, Professor of Logic, Rhetoric and Medicine, Schaffhausen, Switzerland, described the lymph follicles in the intestine in 1677.

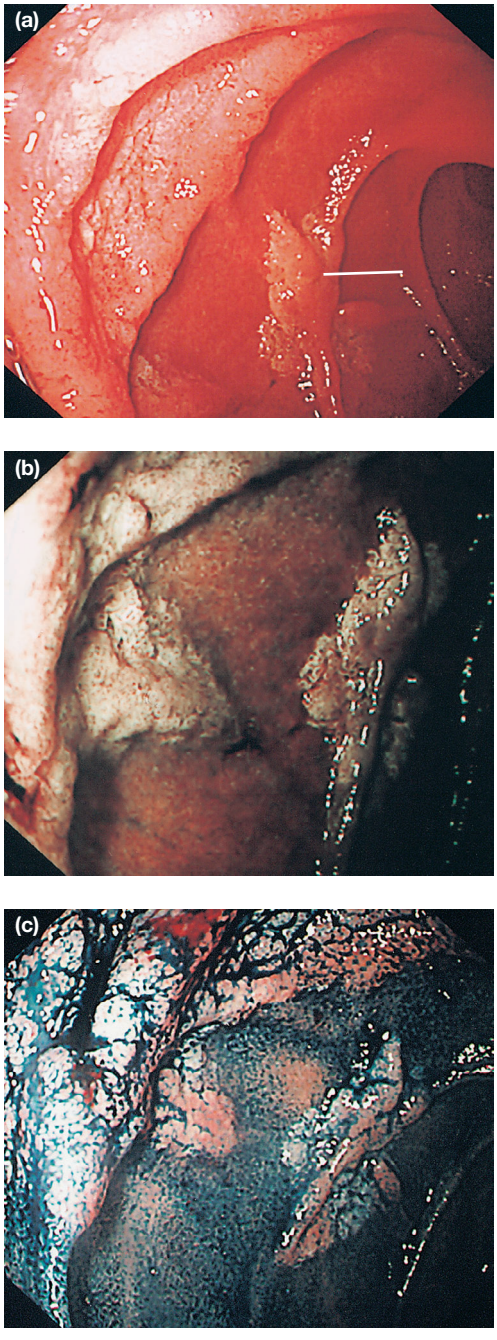

Figure 9.15 Endoscopic diagnostic accuracy can be improved by novel endoscopic techniques. This duodenal adenoma can be seen with conventional white light (a) (arrow), but its full extent is more clearly delineated using narrow band imaging (b) or chromoendoscopy with indigo carmine (c).

capillaries, veins and other subtle tissue structures by optimising the absorbance and scattering characteristics of light. NBI uses two discrete bands of light: one blue at 415 nm and one green at 540 nm. Narrow band blue light displays superficial capillary networks, whereas green light displays subepithelial vessels; when combined they offer an extremely high contrast image of the tissue surface. Similar modalities such as i-Scan (Pentax) and Blue Light Imaging (BLI; Fujifilm) are also available.

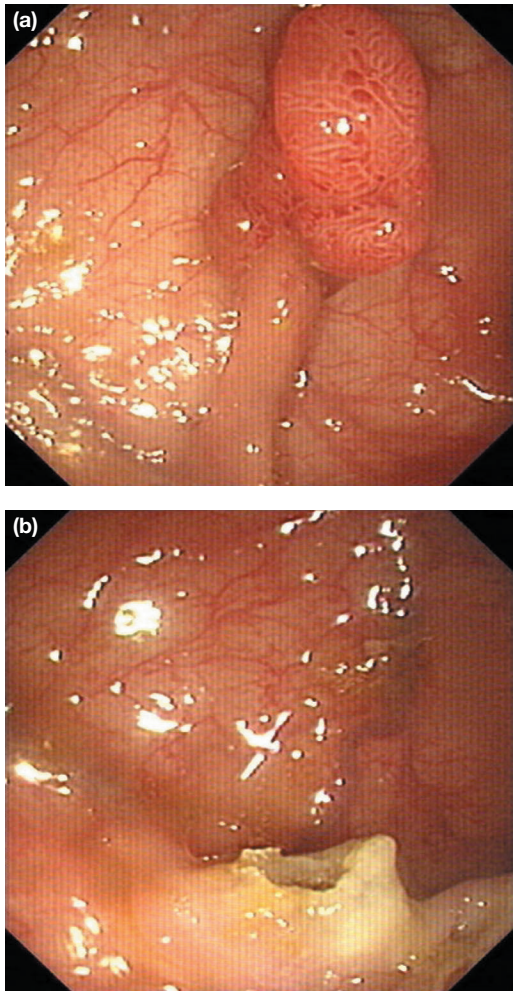

Figure 9.16 Colonoscopy is the most appropriate investigation to detect colonic polyps (a), which can be removed by snare polypectomy during the same procedure, leaving a clean polyp base (b).

Dye-based and digital enhancement, particularly when combined with magnification endoscopy, can differentiate between hyperplastic, serrated, adenomatous and malignant pathology. Combining this with a detailed white light assessment allows endoscopists to determine endoscopic resectability, avoiding more extensive surgery in some cases.

Therapeutic colonoscopy

The most common therapeutic procedure performed at colonoscopy is resection of colonic polyps (*Figure 9.16*). Retrieved specimens can be assessed for risk factors for neoplastic progression and an appropriate surveillance strategy determined (https://www.bsg.org.uk/wp-content/uploads/2019/09/201.full_.pdf). Non-pedunculated polyps up to 15 mm should be removed by cheese wiring with a dedicated 'cold' snare. Stalked polyps can be resected using 'hot' snare polypectomy. Here, diathermy is used with either a 'cut', 'coagulation' or a blended current. Postpolypectomy bleeding can be prevented by preinjection of the stalk with adrenaline, or with application of endoclips or an Endoloop®.

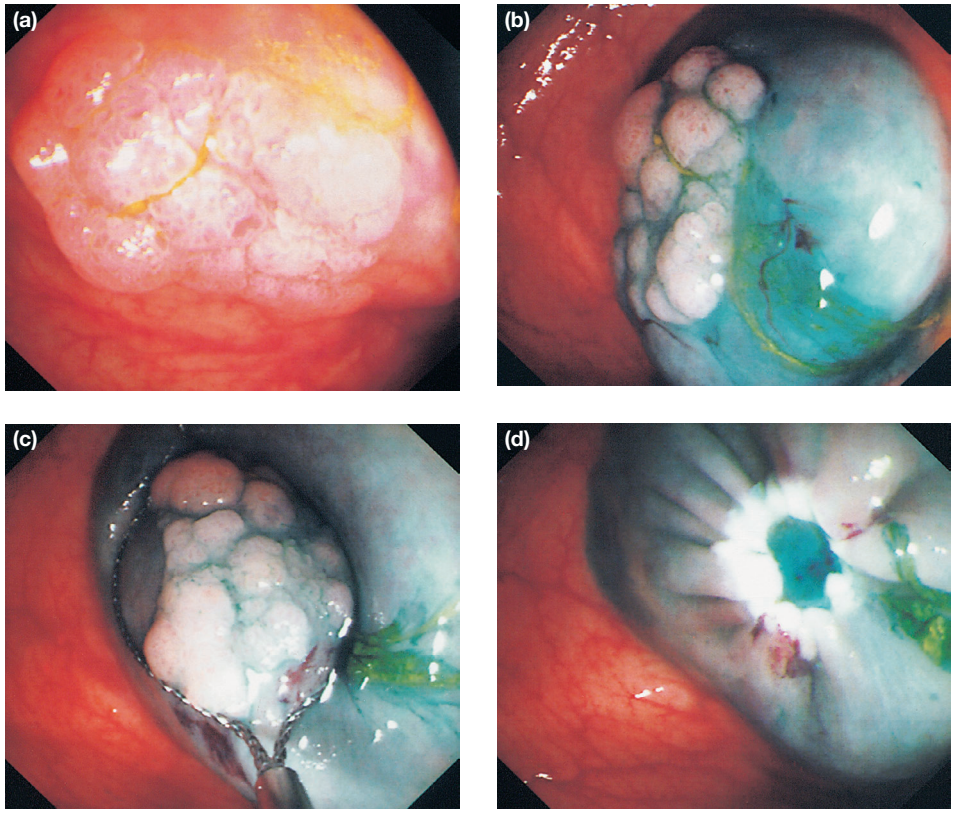

Figure 9.17 Large sessile polyps **(a)** can be removed by endoscopic mucosal resection. First the polyp is raised on a bed of injected saline containing dye **(b)**. This ensures that there is no submucosal invasion and protects from transmural perforation. A snare is closed around the polyp **(c)**, which is then resected leaving a clean excision base **(d)**.

Non-pedunculated polyps of between 10 and 19 mm can be removed en bloc by EMR, which involves lifting the polyp from the muscularis propria with a submucosal injectate to prevent iatrogenic perforation (***Figure 9.17***). Lesions >20 mm can be removed with piecemeal EMR (pEMR); on completion, thermal ablation (with either APC or coagulation) is applied to the edge of the resection site to prevent adenoma recurrence. An alternative to pEMR is ESD, which is typically performed with a knife rather than a snare. This technique involves the injection of a submucosal solution, followed by a circumferential incision and submucosal dissection, with coagulation of blood vessels that are encountered. This enables an en bloc resection of large polyps and superficial submucosal cancers. Although technically challenging with a steep learning curve, benefits include a more accurate histopathological assessment and lower adenoma recurrence rates.

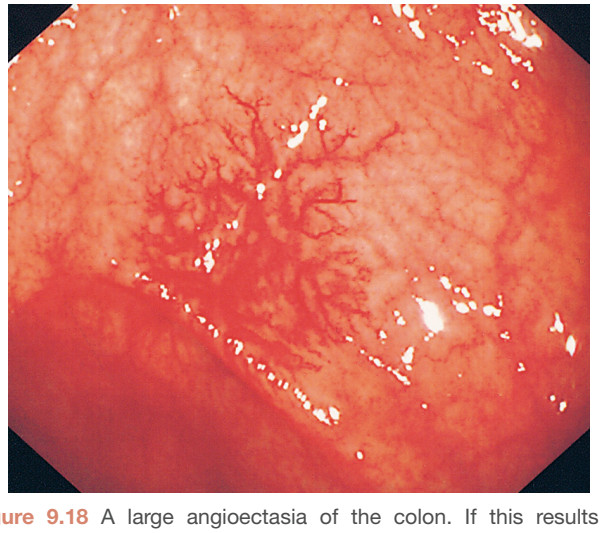

Figure 9.18 A large angioectasia of the colon. If this results in symptomatic anaemia, it should be obliterated with argon plasma coagulation.

APC and alternative thermal therapies such as heater probes are also used in the treatment of symptomatic angioectasias of the colon (***Figure 9.18***). Laser photocoagulation may be used to debulk colonic tumours not suitable for resection. As with benign oesophageal strictures, TTS balloons can be used to dilate short (<5 cm) colonic strictures. The dilatation of surgical anastomoses gives the most durable benefit as inflammatory strictures tend to recur even if intramucosal steroids are injected at the time of the dilatation. Finally, the colonoscopic placement of self-expanding metal stents may provide excellent palliation of inoperable malignant strictures (***Figure 9.19***) and may also play an invaluable role in decompressing an obstructed colon to allow planned as opposed to emergency surgery.

Complications of colonoscopy

Complications during routine diagnostic colonoscopy are rare when performed by an experienced endoscopist. Extensive diverticulosis, diverticulitis and severe colitis are risk factors for perforation during colonoscopy. In the case of colitis, an unprepared flexible sigmoidoscopy is usually sufficient for diagnostic purposes. Polypectomy is associated with an increased rate of perforation (0.1%) and haemorrhage (0.3%). Immediate haemorrhage can be managed with endoclips or snare-tip

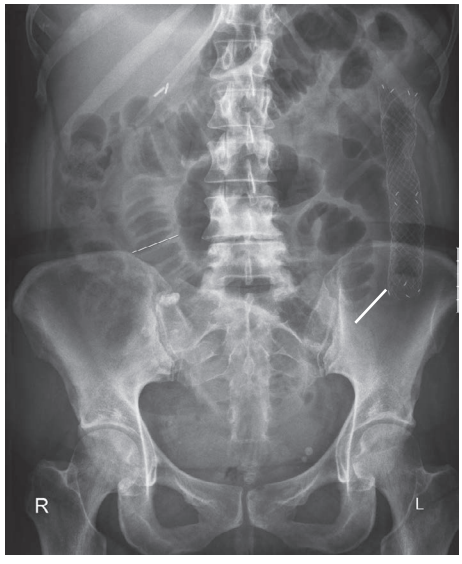

Figure 9.19 Malignant colonic obstruction can be palliated or temporarily relieved by insertion of a self-expanding metal stent (arrow).

coagulation. Delayed haemorrhage may occur 1–14 days post polypectomy and can normally be managed by conservative observation. Transfusion may occasionally be required, and a repeat colonoscopy may be necessary. If recognised at the time of polypectomy, small perforations should be closed using endoclips and the patient may need a period of observation. Symptoms of abdominal pain and cardiovascular compromise after a polypectomy raise the possibility of a delayed perforation and faecal contamination. Patients should be kept nil by mouth and receive intravenous resuscitation and antibiotics. Prompt assessment with a CT scan will often distinguish between a frank perforation and a transmural burn with associated localised peritonitis (the postpolypectomy syndrome). Assessment by an experienced colorectal surgeon is essential, as surgery is often the most appropriate course of action.

ENDOSCOPIC ULTRASOUND

One disadvantage of conventional endoscopy is that examination is limited to the mucosal surface, and it is not possible to diagnose submucosal or extraintestinal pathology. These limitations can be overcome using EUS, which combines the traditional mucosal image with a separate ultrasound view that clearly depicts the intestinal layers and proximate extraintestinal structures. Its use has revolutionised the staging and management of upper gastrointestinal and hepatobiliary malignancy.

There are two main types of echoendoscope: the radial echoendoscope has a radially arranged ultrasound probe and a forward-viewing lens. This is used for diagnostic work such as local tumour staging in the oesophagus and stomach. The linear echoendoscope is a side-viewing scope with a working channel much like an ERCP scope, and a linearly arranged ultrasound probe. This conformation allows ultrasound assessment and ultrasound-guided sampling of tissues to be performed (***Figures 9.20 and 9.21***). Sampling of paraoesophageal and coeliac lymph nodes and pancreatic, biliary and other solid abdominal lesions as well as drainage of peripancreatic abscess or pseudocysts can be performed. Using TTS Cystotomes™ it is possible to perform EUS cystgastrostomy and stent placement, and increasingly biliary interventional procedures are being performed with EUS assistance.

EUS requires dedicated training, in both scope manipulation and radiographic interpretation. Owing to the width and lack of flexibility of the endo-ultrasound scope as well as the duration of complex therapeutic procedures, sedation is normally required, and some units perform tests using propofol-based anaesthesia. The main indications for EUS are listed in ***Table 9.6***. All patients undergoing therapeutic EUS require a normal coagulation screen. Complications include oversedation and oesophageal perforation during diagnostic procedures and haemorrhage/perforation during therapeutic procedures.

Diagnostic	Staging of oesophageal/gastric malignancy
	Staging of hepatobiliary malignancy
	Diagnosis of choledochal microlithiasis
Therapeutic	Biopsy of paraoesophageal lymph nodes
	Biopsy of submucosal upper gastrointestinal lesions
	Biopsy of pancreaticobiliary mass
	Biopsy of portal lymphadenopathy
	Biopsy of left adrenal and left liver masses
	Transgastric drainage of pancreatic pseudocyst
	Coeliac plexus block

CONCLUSIONS

Over the last 30 years endoscopy has become an integral part of the diagnostic work-up of patients with gastrointestinal disease. Whereas advances in radiology and capsule studies may obviate the need for some diagnostic procedures, the ability to take mucosal biopsies will ensure that it retains a vital role. Ongoing developments in technology such as magnifying endoscopy and chromoendoscopy give near-histological quality definition and there is considerable interest in the role of artificial intelligence to augment near-patient diagnosis. There have also been major advances in the range of conditions that are amenable to endoscopic therapy; such therapy may have substantially lower associated morbidity rates than traditional surgical approaches. However, as the scope of procedures widens and the age range/comorbidities of the patients increases, it is beholden on the endoscopist to ensure that he or she adheres to appropriate governance/consent and sedation practice to minimise complications.

PART 1 | Basic principles

CHAPTER 10

Principles of minimal access surgery

Learning objectives

To understand:

- The principles of minimal access surgery
- The advantages and disadvantages of minimal access approaches
- The safety issues and indications for minimal access surgery
- The perioperative assessment of patients undergoing minimal access surgery
- Novel advances in minimal access surgery and its adjuncts
- The application of artificial intelligence to minimal access surgery

DEFINITION

Minimal access surgery is a product of modern technology and surgical innovation that aims to accomplish surgical therapeutic goals with minimal somatic and psychological trauma. This type of surgery has reduced wound access trauma and is less disfiguring than conventional techniques. It can offer cost-effectiveness to both health services and employers by shortening operating times, shortening hospital stays, improving operative precision compared with open surgery in some (but not all) cases and allowing faster recuperation.

History of minimal access surgery

The first experimental laparoscopic procedure was performed by Kelling in 1901. Jacobaeus performed the first thoracoscopy in 1910, again using a cystoscope; however, it took another 70 years before Steptoe in the UK developed laparoscopy for treatment of infertility and Mouret performed the first video-laparoscopic cholecystectomy in 1987. Since laparoscopic techniques became widely adopted in the mid-1990s, minimal access surgery has developed into a multidisciplinary approach that crosses all traditional specialty boundaries and serves the patient as a whole and not specific organ systems.

MINIMAL ACCESS APPROACHES

Laparoscopy

A rigid endoscope is introduced through a port into the peritoneal cavity. Full details of laparoscopy including the principles of pneumoperitoneum can be found in *Chapter 7*.

Thoracoscopy

A rigid endoscope is introduced through an incision placed between the ribs to gain access to the thorax. In the majority of cases, specialist anaesthetic support is required to ensure isolation of the lung on the side of surgery, enabling the patient to be ventilated only on the non-operative side. This is achieved through the use of right- or left-sided double lumen endotracheal tubes that comprise both a bronchial and a tracheal lumen. Usually there is no requirement for gas insufflation as the operating space is held open by the rigidity of the thoracic cavity. In specific cases, such as mediastinal tumour resection and diaphragmatic surgery, gas insufflation at low pressure (5–8 mmHg) may be applied. Further information on the general principles of thoracoscopy are found in *Chapter 60*.

Single-incision minimal access surgery

Single-incision minimal access surgery has varied in popularity with both strong advocates and others who are sceptical of any advantages. Single-incision laparoscopic surgery (SILS) involves insertion of all instrumentation through a multiple channel port via a single incision at the umbilicus. The benefits are that the incision, through a natural scar (the umbilicus), is virtually 'scarless' and that fewer port sites potentially reduces pain and lessens the risks of port site bleeding and the potential for port site hernia.

SILS requires specially manufactured multichannel ports and often roticulating instruments. It has most commonly been adopted in gallbladder and hernia surgery, although more

Georg Kelling, 1866–1945, surgeon, Dresden, Germany, performed the first 'celioscopy' on a dog in 1901 using air insufflation and a Nitze-cystoscope.
Hans Christian Jacobaeus, 1879–1937, physician, Karolinska Institutet, Sweden.
Patrick Christopher Steptoe, 1913–1988 gynaecologist, Oldham, UK, a pioneer of *in vitro* fertilisation.
Phillippe Mouret, 1938–2008, surgeon, Lyon, France.

complex colon and rectal surgery can be performed. There remains debate as to whether the increased procedural difficulty, steep learning curve and increased direct costs in terms of devices, instruments and operating time can be offset by significant clinical benefit.

Uniportal thoracic surgery requires less specialist equipment; many minor thoracic procedures are commonly performed using this technique. More complex resectional procedures are less commonly performed, largely because of technical complexity when compared with multiport techniques, which are on the whole very well tolerated.

Endoluminal endoscopy and natural orifice surgery

Flexible or rigid endoscopes are introduced into hollow organs or systems, such as the urinary tract, upper or lower gastrointestinal tract and the respiratory and vascular systems. Advances in endoluminal technology now enable more complex procedures to be completed endoscopically where previous transabdominal or transthoracic surgical resection would have been advocated. Examples include endoscopic submucosal resection of complex colonic polyps, transanal endoscopic microsurgery and endobronchial laser resection of tracheal pathology.

Natural orifice translumenal endoscopic surgery (NOTES) offers the opportunity for 'scar-free' surgery by performing entire procedures via natural body orifices. While these techniques have been applied in the pelvis, abdomen and thorax, technical limitations and safety concerns have limited adoption. Concern over closure of the visceral puncture site is the principal issue that has prevented widespread uptake, as transgastric and transcolonic closure of peritoneal entry sites in a safe manner remains problematic. In addition, there are significant cost and training implications that have limited more widespread adoption.

Perivisceral endoscopy

Body planes can be accessed even in the absence of a natural cavity. Examples are mediastinoscopy, retroperitoneoscopy and retroperitoneal approaches to the kidney, aorta and lumbar sympathetic chain. Some of these approaches have been in place for many years (cervical mediastinoscopy was first performed in 1959); however, the availability of novel videoscopes has enhanced visualisation, thus improving the safety and accuracy of dissection.

Extraperitoneal approaches to the retroperitoneal organs, as well as hernia repair, are now commonplace, further decreasing morbidity associated with manipulation of the visceral peritoneum. Other examples include subfascial endoscopic perforator surgery for ligation of incompetent perforating veins in varicose vein surgery and endoscopic harvesting of the saphenous vein for use in coronary artery bypass grafting.

Arthroscopy and intra-articular joint surgery

Arthroscopy was one of the earliest applications of endoscopic techniques, first being applied in the knee as early as the 1930s. In the 1950s Watanabe developed arthroscopic techniques that have evolved such that shoulder, wrist, elbow and hip arthroscopy is now commonplace. Novel approaches to smaller joints such as the temporomandibular and metatarsal joints are being developed.

Hybrid minimal access surgery

Hybrid surgery may utilise a combination of flexible and straight stick endoscopic approaches or a combination of open and endoscopic surgery.

Totally endoscopic hybrid approach

The diseased organ is visualised and treated by an assortment of endoluminal and extraluminal endoscopes and other imaging devices. In the abdomen, examples include the combined laparo-endoscopic approach for the management of biliary lithiasis, colonic polyp excision and several urological procedures, such as pyeloplasty and donor nephrectomy. In the thorax, navigational bronchoscopy with placement of fiducial markers has been employed as a means of marking lung nodules that can then be resected via a minimal access video-assisted approach. Cardiovascular surgeons have for some time employed hybrid technologies to facilitate catheter-based placement of cardiac valves, atrial devices and intravascular stents.

Hybrid techniques offer improved visualisation, facilitating the primary procedure to be carried out either via a smaller incision or a minimal access approach where otherwise open surgery would have been necessary. Such approaches may necessitate the availability of 'hybrid' theatre facilities, limiting this approach to tertiary centres where such technology is available (***Figure 10.1***).

Open and endoscopic hybrid approach

Hand-assisted laparoscopic surgery (HALS) is a well-developed technique. It involves the intra-abdominal placement of a

Figure 10.1 Modern hybrid theatre set-up (courtesy of Mr Kelvin Lau, Barts Thorax Centre, London, UK).

Masaki Watanabe, 1911–1995, orthopaedic surgeon, Tokyo, Japan, known as the 'founder of modern arthroscopy'.

hand or forearm through a minilaparotomy incision, while pneumoperitoneum is maintained. In this way, the surgeon's hand can be used as in an open procedure. It can be used to palpate organs or tumours, reflect organs atraumatically, retract structures, identify vessels, dissect bluntly along a tissue plane and provide finger pressure to bleeding points, while proximal control is achieved. This approach has been suggested to offer technical and economic efficiency when compared with a totally laparoscopic approach, in some instances reducing both the number of laparoscopic ports and the number of instruments required. Indeed, some advocates argue that if such an incision is necessary for extraction of the final specimen then HALS does not significantly increase surgical trauma over totally laparoscopic approaches. Furthermore, for those trained in open surgery it may be easier to learn and perform than totally laparoscopic approaches, subsequently improving patient safety. With the new generation of surgeons training in totally laparoscopic surgery it is likely that use of HALS will diminish, although it should remain part of the minimally invasive surgeon's armamentarium.

SURGICAL TRAUMA IN OPEN, MINIMALLY INVASIVE AND ROBOTIC SURGERY

Most of the trauma of an open procedure is inflicted because the surgeon must have a wound that is large enough to give adequate exposure for safe dissection at a target site. The wound is often the cause of morbidity, including infection, dehiscence, bleeding, herniation and nerve entrapment. Wound pain prolongs recovery time and, by reducing mobility, contributes to an increased incidence of pulmonary atelectasis, chest infection, paralytic ileus and deep venous thrombosis.

Mechanical and human retractors cause additional trauma. Body wall retractors can inflict localised damage that may be as painful as the wound itself. In contrast, during laparoscopy, the retraction is provided by the low-pressure pneumoperitoneum, giving a diffuse force applied gently and evenly over the whole body wall, causing minimal trauma.

Exposure of any body cavity to the atmosphere also causes morbidity through cooling and fluid loss by evaporation. The incidence of postsurgical adhesions is reduced by use of minimally invasive approaches because there is less damage to delicate serosal coverings. In the manual handling of intestinal loops, the surgeon and assistant disturb the peristaltic activity of the gut and provoke adynamic ileus.

While minimal access methods were initially established in elective surgery, the advantages have led to increased uptake for a number of emergency surgical procedures, including perforated viscus repair, such as omental patch repair of a peptic ulcer perforation, lavage of localised perforation of diverticular disease, intrathoracic debridement of empyema and pneumothorax and haemothorax surgery. More recently, some experienced surgeons have chosen to employ minimal access approaches to trauma situations for initial assessment and treatment in stable patients.

Summary box 10.1

Advantages of minimal access surgery

- Decrease in wound size
- Reduction in wound infection, dehiscence, bleeding, herniation and nerve entrapment
- Decrease in wound pain
- Improved mobility
- Decreased wound trauma
- Decreased heat loss
- Improved visualisation

LIMITATIONS OF MINIMAL ACCESS SURGERY

Minimal access surgery has limitations. A number of these have been addressed with advances in instrumentation and endoscopic systems; however, the basic principles remain. Surgical robots further address a number of these limitations but present novel challenges.

Endoscopic surgery

Lack of three-dimensional vision

To perform minimal access surgery with safety, the surgeon must operate using an imaging system that provides a two-dimensional (2D) representation of the operative site. The endoscope offers a whole new anatomical landscape, which the surgeon must learn to navigate without the usual 'open approach' clues that make it easy to judge depth. The instruments are longer and sometimes more complex to use than those commonly used in open surgery. This results in the novice being faced with significant problems of hand–eye coordination. There is a well-described learning curve for novice surgeons and experienced 'open' surgeons when adopting the minimally invasive approach. Simulation training and mentoring are required to attain competence.

Three-dimensional (3D) imaging systems are available but are expensive and currently are not commonplace. Many surgeons feel that endoscopic 3D technology does not yet offer the technical enhancement necessary to improve safety. Indeed, 3D technology has been associated with ergonomic problems such as headache without quantifiable benefit in terms of accuracy and time to perform directed tasks. Future improvements in these systems carry the potential to enhance manipulative ability in critical procedures, such as knot tying and dissection of closely overlapping tissues. There are, however, some drawbacks, such as reduced display brightness and interference with normal vision because of the need to wear specially designed glasses for some systems. It is likely that brighter projection displays will be developed; however, the need to wear glasses is not easily overcome. These factors currently limit stereoscopic straight stick endoscopic surgery, which has largely been superseded by the development of robotic technology incorporating 3D vision.

Increased operative time

Minimal access surgery can be more technically demanding and slower to perform than conventional open surgery. On occasion, a minimally invasive operation is so technically demanding that both patient and surgeon would be better served by conversion to an open procedure. Prolonged anaesthetic and operative times may negate a number of the beneficial effects of minimal access surgery and increase the risk of respiratory and wound complications as well as compression neuropathy and venous thromboembolism. It is vital for surgeons and patients to appreciate that the decision to convert to an open operation is not a complication but, instead, usually implies sound surgical judgement in favour of patient safety.

Control of bleeding and haemostasis

Haemostasis may be difficult to achieve endoscopically because blood may obscure the field of vision with reduced image quality owing to light absorption. Experienced surgeons may be able to manage a degree of bleeding via an endoscopic approach; however, this requires a significant degree of experience and skill to be achieved safely. Such scenarios are also reliant on an experienced assistant able to reduce visual loss through optimal camera positioning. It should be remembered that a situation of controlled conversion can easily become uncontrolled, negating any benefit a minimally access approach would have achieved.

Advanced electrosurgery/diathermy and laser technology have improved dissection precision and haemostatic efficacy in endoscopic surgery. Ultrasonic dissection and tissue fusion devices continue to evolve with incremental technical improvements and surgeons are increasingly familiar with their use. Some devices now combine the functions of three or four separate instruments, reducing the need for instrument exchanges during a procedure. This flexibility, combined with the ability to provide a clean, smoke-free field, facilitates dissection, improves haemostasis and reduces operating times.

Loss of tactile feedback

Minimal access surgery is associated with some loss of tactile feedback, although this is less with straight stick endoscopy than with robotic procedures. This is an area of ongoing research in haptics and biofeedback systems. Early work suggested that laparoscopic ultrasonography might be a substitute for the need to 'feel' in intraoperative decision-making. Rather than producing tactile feedback, endoscopic ultrasound provides a visual representation of structures that in open surgery would rely on palpation for accurate localisation and appraisal. Widely used examples include appraisal of nodal disease in cancer surgery and biliary tract exploration.

Tissue extraction

Large pieces of tissue, such as the lung or colon, may have to be extracted from the body cavity following resection. In some circumstances this significantly increases the surgical trauma of the procedure that could otherwise be carried out via two or three small port incisions. Although tissue 'morcellators, mincers and liquidisers' can be used in some circumstances, they have the disadvantage of disrupting gross specimen morphology and cannot be used in surgery for malignancy. Typically, extraction is performed by enlarging one incision so as to facilitate removal without disruption to the specimen. Strategies to reduce surgical trauma have been considered. These include removal of lung via a subxiphoid approach so as to reduce intercostal neuropraxia or natural orifice extraction of abdominal resection specimens. However, such approaches are themselves associated with different complications such as herniation and injury to structures outside the direct operative field.

While tumour implantation and localisation at port sites initially raised important questions about the future of the laparoscopic treatment of malignancy, large-scale trials have shown concerns to be minimised by appropriate tissue handling, separating any tumours by bagging, irrigation and protecting the extraction site.

Cost

Initially high consumable costs and factors such as surgical learning curve and high conversion rates led to increased costs of minimal access approaches compared with their open equivalents. This is now largely no longer the case for straight stick endoscopic surgery such as laparoscopy and thoracoscopy. Indeed, despite higher direct consumable costs, improvements in outcomes, hospital stay and general upscaling of the procedural volume have resulted in improved cost-effectiveness for many minimal access procedures.

Future reductions in the costs of image-processing technology will result in a wide range of transformed presentations becoming available. It should ultimately be possible for a surgeon to access any view of the operative region accessible to a camera and present it stereoscopically in any size or orientation, superimposed on past images taken in other modalities. Such augmented reality systems continue to improve and are discussed in more detail below.

Summary box 10.2

Limitations of minimal access surgery

- Lack of 3D vision
- Loss of tactile feedback
- Haemostasis
- Extraction of large specimens
- Learning curve and increased operative time
- Cost
- Reliance on new technologies

ROBOTIC SURGERY

A robot is a mechanical device that performs automated physical tasks according to direct human supervision, a predefined program or a set of general guidelines, using artificial intelligence (AI) technology. In surgery, robots can be used to assist surgeons to perform operative procedures, primarily in the form of automated camera systems and telemanipulator

systems, thus resulting in the creation of a human–machine interface. Reduced degrees of freedom of movement and difficult ergonomic positioning for the surgeon can limit the application of straight stick endoscopy to a number of specialties owing to a loss in surgical precision. This has driven the uptake of robotic surgical systems, currently existing as two main categories:

- **Teleoperated (master–slave) systems:** a surgeon performs an operation via a robot and its robotic instruments through a televisual computerised platform (where the surgeon is the master, i.e. the operator, and the robot is the slave). This may be via onsite connections or remotely through the internet or other digital channels – hence the publicity of 'operating on a patient from another country' (such 'remote' operations are currently rarely performed but their existence is established).
- **Active or semiactive systems: these are typically image-guided or pre-programmed.** In active systems, a surgical robot completes a pre-programmed surgical task. This is guided by preoperative imaging and real-time anatomical constraints and cues through the application of in-built navigation systems. In semiactive systems, the robotic device may be in part pre-programmed and in part surgeon driven.

History of robotic surgery

The first documented clinical robotic procedure was a computed tomography (CT)-guided brain biopsy performed in 1985 utilising the PUMA (Programmable Universal Machine for Assembly) 560 system. This was followed by the ROBODOC, a pre-programmed active robot that enabled precise preparation of the femoral implant cavity during hip replacement. The benefit of such a device was the ability to perform tasks to a high degree of accuracy, thus minimising error and variation. While this and other active surgical robots demonstrated a number of advantages, they were largely superseded by the advent of wider laparoscopy and thoracoscopy, which became increasingly commonplace across during the 1990s and 2000s.

In 1992, Computer Motion developed the AESOP (Automated Endoscopic System for Optimal Positioning) system, which mounted the endoscopic camera on a single robotic arm, allowing the surgeon to control it remotely via voice command. The system was widely used in cholecystectomy and hernia surgery and for harvesting the mammary conduit in coronary artery bypass. This was followed by the development of the ZEUS robot in 1996, a master–slave teleoperated system that provided three robotic arms, one for the voice-controlled endoscope and two further instrument arms. The surgeon was positioned at a remote console and the device was capable of motion scaling and tremor correction, facilitating its use for microsurgical procedures. ZEUS was used for the first fully endoscopic robotic surgical procedure, the reanastomosis of a Fallopian tube in 1998. The first remote surgical procedure was performed in 2001, also utilising the ZEUS system. Here a cholecystectomy was performed on a patient in Paris by a surgeon in New York, demonstrating the feasibility of remote operating. ZEUS was discontinued in 2003 after the merger of Computer Motion with Intuitive Surgical.

The current era of surgical robots is dominated by the da Vinci® surgical system, which was first approved for clinical use in 2000. The system offers a number of advantages, including 3D surgical vision, EndoWrist® precision instruments, tremor reduction, motion scaling and improved ergonomics. The initial system was released in 1999 and provided three robotic arms, one of which held the endoscope. This was upgraded to the da Vinci S (2006), the da Vinci Si (2009) and subsequently the da Vinci Xi in 2014 (***Figure 10.2***). With each iteration came improvements in vision and instrumentation, along with which came integrated fluorescence imaging. More recently, novel technologies include the development of a single port system (da Vinci SP), which combines multijointed wristed instrumentation with a wristed camera through a single port to further improve dexterity and minimise surgical trauma.

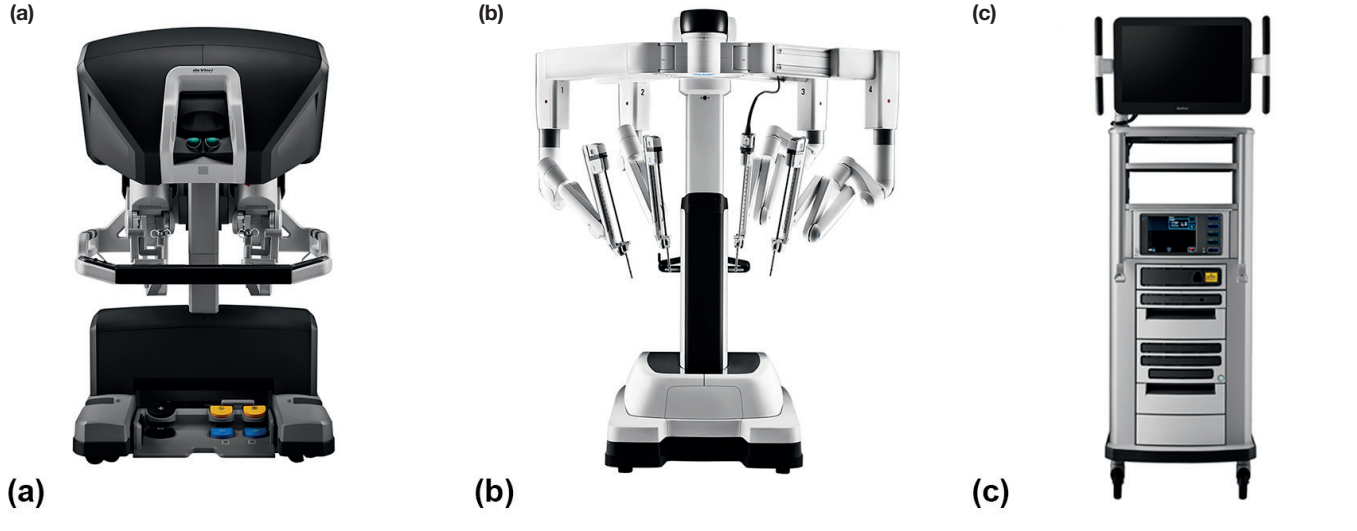

Figure 10.2 The da Vinci Xi system: **(a)** surgeon console; **(b)** da Vinci Xi robot; **(c)** vision cart (courtesy of Intuitive Surgical).

Advantages of robotic surgery

Surgical robots have been considered to offer many benefits, which have arisen as a result of new technology in lenses, cameras and computer software. Just as laparoscopic surgery benefited from advances in light technology allowing the targeted transmission of light down tubing, robotic surgery benefits from computer integration of mechanical (surgical) arms that have paved the way for computer-integrated surgery.

Vision

Modern robotic camera systems offer 3D high-definition imaging, providing stereoscopic vision with true depth perception that enhances the visualisation of tissue planes and key structures. Multiport systems typically employ a rigid endoscope with or without angulation. As with conventional endoscopes, angulation to 30° allows for a wider range of vision through manipulation of the camera position, which, in the case of robotic surgery, can be controlled by the surgeon at the console or, if required, by the assistant at the bedside. A reference horizon is commonly provided to the surgeon at the console system so as to maintain orientation throughout the procedure. More recently, modern single-port systems such as the da Vinci SP employ a wristed camera system that, in combination with fully wristed instruments, may allow for operative triangulation while at the same time maintaining a small, single skin incision.

Manoeuvrability, motion scaling and tremor suppression

Improved manoeuvring as a result of the 'robotic wrist' in some systems allows for up to seven degrees of freedom, thus improving dexterity for the surgeon. This has particular benefits in fields with significant space restraints such as transoral surgery, where conventional laparoscopy has limited applicability. Furthermore, the increased dexterity of surgical robots may facilitate a minimal access approach to more complex procedures where the technical difficulty of applying conventional laparoscopy may be prohibitive. As the motion of the surgeon's hand is translated to the 'slave' motion of the robotic arm, modern surgical robots are able to scale down large external movements of the surgical hands to limited internal movements. At the same time, the computer may filter out tremor in the surgeon's hands, thus ensuring stability of the instrument tips and enhancing surgical precision.

Ergonomics

Although the advent of straight stick laparoscopic surgery had many advantages for the patient, for the surgeon there was a trade-off in terms of operative ergonomics. Increased operative time in addition to unergonomic positioning can result in significant physical discomfort for the surgeon. This is particularly true in specialties such as bariatric surgery, where the patient's body habitus and the use of long, fulcrumed instruments puts further strain on the surgeon's back, neck and upper arms. The advent of robotic surgery vastly improves upon the ergonomic environment for the surgeon; in the case of many of the current master–slave systems, allowing for the surgeon to be seated at a console remote from the operating table (***Figure 10.3***). The console positioning can be optimised to fit the individual profile of the operator, thus reducing physical stress and fatigue. The enclosed console system of many robotic systems also provides the advantage of surgical isolation from external distractions that may impact on the operator's concentration. The disadvantage is reduced awareness of non-verbal communication, thus highlighting the importance of team training and regular verbal cues.

Motion compensation

Although not commonplace in current clinical practice, robotic surgical systems may in future provide motion compensation to facilitate surgery on a moving target. Examples where this may be beneficial are in beating heart cardiac surgery, such as coronary artery bypass grafting and mitral valve repair. In this setting, the increased dexterity of robotic surgery combined with removing the need for cardioplegia and cross-clamping may be particularly beneficial in terms of reducing the post-operative inflammatory response and improving its associated morbidity.

Disadvantages of robotic surgery

Cost

Robotic surgery remains more costly than minimally invasive alternatives. Through upscaling of use between surgical specialties, the direct costs of purchasing a novel robotic system can be partially offset; however, consumable costs remain high. When compared with open techniques, robotic surgical procedures can reduce hospital stay, thus in part offsetting this expenditure; however, it remains difficult to demonstrate significant improvement in length of stay or clinical outcomes when compared with other minimally invasive alternatives. Another consideration is the increased operating time and overall learning curve requirement when establishing a robotic surgical programme. While some specialties have reported shorter learning curves than in the early days of laparoscopic surgery, this is highly heterogeneous, across both specialties and practitioners. Furthermore, although shared interspecialty

Figure 10.3 Robotic theatre set-up demonstrating the da Vinci Xi system. The surgeon and trainee surgeon are positioned at joint consoles remote from the operating table with the surgical assistant and scrub nurse at the bedside (courtesy of Mr Tom Routledge, Guy's and St Thomas' NHS Foundation Trust, London, UK).

use increases cost-effectiveness for the institution, it also consequently reduces the access opportunities for each individual user, potentially prolonging the learning curve.

Uptake of robotic surgery

Many surgical specialties have embraced robot-assisted techniques, including general surgery, cardiothoracic surgery, urology, orthopaedics, ear, nose and throat surgery, gynaecology and paediatric surgery. Specialties that use microsurgical techniques also benefit from this technology. Current robotic systems were designed to offer multifunctionality, including multianatomy and specialty capability in both operating theatre and remote environments. Currently, despite a small number of reports of remote surgical procedures, robotic surgery remains focused on in-house operating.

New entrants

In 2017, Intuitive Surgical released the da Vinci X, a low-cost entry point in its robotic surgical portfolio that includes features of the Xi while sacrificing some flexibility in terms of multiquadrant surgery. In the same year, Korean company Meere gained a licence for the use of its surgical robot, the REVO-I, by the local Ministry for Food and Drug Safety. Similar to the da Vinci, this four-arm robot is mounted on a single cart. The surgeon is seated at an open vision cart and, by use of 3D glasses, can achieve three-dimensional high-definition (3D-HD) vision. In March 2019, CMR Surgical received a European CE mark for its novel modular robot, the Versius (***Figure 10.4***). This system incorporates individual cart-mounted modular robotic arms that can be configured to fit the procedure and the operating room environment. The design differs from other robotic arms in that it aims to more closely mimic a human arm, improving freedom of port placement. Its vision cart similarly allows for ergonomic operating with 3D-HD vision, through the use of 3D glasses.

Bridging the gap between laparoscopic and robotic surgery the Senhance® robotic system received its CE mark in 2016. In order to reduce cost and sustain familiarity with conventional laparoscopy, the system uses independent robotic arms mounted on separate carts that can be placed in accordance with the procedure required. The system utilises reusable nonwristed instruments that can be inserted through standard laparoscopic trocars so as to reduce consumable cost. This system also creates familiarity with conventional laparoscopy and facilitates hybrid techniques where this may be beneficial. Surgery is enhanced though a 3D-HD system with the use of 3D glasses and eye-tracking camera control.

Figure 10.4 The Versius robotic system (courtesy of CMR Surgical).

As the field of robotic surgery continues to expand and innovate, there also remain a number of systems in development that are not yet approved for clinical use. Examples similar to existing technologies include the Medtronic Hugo Robotic-Assisted Surgery (RAS) system, which was launched in late 2019. This modular system aims to provide a lower cost alternative by means of a more readily upgradeable model that may be used flexibly across surgical specialties and procedures. Moving forward, companies such as Verb Surgical strive to build on the currently dominant master–slave model, incorporating robotic autonomy and machine learning. While this may in time revolutionise robotic surgery, such technologies remain in the early phase of development.

Direct robotic systems and hybrid robotic surgery

In addition to the remote master–slave platform design, direct robot systems also exist. Each of these systems offers different advantages to the operating surgeon, ranging from reducing the need for assistants and providing better ergonomic operating positions to providing experienced guidance from surgeons not physically present in the operating theatre. Examples include:

- tremor suppression robots;
- active guidance systems;
- articulated mechatronic devices;
- force control systems;
- haptic feedback devices.

PERIOPERATIVE PLANNING FOR MINIMAL ACCESS SURGERY

Preparation of the patient

Although the patient may be in hospital for a shorter period, careful preoperative management is essential to minimise morbidity. Recognition of patient- or procedure-related factors that may in turn complicate a minimal access approach is vital to optimise outcomes.

History

Patients must be fit for general anaesthesia and open operation if necessary. Potential coagulation disorders are particularly dangerous in minimal access surgery where options for haemostasis may be more limited. A prior history of surgical intervention in the same area is vitally important and should be carefully documented, so as to best predict factors such as adhesions that may preclude a minimal access approach. Previous oncological treatment can also create a more hostile surgical environment and an appropriate threshold for conversion to open access should be set prior to the procedure and communicated clearly with the patient.

Summary box 10.3

Preparation for minimal access surgery

- Overall fitness: cardiac arrhythmia, lung function, medications, allergies
- Previous surgery or oncological intervention: scars, adhesions
- Body habitus: obesity, skeletal deformity
- Normal coagulation
- Thromboprophylaxis
- Informed consent
- Operative difficulty is predicted when possible with appropriate risk model
- Appropriate theatre time and facilities are available (especially important for robotic cases)

Examination

Routine preoperative physical examination is required as for any major operation. Although, in general, minimal access surgery allows quicker recovery, it may involve longer operating times and carbon dioxide insufflation in both the chest and abdomen may provoke cardiac arrhythmias. Severe chronic obstructive airways disease and ischaemic heart disease may be contraindications to a minimal access approach. Moderate obesity does not increase operative difficulty significantly, but morbid obesity may require specialist instrumentation and trocars. Patients with a particularly low body mass index and small body habitus may present separate challenges in terms of port placement, particularly when adopting a robotic approach. Severe spinal deformity including kyphosis and scoliosis may present problems in terms of positioning as well as impact on overall recovery if there are associated problems with sputum clearance and mobility.

Prophylaxis against thromboembolism

Venous stasis induced by the reverse Trendelenburg position during laparoscopic surgery coupled with prolonged duration of operation are risk factors for deep vein thrombosis. Subcutaneous low-molecular-weight heparin and antithromboembolic stockings should be used routinely in addition to pneumatic calf compression during the operation. Patients already taking anticoagulation should have this stopped temporarily or, where appropriate, be converted to intravenous or subcutaneous heparin, depending on the underlying condition and local thromboprophylaxis protocols. In most cases patients can continue on aspirin when the benefits outweigh the slight increase in bleeding potential.

Urinary catheters and nasogastric tubes

In the early days of minimal access surgery, routine bladder catheterisation and nasogastric intubation were advised. Most surgeons now omit these in favour of enhanced recovery, which has demonstrated benefits in terms of both length of stay and morbidity outcomes. It remains essential to check that the patient has fasted and has recently emptied their bladder, particularly before creating pneumoperitoneum for minimal access surgery approaches to the abdomen.

Informed consent

It is essential that the patient understands the nature of the procedure, the risks involved and, when appropriate, the alternatives that are available. A locally prepared explanatory booklet concerning the minimal access procedure to be undertaken is extremely useful (***Chapter 14***). The patient should understand that the procedure may be converted to an open operation. Common complications should be mentioned, such as shoulder tip pain and minor surgical emphysema, as well as rare but serious complications, such as inadvertent visceral injury from trocar insertion or diathermy. Patients may also have specific questions or requests in terms of the application of minimal access surgery. It is important to be considerate and address these. Some patients remain concerned about the application of technology, particularly robotics, to their care and it is important to ensure they understand and agree with the proposed surgical approach.

THEATRE SET-UP AND TOOLS

Operating theatre design is key to efficiency. Modern theatres are designed with moveable booms for video, diathermy and laparoscopic equipment with at least two high-resolution, high-definition (HD) or ultra-high-definition (4K) monitors, a carbon dioxide supply and flow monitor and appropriate audiovisual kit (***Figure 10.1***).

Image quality is vital to the success of minimal access surgery. New camera and lens technology allows the use of smaller cameras while maintaining excellent resolution. Automatic focusing and charge-coupled devices (CCDs) are used to detect different levels of brightness and adjust for the best image possible.

Efficient teamwork is crucial for high-quality surgery and quick yet safe turnover. This is particularly important in robotic surgery, where verbal interaction between all team members is paramount throughout the procedure. The robotic team must carefully rehearse protocols for both controlled and uncontrolled conversion in the event of emergency.

GENERAL INTRAOPERATIVE PRINCIPLES

Many minimal access procedures have a unique set of procedural steps that may often be in a distinctly different sequence from those of the open alternative.

Methods for creating a pneumoperitoneum are described in ***Chapter 7***. Preoperative evaluation is necessary to assess the type and location of surgical scars and potential for perivisceral adhesions. In the setting of redo surgery, trocar insertion may be complex and should be performed by an open approach with direct visualisation on entry to the body cavity (abdomen

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895), Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

or thorax). Before trocar insertion, the introduction of a fingertip helps to ascertain penetration into the body cavity and allows adhesions to be gently removed from the entry site. The endoscopic camera may be used as a blunt dissector to tease adhesions gently away and form a tunnel towards the quadrant where the operation is to take place. With experience, the surgeon learns to differentiate visually between thick adhesions that should be avoided and thin adhesions that would lead to a window into a free area.

In obese patients the location of some of the ports may need to be modified and, in some instances, larger and longer instruments may be necessary. It is important to recognise this preoperatively to ensure that adequate measures are put in place to ensure safe and efficient surgery when the patient arrives. It is also important to consider the weight and dimension restrictions of the operating table. In some cases, specialist operating tables will be required (*Chapter 68*).

Operative problems

Intraoperative perforation of a viscus or vascular injury

Perforation of any viscus, such as bowel, is a potential hazard that may occur inadvertently and go unrecognised or be of a severity that may require emergency conversion. The added time required for this to take place may result in increased blood loss and haemodynamic instability that would not have occurred should the same injury have occurred in an open setting. With surgical experience, education, preparation and patient selection many of these emergencies and their resultant complications can be avoided. It is vital for the surgical team to both recognise its own limitations and continually reflect throughout the procedure on the surgical progress and operative difficulty.

Bleeding

Bleeding is the most common cause of conversion to open surgery. The impact of light absorption is particularly important in robotic surgery, and regular haemostasis is paramount to facilitate dissection and surgical progress. Risk factors that predispose to increased bleeding include:

- liver disease impacting on the production of vitamin K-dependent clotting factors, e.g. cirrhosis, autoimmune liver disease;
- inflammatory conditions (acute cholecystitis, diverticulitis);
- patients on anticoagulants;
- coagulation defects: these may be contraindications to both open and minimal access surgery and require thorough discussion with haematology colleagues to determine, where possible, how to optimise the patient for surgery.

Damage to a large vessel requires immediate assessment of the magnitude and type of bleeding. It is paramount that as soon as bleeding is identified this is communicated clearly to all members of the theatre and anaesthetic team. There should be a relatively low threshold for early conversion; however, this will depend on the expertise of the operating team. It is pertinent to achieve early control by whatever means necessary. When the bleeding vessel can be identified and grasped, control may be achieved by clipping, stapling or use of an energy device, depending on vessel size. Occasionally suturing may be possible; however, this may be significantly more complex via a minimal access approach. When the vessel is not identified, compression should be applied immediately with a blunt instrument, a cotton swab or with the adjacent organ. Good suction and irrigation are of utmost importance. Once the area has been cleaned, pressure should be released gradually to identify the site of bleeding. Insertion of an extra port may be required. There should be no delay in converting to an open procedure when necessary. This is of particular importance in robotic surgery as some or all of the robotic arms may need to be urgently undocked to facilitate the surgeon gaining bedside access to the patient. The bedside assistant should be confident to perform this process. It is sometimes appropriate for a single robotic arm to be left in place to help maintain pressure on the bleeding vessel while direct access is achieved. Alternatively, pressure may be maintained via an assistant port (if present), allowing the robot to be undocked completely and removed from the surgical field.

Bleeding from organs encountered during surgery

Excessive retraction can tear a visceral surface, resulting in bleeding. This is particularly so in robotic surgery, where instrument graspers have a small surface area, increasing the potential for injury to retracted tissue. Here rolled swabs may be inserted into the surgical field and held within the grasper, producing a larger surface for retraction and reducing tissue injury. Surgicel® (absorbable fibrillar oxidised cellulose polymer) or other clot-promoting strips, tissue glues or other haemostatic agents may also be used to aid haemostasis, e.g. from the gallbladder bed during cholecystectomy.

Bleeding from a trocar site

Bleeding from the trocar sites is usually treated by localised diathermy or applying upwards and lateral pressure with the trocar itself. Considerable bleeding may occur if a vessel such as the inferior epigastric or intercostal artery is injured. Haemostasis can be accomplished either by pressure or by suturing the bleeding site. Devices such as the EndoClose™ may also be used to apply transabdominal sutures under direct laparoscopic view to close port sites that bleed.

When a bleeding vessel cannot be easily identified, mass ligation of the vessel around the port site can be performed. This manoeuvre is accomplished by extending the skin incision by 3 mm at both ends of the bleeding trocar site wound. Two figure-of-eight sutures are placed in the path of the vessel at both ends of the wound (*Figure 10.5*). Alternatively, pressure can be applied using a Foley balloon catheter. The catheter is introduced into the abdominal cavity through the bleeding trocar site wound, the balloon is inflated and traction is placed on the catheter, which is bolstered in place to keep it under tension. The catheter is left *in situ* for 24 hours and then removed.

If significant continuous bleeding from the falciform ligament occurs, haemostasis is achieved by percutaneously inserting a large, straight needle at one side of the ligament. A monofilament suture attached to the needle is passed into the abdominal cavity and the needle is exited at the other side

of the ligament using a grasper. The loop is suspended and compression is achieved. Maintaining compression throughout the procedure usually suffices. After the procedure has been completed, the loop is removed under direct laparoscopic visualisation to ensure complete haemostasis.

Evacuation of blood clots

Careful haemostasis is important as even small, localised pools of blood or clot absorb light and can significantly impair the surgical view. Carefully directed suction is usually sufficient in open cases; however, suction may be problematic in laparoscopic and robotic procedures that are reliant on carbon dioxide insufflation to maintain the surgical field. It is important that suction is applied below a fluid level, or, if used in the operative field, only in short bursts as required. Should tissue be inadvertently sucked into the end of the suction device, the tubing can be kinked to allow the tissue to drop away before removing. Rolled swabs or sponges can be used to remove blood from the surgical field without need for suction (***Figure 10.6***). These can also be used for gentle retraction, minimising tissue damage and thus further reducing blood loss. Such swabs may be inserted and removed via a 15-mm assistant port or in some cases a 12-mm robotic trocar with the port cap removed. Care should be taken to avoid carbon dioxide loss during extraction. Finally, the surgeon may choose to use a specially designed robotic sucker that integrates with the robotic system. Alternatively, non-wristed suction can be provided via an assistant port if included in the operative set-up.

Principles of electrosurgery during laparoscopic surgery

Inadvertent electrosurgical injuries during minimal access surgery are potentially serious and are often unrecognised at the time. The vast majority occur following the use of monopolar diathermy. For conventional laparoscopy, the overall incidence is thought to be between one and two cases per 1000 operations. Injuries can occur through inadvertent touching or grasping of tissue during current application; direct coupling between tissue and a metal instrument that is touching the activated probe; insulation breaks in the laparoscopic or robotic instruments; direct sparking from the diathermy probe; or current passage from recently coagulated, electrically isolated tissue. Bipolar diathermy is safer and should be used in preference to monopolar diathermy, especially in anatomically crowded areas. If monopolar diathermy is to be used, important safety measures include attainment of a perfect visual image, avoiding excessive current application and meticulous attention to insulation. Alternative methods of performing dissection, such as the use of ultrasonic devices, may improve safety.

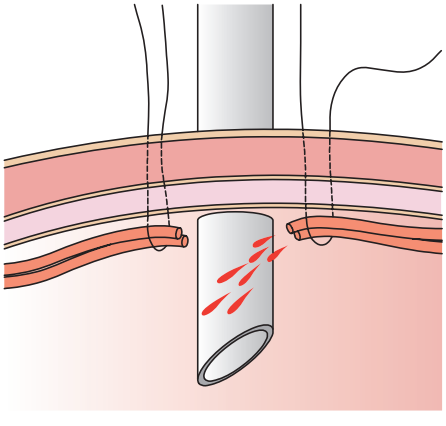

Figure 10.5 Management of bleeding from a surgical trocar site.

POSTOPERATIVE CARE

The postoperative care of patients after minimal access surgery is generally straightforward, with a low incidence of pain or other problems when compared with their open counterparts. It is a good general rule that if the patient develops a fever or tachycardia, or complains of severe pain at the operation site, something is wrong and close observation or intervention is necessary (see also ***Chapter 24***).

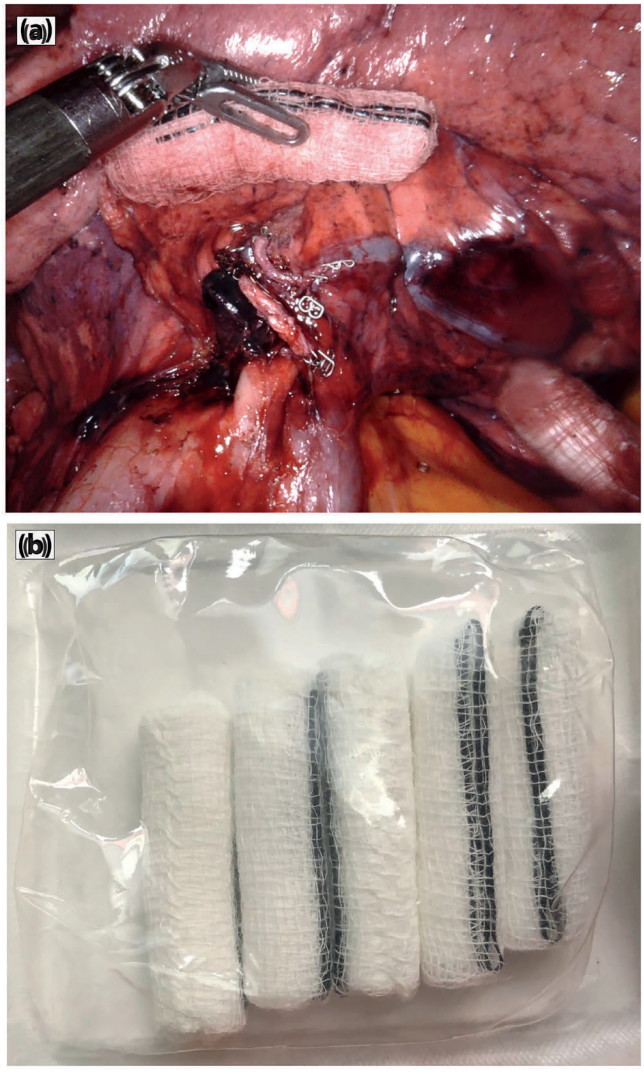

Figure 10.6 Use of rolled swabs for retraction of the lung during pulmonary lobectomy (courtesy of Mr Tom Routledge, Guy's and St Thomas' NHS Foundation Trust, London, UK).

Nausea

About half of patients experience some degree of nausea after minimal access surgery. It usually responds to an antiemetic, such as ondansetron, and settles within 12–24 hours. It is made worse by opiate analgesics and these should be rationalised or avoided where at all possible.

Shoulder tip pain

Patients should be warned about this preoperatively and informed that the pain is referred from the diaphragm and that it is not due to a local problem in the shoulders. It can be at its worst 24 hours after the operation. It usually settles within 2–3 days and is relieved by simple analgesics, such as paracetamol.

Port site pain and numbness

Pain in one or other of the port site wounds is not uncommon and is worse if there is haematoma formation. It usually settles very rapidly. In the case of thoracoscopy, intercostal nerve pain may be more common in those with smaller intercostal spaces. Nerve blockade by means of directed local anaesthesia is effective at reducing pain and the need for opiate medication in the immediate postoperative period. Increasing pain after 2–3 days may be a sign of infection and, with concomitant signs, antibiotic therapy is occasionally required. Occasionally, herniation through a port may account for localised pain and should be considered, particularly if occurring late with a relevant preceding history (e.g. coughing). Failure of a patient to follow the expected recovery pathway should prompt senior review with appropriate imaging and relook surgery if considered necessary.

Analgesia

The type and extent of analgesic requirement will depend on both the patient and procedural factors. Prior experience of opiate analgesia may increase patient tolerance to similar agents, necessitating larger doses. There is also evidence to suggest that those patients struggling with chronic pain preoperatively often present a more complex postoperative analgesic problem. The extent and region of surgery will also dictate the analgesic regimen. For example, even minimal access thoracic surgical procedures commonly require patient-controlled opiate analgesia with or without local nerve blockade (intercostal or paravertebral) in the initial 48 hours after surgery. This may be avoided for some abdominal surgery by careful use of non-steroidal agents and paracetamol. Opiate analgesics cause nausea, impair gut motility and should be avoided unless the pain is very severe. When pain is disproportionate to the presenting problem, suspect a complication (see also *Chapter 23*).

Orogastric or nasogastric tube

An orogastric or nasogastric tube may be placed for some abdominal surgery if the stomach is distended and obscuring the view. It is not necessary in all cases and is very rarely used in other minimal access surgery. Where possible, it should be removed as soon as the operation is over and before the patient regains consciousness. This is most commonly used in bariatric and oesophagogastric surgery, where a larger (32F or 34F) tube is used.

Oral fluids

There is no significant ileus after minimal access surgery, except in abdominal resectional procedures, such as colectomy or small bowel resection. Patients may resume oral fluids as soon as they are conscious; they usually do so 4–6 hours after the end of the operation.

Oral feeding

Provided that the patient has an appetite, a light meal can be taken 4–6 hours after the operation. Some patients remain slightly nauseated at this stage, but almost all eat a normal breakfast on the morning after surgery. Subsequently a balanced diet is recommended in most cases and where specific procedural recommendations are needed these should be clearly communicated to both the patient and relatives with appropriate dietetic referral made.

Urinary catheter

The requirement for a urinary catheter depends on the operation. In shorter (<4 hours) minimal access procedures a urinary catheter is not usually required. If a urinary catheter has been placed in the bladder during an operation with likely short stay, it can be removed before the patient regains consciousness if the procedure has been uneventful. Postoperatively it is important to check that the patient has been able to pass urine and empty their bladder without difficulty. When there is uncertainty point-of-care bladder scanning can assess residual bladder volume.

Drains

The use of postoperative drains depends on the operation performed. Drain output should initially be documented at least hourly or more regularly in the event of concern regarding high drain output. Given the heterogeneity of drainage systems available it is paramount that nursing staff are familiar with the system used. The exact location and size of any drains should be clearly documented in the operation notes and the tubing labelled accordingly. This avoids inadvertent removal of the wrong drain or confusion for the ward team. Continued blood loss from a drain is an indication for re-exploration and should be immediately highlighted to the operating surgeon.

DISCHARGE FROM HOSPITAL

The discharge of patients is based on clinical indicators and the patient's fitness for recuperating in a non-hospital environment. One of the core drivers for the application of minimally invasive surgery is an earlier recovery and therefore discharge from hospital. Patients should not be discharged until they are comfortable, have passed urine and are eating and drinking

Summary box 10.4

Principles of minimal access surgery

- Meticulous care in the creation of a pneumoperitoneum
- Controlled dissection of adhesions
- Adequate exposure of operative field
- Avoidance and control of bleeding
- Avoidance of organ injury
- Avoidance of diathermy damage
- Vigilance in the postoperative period

satisfactorily. They should be told that if they develop worsening pain or other severe symptoms they should return to the hospital or to their general practitioner. Even for more major cases, some units have demonstrated safe and feasible protocols for a 23-hour stay.

Skin sutures

If non-absorbable sutures or skin staples have been used, they can be removed from the port sites after 7–10 days.

Mobility and convalescence

Patients can get out of bed to go to the toilet as soon as they have recovered from the anaesthetic and they should be encouraged to do so. Such movements are remarkably pain free when compared with the mobility achieved after an open operation. Similarly, patients can cough actively and clear bronchial secretions, and this helps to diminish the incidence of chest infections.

FURTHER DEVELOPMENTS

Augmented reality and minimal access surgical adjuncts

The future of minimal access surgery will almost certainly feature more advanced applications of adjuncts to facilitate anatomical recognition and the localisation of pathology. These are becoming commonplace in both video-assisted and robotic-assisted procedures.

Augmented reality

Augmented reality by definition comprises the fusion of projected computerised images with a real environment. In surgery, this involves the application of real-time imaging or other data overlaid via computer processing software onto the surgical field. Such technology may be particularly beneficial in minimal access surgery where the localisation of pathology and identification of anatomy may be more difficult than in open surgery because of the lack of digital palpation of the relevant structures. At an elementary level, examples include the use of indocyanine green for immunofluorescent localisation of tumours as well as vascular, bronchial or lymphatic structures. When bound to plasma proteins, indocyanine green emits light with a peak wavelength of around 820–830 nm on illumination with near-infrared light. Through use of a specifically designed HD camera and software system with imposed pseudo-colour, areas of differential tissue density and vascular supply can be detected clearly without the need for digital palpation, thus facilitating complete resection and clear surgical margins. Its use is now well established in procedures such as minimal access liver, lung, renal and prostatic resections, and its role in other specialties such as colorectal surgery is also under investigation. The technology can be integrated into both video-assisted and robotic-assisted surgical procedures and is available within the da Vinci Xi and X robotic surgical systems as the Firefly® mode, which can be turned on as required from the surgical console (***Figure 10.7***).

Another role for augmented reality in minimal access surgery is the overlay of imaging beside or directly onto the surgical field, 'navigating' the surgeon to the site of interest without the need to look away from the patient to review imaging. Such navigational techniques originated in image-guided diagnostics, enabling identification of pathology in areas more difficult to reach anatomically. Through increasing adoption of hybrid theatre complexes, these approaches may be utilised for both diagnosis and treatment in a single setting. An example is the use of navigational bronchoscopy to identify, diagnose and treat difficult to reach or small lung nodules. Preoperative planning CT scan is reconstructed by specialist software. The result is a 3D 'road map' of the bronchial tree and a side-by-side picture of real-time endobronchial images with those from the imaging system (***Figure 10.8***). The surgeon is then guided directly along the airway to the lesion of interest that can be biopsied with on-site frozen section. Where the lesion is resectable but difficult to localise, a fiducial marker may be placed to enable localisation under fluoroscopy guidance in a second-stage procedure performed in a hybrid theatre (***Figure 10.9***). Where resection is not possible, ablation or other treatment may be offered in the same setting, both reducing surgical invasiveness and increasing the provision of curative surgery to patients who may not otherwise be candidates for resection.

An area of interest is the application of head-mounted displays and eyeglasses to minimal access surgery. Although the majority of applications remain in the realm of simulation and training, the promise of real-time image guidance by means of multiplanar or imaging overlay of the surgeon's view is particularly attractive. Head-mounted displays may also provide data display or communication tools, reducing the need for the surgeon to look away from the operative field and allow real-time guidance by a trainer or proctor. To date, clinical application is limited owing to time lag, the need for high-speed wireless Internet or Bluetooth connection and device weight and battery life; application to minimal access surgery remains under development.

THE FUTURE

Minimal access surgery has changed surgical practice; however, it has not changed the nature of disease. The basic principles of good surgery still apply, including appropriate case selection, excellent exposure, adequate retraction and a high level of technical expertise. Endoscopic and robotic surgery training is

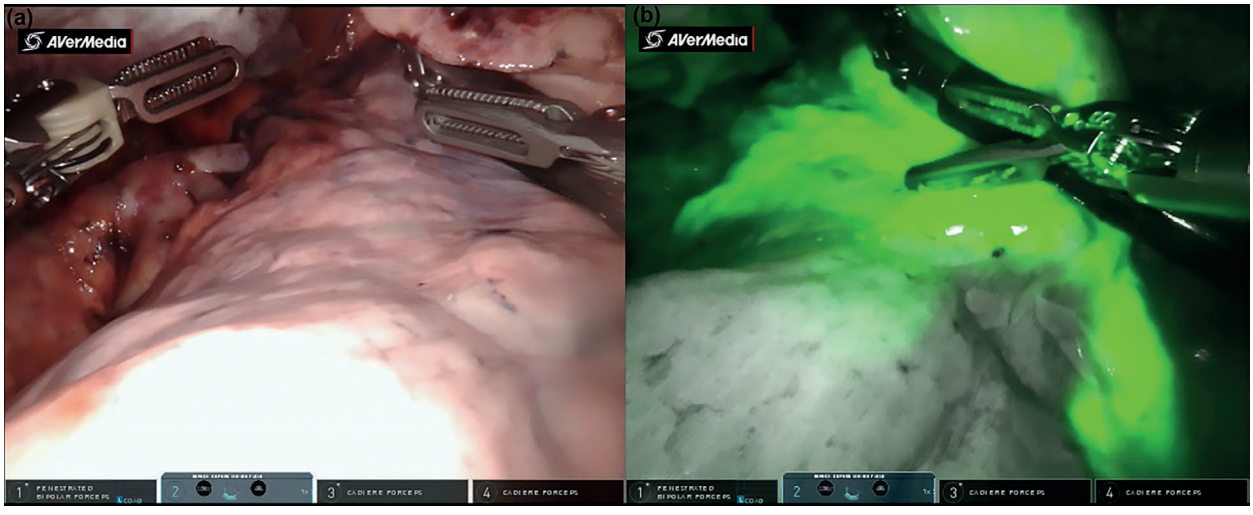

Figure 10.7 Robotic-assisted lung segmentectomy utilising indocyanine green administered endobronchially to highlight the segment for resection. **(a)** Robotic dissection of the superior (S6) segment. **(b)** Indocyanine green immunofluorescence of the marked segment, enabling clear identification of the area for resection.

key to allow the specialty to progress. The pioneers of yesterday have to teach the surgeons of tomorrow not only the technical and dexterous skills required but also the decision-making and innovative skills necessary for the field to continue to evolve. Training is often perceived as difficult, as trainers have less control over the trainees at the time of surgery and caseloads may be smaller, especially in centres where laparoscopic and robotic procedures are not common. However, trainees now rightly expect exposure to these procedures, and training systems should be adaptable for international exposure so that these techniques can be disseminated worldwide.

The predominant video and digital component of these new techniques opens the door for simulation approaches for training in these modalities, which have demonstrated benefits in reducing learning curves and in turn are aimed at improving patient outcomes. The ultimate goal for this educational approach is to develop expert surgeons through the 'totally safe' and 'risk-free' environment of simulation before they

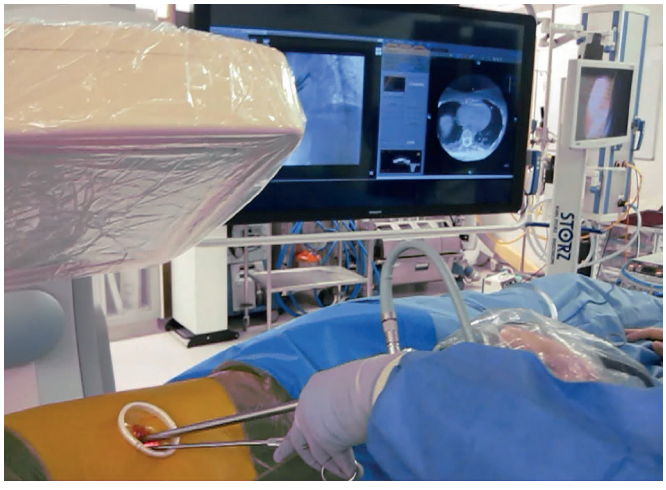

Figure 10.9 Image-guided video-assisted thoracoscopic surgery with the use of a navigationally placed fiducial marker to guide tumour resection (courtesy of Mr Kelvin Lau, Barts Thorax Centre, London, UK).

actually have to operate on patients. Indeed, both videoscopic and robotic platforms now have established simulation programs that are a prerequisite for surgical trainees. Modern robotic simulation modules are able to create an environment that mirrors console use (face validity) and subsequently provide hierarchical training compatible with the user's expertise. The combination of simulation with proficiency-based 'mastery' training may be the key to optimising the impact that simulation may have on the surgical learning curve and remains the subject of research in a range of surgical specialties.

With widespread uptake of minimal access surgery, trainees are now facing a new problem owing to lack of experience in open surgery. Surgeons must have sufficient open surgical experience to feel comfortable converting cases in the event of difficulty or emergency. A minimal access approach to a particular procedure may differ significantly in the order of operative steps and dissection technique. It is therefore vital that the new generation of surgeons continues to receive training in open surgery so that they can apply either technique as appropriate.

Advances in robotic surgery lend themselves to further AI integration, with potential advantages such as providing enhanced clinical decision support, warning of deviations from optimal workflow or detecting and overlaying potentially at-risk structures. In this way, artificially intelligent systems may streamline procedural technique, reduce error and improve patient outcomes. Intelligent operating theatres may provide automated optimisation of a wide range of ergonomic features such as table positioning, lighting and temperature, further facilitating procedural efficiency and effectiveness. In turn, more advanced artificial systems may also develop a degree of supervised autonomy whereby basic surgical procedures can be independently performed by the robotic system. Indeed, in a preclinical setting, the STAR (Smart Tissue Autonomous Robot) robotic system has demonstrated superiority over human surgeons in porcine bowel anastomosis.

Translation of such laboratory-based experiments to real-world surgery is not simple. Application requires detailed understanding of surgical workflow and integration of complex data. To provide a fully comprehensive, annotated training data set on which deep learning may be established, all devices and systems in the dynamic operating environment must be integrated, including operating room set-up, tool and camera usage and the variable patient and procedural factors. In addition there are complex questions in terms of data protection and confidentiality, not to mention the ethical considerations and accountability of autonomous or semi-autonomous robotic surgeons. The most promising elements of AI integration into minimal access surgery remain enhanced object detection, speech recognition, video characterisation and integration with next-generation technologies. Real-time metabolic profiling and tissue-level diagnosis may differentiate between cancerous and non-cancerous tissues on the basis of their metabolic signature. An example is the iKnife, which uses a rapid evaporative ionisation mass spectrometric (REIMS) technique to report tissue histology in real time by analysing aerosolised tissue during electrosurgical dissection.

Artificially intelligent systems also hold potential to dramatically improve the fidelity of simulation training in minimal access surgery, through the creation of a 'real-world' training environment based on the vast data accrued in their development. Such data may be used to create a dynamic simulation environment for any procedure, much more akin to that of 'real-life' surgery. This holds potential for a stepwise tutorial system similar to that of bedside teaching, with objective feedback provided against standardised proficiency benchmarks that can be easily integrated into national training programmes.

One major obstacle for minimally invasive technology remains the cost efficiency and device financing in an increasingly rationed global healthcare environment; this is an issue that will require surgical liaison with hospital management and national policy providers. Surgeons need to continue to have a dialogue, discussing their experiences and ideas in order to effectively progress minimal access surgery and continue to adopt novel technology. As technological advancements are adopted, carefully designed outcomes research is required to provide a clear evidence base to support changes to clinical practice. In this way the comparative effectiveness of novel minimal access technologies will be better understood in terms of both clinical outcomes and cost-effectiveness, allowing selection of those with the greatest potential to provide lasting improvements in patient care.

> The cleaner and gentler the act of operation, the less the patient suffers, the smoother and quicker his convalescence, the more exquisite his healed wound.
>
> Berkeley George Andrew Moynihan (1920)

Berkeley George Andrew Moynihan (Lord Moynihan), 1865–1936, Professor of Clinical Surgery, Leeds, UK. Moynihan felt that English surgeons knew little about the work of their colleagues both at home and abroad. Therefore, in 1909, he established a small travelling club which in 1929 became the Moynihan Chirurgical Club. It still exists today. He took a leading part in founding the *British Journal of Surgery* in 1913 and became the first chairman of the editorial committee until his death.

PART 1 | Basic principles

CHAPTER
11 Tissue and molecular diagnosis

Learning objectives

To understand:
- The value and limitations of tissue diagnosis
- Approaches to tissue processing

To be aware of:
- The principles of microscopic diagnosis
- The features of neoplasia
- The importance of clinicopathological correlation
- The role of additional techniques, including special stains, immunohistochemistry and molecular pathology

INTRODUCTION

Pre-nineteenth century tissue diagnosis depended on naked eye examination of autopsy material and of a small selection of surgical specimens. The development of the light microscope allowed closer examination of tissue from autopsies and surgical procedures, with visualisation of cells, nuclei and tissue structure. Microscopic diagnosis was initially controversial, partly as a result of the 'Kaiser's cancer' (a histological diagnosis by Virchow of a non-malignant laryngeal lesion, after which Kaiser Friedrich III died of laryngeal malignancy), but the medical and surgical community eventually accepted its value.

Tissue analysis is now an integral and routine element of clinical practice. It is heavily dependent on microscopic assessment, although newer methods of tissue analysis will increasingly provide additional information. Assessment of tissue is usually the responsibility of a histopathologist/cellular pathologist (a medically qualified practitioner), who depends on support from technical staff. In the UK, the staff responsible for tissue processing and the production of sections on glass slides are known as biomedical scientists (BMSs). The specialty variably known as Histopathology, Anatomic Pathology or Cellular Pathology encompasses histopathology, cytopathology, autopsy work and molecular tissue diagnosis.

Developments and changes in cellular pathology are continuous. The volume of biopsies continues to increase as a result of increasing clinical demands, expectations of greater diagnostic precision, widespread flexible endoscopy and an ageing population with a higher prevalence of cancer and other illnesses. Cancer screening programmes also have an impact as they often depend heavily on cellular pathology. New techniques to refine histological assessment require additional resources. There is an increasing obligation to comply with national or international standards of reporting, e.g. for cancer, and participation by pathologists in multidisciplinary team meetings is now routine rather than occasional. Other developments may reduce activity. Newer, less invasive methods may replace tissue analysis, e.g. human papilloma virus (HPV) testing for cervical pre-neoplastic lesions is replacing cytological assessment. New methods in imaging may reduce the need for tissue analysis.

The location of a modern cellular pathology department is usually within or near a medium-sized or large hospital or in a purpose-built off-site centre. Typically, more than 80% of specimens are from the gastrointestinal tract, gynaecological tract, skin or urological system. In line with clinical services, highly specialised work such as neuropathology takes place in major regional centres. Consolidation of clinical services may result in reconfiguration of relevant pathology services and molecular testing facilities.

REASONS FOR ASSESSMENT OF TISSUE

The contributions that tissue analysis makes to clinical management include diagnosis, staging, prediction of outcome and assistance with selection of therapy. These are often interrelated. The process of tissue assessment may make a new diagnosis or may confirm or refute a suspected or existing clinical diagnosis. There may be pointers towards a cause. Analysis may also reveal additional diagnoses that may be unsuspected.

As an example, pathological assessment of an appendicectomy specimen most often confirms a suspected clinical diagnosis of acute appendicitis. However, the appendix sometimes contains an incidental neuroendocrine neoplasm, mucinous

Rudolf Ludwig Carl Virchow, 1821–1902, pathologist, Charité Hospital, Berlin, Germany, known as the 'father of modern pathology'.

neoplasm or carcinoma. Sometimes, an inflamed appendix contains granulomas, raising the possibility of Crohn's disease or infection. Also, a specific cause of abdominal pain other than appendicitis, e.g. endometriosis, may be apparent in the appendiceal tissue. Absence of any histological abnormality raises the possibility of an extra-appendiceal cause. Similarly, biopsies from a patient with inflammatory bowel disease may confirm the diagnosis but may sometimes reveal or suggest an alternative cause of intestinal inflammation such as tuberculosis, amoebiasis, ischaemia or mucosal prolapse.

Summary box 11.1

Reasons for analysis of tissue

- Diagnosis
  - Confirmation/rejection of a clinical diagnosis
  - Additional diagnoses
  - Classification of neoplasia
  - Classification of non-neoplastic disease
- Staging of malignancy
- Prognosis
- Management
  - Selection of therapy
  - Assessment of response to treatment
- Cancer screening programmes and related programmes
  - Cervical, bowel, breast, inflammatory bowel disease, Barrett's oesophagus
- Clinical trial support
- Audit

Tissue analysis also helps, increasingly, to determine or refine treatment and prognosis. For example, the assessment of a breast, lung, colorectal or other major cancer resection specimen helps to confirms the diagnosis but, more importantly, provides crucial information about features such as tumour stage, vascular invasion, perineural invasion and resection margin involvement, which in turn help to predict clinical outcome and determine postoperative treatment. The degree of tumour regression in a resection after neoadjuvant therapy may also have prognostic value. Additionally, pathological assessment of resections helps surgeons and radiologists to audit their accuracy and performance.

Molecular pathological analysis of cancer tissue (see ***Diagnostic molecular pathology***) increasingly contributes to management, including diagnostic categorisation, prognostic predictions and selection of drug therapy. The molecular test or group of tests that an oncologist chooses depends on patient status, tumour location, tumour morphology and stage, among other factors. The identification of a particular biomarker may provide an indication for targeted therapy. For example, detection of high microsatellite instability (MSI) in metastatic colorectal carcinoma (CRC) may predict responsiveness to immune checkpoint inhibition.

Of course, a tissue sample does not represent the entire patient. Correlation with the clinical picture and the macroscopic findings enhances the interpretation of pathological changes considerably. Therefore, absence of relevant details may cause unnecessary delays and even errors. For example, radiation therapy can have profound effects on tissue morphology, including mimicry of other inflammatory conditions or neoplasia. Accordingly, a request form with adequate information should accompany all specimens. Examples of important details include site of biopsy/resection, clinical setting, reasons for the procedure, patient details, medications, relevant risk factors and past medical and surgical history, including previous chemotherapy and radiotherapy. A request form stating 'cancer' or 'Crohn's' is better than a form with no details but is clearly not sufficient.

For small and large resection specimens, good quality macroscopic assessment and sampling is an important precursor to microscopic assessment (see ***Specimen processing***).

TISSUE SPECIMENS

Routine tissue specimens received by a histopathology department include those intended for histopathological analysis and those for cytopathological assessment. These may overlap, and 'cytology' preparations sometimes undergo reprocessing to become histological specimens.

Histology

Specimens for histology are classified as biopsies and resections, although strictly speaking all samples are biopsies. The reasons for taking small biopsies include diagnosis, further assessment and prognostic prediction. Types of small biopsy include punch biopsy, needle core biopsy and mucosal biopsy (***Summary box 11.2***).

The purpose of a resection is usually treatment of a lesion (e.g. a tumour) by removing it. Other reasons for a resection exist, e.g. sleeve gastrectomy for obesity or creation of an ileostomy or colostomy. The pathologist's approach depends on the reason for surgery. For example, assessment of a cancer resection has multiple purposes, including confirmation of the diagnosis, classification, grading, staging, determination of further management and prediction of outcome.

An excision biopsy is larger than the common types of small biopsy and serves as both a diagnostic biopsy and as a resection. For example, excision of a small skin lesion achieves its removal and also allows histological diagnosis and classification.

Ultrasound-guided and computed tomography (CT)-guided biopsies of focal and less accessible lesions have become more common and may pose challenges to the pathologist because of limited sample size.

Material from biopsies or resections is usually suitable for molecular analysis. Increasingly, the role of pathologists includes the identification of appropriate material for various

Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA.
Norman Rupert Barrett, 1903–1979, surgeon, St Thomas's Hospital, London, UK.

Summary box 11.2

Common types of tissue sample

Histology

- Formalin-fixed tissue
  - Biopsy
    - Mucosal, e.g. gastrointestinal, bronchial, oral
    - Punch, e.g. skin
    - Needle (core), e.g. liver
    - Curettings, e.g. endometrium, prostate
    - Excision biopsy
  - Resection
- Fresh tissue
  - Frozen section diagnosis
  - Research
  - Tissue banking
  - Occasional special stains that require fresh tissue

Cytology

- Cervical
- Washings, brushings, scrapes
- Fine-needle aspirate
- Fluids, e.g. ascites, pleural fluid
- Sputum

molecular tests and assessment of tissue suitability for molecular testing. For example, some tumour biopsies may contain insufficient tumour for molecular testing. Of course, correct diagnosis and grading are essential before molecular testing occurs, and attempts to bypass this step and take tissue for molecular testing without including the step of histological assessment run many unnecessary risks such as absence of tumour in the sample or the presence of a tumour that is different from that expected clinically.

All samples for routine histology are immediately placed in a fixative, usually formalin (10% formaldehyde), by the surgical team or by other clinical staff to preserve morphology. This usually happens before delivery to the pathology laboratory.

Cytology

There are various approaches to the procurement of a cytology sample. Some samples are easy to obtain, e.g. urine and sputum, whereas others require more intervention. A conventional cervical smear is obtained by sampling the cervical transformation zone with a brush/broom. Bronchial aspirates and washings and bronchial, gastrointestinal and biliary brushings sample a relatively wide area and may therefore be useful for the diagnosis of malignancy.

Fine-needle aspiration (FNA) cytology may sample accessible sites such as the breast, thyroid and superficial lymph nodes, while ultrasound or CT guidance assists FNA from deeper and less accessible structures, e.g. liver, pancreas, kidney and lung. Ultrasound-guided transbronchial FNA may allow sampling of mediastinal masses and transmucosal FNA may be appropriate for submucosal gastrointestinal lesions or perivisceral lesions. A biopsy taken at the same procedure may accompany FNA cytology samples. Fluids may be submitted directly to the laboratory for cytological assessment.

Fresh tissue

The most common indication for submission of a fresh tissue sample (i.e. without the usual formalin or any other fixative) is rapid frozen section diagnosis, usually done intraoperatively. Other indications are microbiological assessment, electron microscopy, chemical analyses (e.g. quantification of iron in the tissue), research work, tissue banking and some types of molecular pathological analysis.

RISK MANAGEMENT

Safety and risk management are priorities in the laboratory. The use of warning labels helps to reduce the risk of contamination by transmissible infection, e.g. hepatitis B virus or human immunodeficiency virus (HIV). This is especially important when submitting and handling fresh (unfixed) tissue. Formalin kills many microorganisms, but a risk of transmissible infection still requires notification. Also, formalin itself is toxic to the eyes and skin. Accordingly, laboratory staff and indeed any staff should discard leaking or faulty specimen containers and deal immediately with formalin spillages. Patient details should be present on all specimen containers so as to avoid errors of identity (***Figure 11.1***). Rigorous systems are in place to avoid interchange of specimens or confusion between different patients' samples.

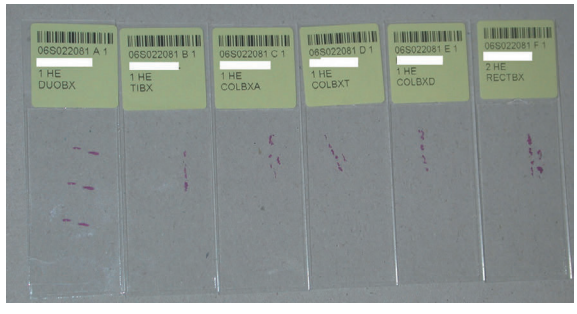

Figure 11.1 Sections on glass slides stained with haematoxylin and eosin. Each slide has a unique specimen identifying number (06S022081), a letter corresponding to the biopsy site (A–F) and a site label (e.g. DUOBX for duodenal biopsy).

SPECIMEN PROCESSING

Histology specimen

On arrival in the pathology laboratory, specimens receive a unique identification number, usually with a barcode. They proceed to macroscopic assessment and sampling (colloquially known as 'cut up'). The largest specimens require initial opening (e.g. gastrointestinal tract) or slicing (e.g. uterus, pancreas, breast) to allow further and adequate fixation in formalin, usually over 24–48 hours (***Figure 11.2***). When fixation is complete and the specimen is in a suitable condition for cutting and sampling, a pathologist or BMS describes the appearances and lists the method of sampling. Specimens a few millimetres

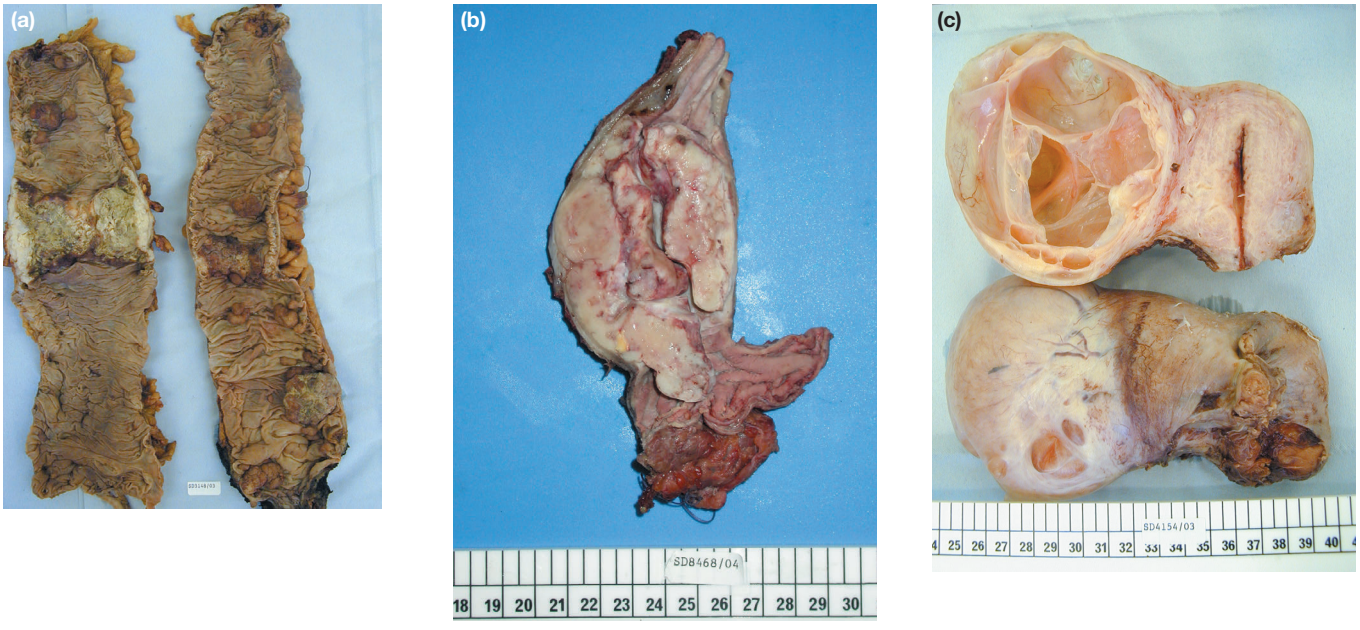

Figure 11.2 (a) A colon from a patient with familial adenomatous polyposis has been opened longitudinally, and the brown appearance reflects adequate fixation. Numerous polyps and a carcinoma are apparent. **(b)** An oesophagogastrectomy containing a distal oesophageal tumour after opening. In this example, there is less fixation, as a result of which the mucosa in the lower part of the picture remains red rather than brown. **(c)** A uterus and an adjacent cystic lesion after slicing to allow fixation (all figures courtesy of Dr J Chin Aleong, Barts Health NHS Trust, London, UK).

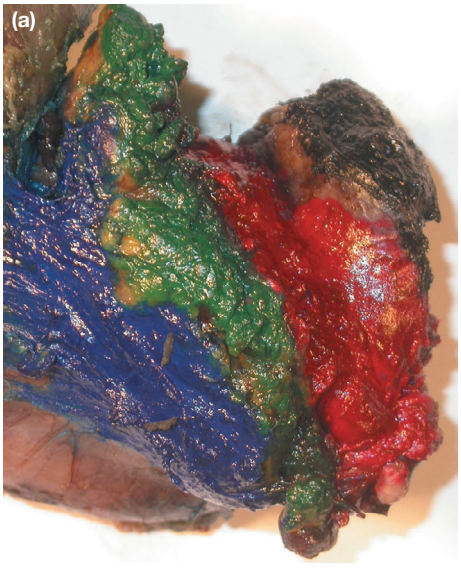
in size such as endoscopic biopsies are suitable for submission in their entirety. Small resections, e.g. skin excision biopsies, may be suitable for slicing into two or more pieces and, again, submission in their entirety. For any specimen that is too large for these approaches, the prosector takes representative samples of areas of interest or relevance (***Figure 11.3***). This is traditionally the remit of the histopathologist, but BMSs or other non-medical staff with specific training increasingly contribute.

In the UK and many other countries, there is often adherence to a regional, national or international guideline that includes a protocol for sampling. For example, samples from most types of cancer should include tumour, resection margins, lymph nodes, non-neoplastic tissue and any other abnormal areas. Inks of various colours help to identify resection margins and surfaces during microscope assessment as they remain in place after processing (***Figure 11.4***).

The prosector places specimens, or samples from specimens, in plastic cassettes (***Figure 11.5***). BMSs/technical staff then embed the tissue in paraffin wax while in the cassette to produce a tissue block (***Figure 11.6***). BMSs then cut sections with a thickness of approximately 5 μm from the block using a microtome (***Figure 11.7***), place the sections on a glass slide and stain them with haematoxylin and eosin (H&E) (***Figure 11.1***). These steps require training and skill. A poor quality section may have various artefacts, such as lines, folds and shatter effect, which impede accurate assessment.

H&E remains by far the most common initial stain for histopathology assessment, probably because it is inexpensive, safe, fast, reliable, familiar and informative. There is a wider variety of stains for cytology preparations including H&E and Giemsa.

Traditionally, a pathologist examines stained sections with a microscope (***Figure 11.8***) and correlates the appearances with the clinical details and the macroscopic description. After completion of any additional studies such as special stains, immunohistochemistry and molecular analysis, the pathologist enters a report onto a computer system and allocates specific topography and morphology codes that will facilitate future searches. Recent improvements in technology and information technology (IT) mean that some laboratories use scanning machines to create digital images of the glass slides that pathologists and others can then access locally or remotely at any time (see ***Digital pathology and artificial intelligence***).



Summary box 11.3

Histological processing: sequence of events

- Receipt of specimen
- Macroscopic (gross) description
- Sampling of specimen (unless small enough to submit in its entirety)
- Specimen or samples placed in cassette(s)
- Production of paraffin wax block(s)
- Cutting of 5-μm sections with microtome
- Sections placed on glass slides
- Sections stained with H&E
- Histopathologist examines slides, taking clinical and macroscopic findings into account
- Further studies on tissue, if necessary
- Entry of report onto computer system
- Authorisation of report by pathologist

Figure 11.3 A pathologist takes a sample from a resection specimen with a scalpel and forceps.

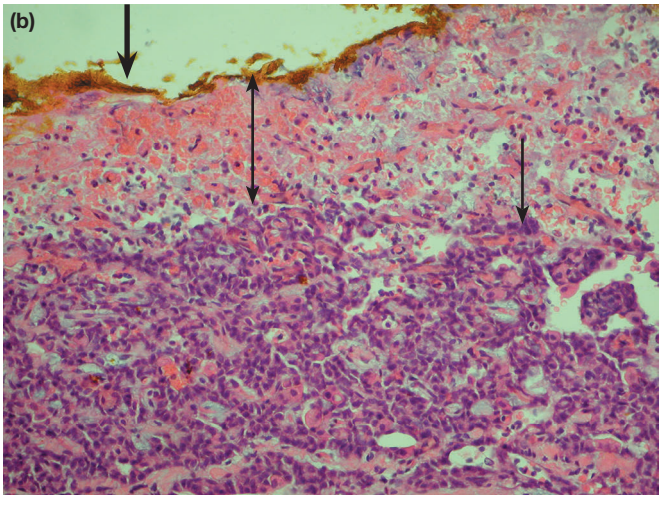


Figure 11.4 (a) An unopened pancreatoduodenectomy specimen (posterior view). Four inks of different colours have been painted onto separate margins and surfaces. **(b)** Yellow ink on the edge of a histology section (thick arrow). Tumour (thin arrow) lies close to the surface. The pathologist can measure the distance between the tumour and a surface or a resection margin (double-headed arrow).

Figure 11.5 A pathologist places a tissue sample from a resection specimen in a cassette.

Figure 11.6 Paraffin wax blocks. Cassettes of different colours allow the organisation of samples and specimens into groups, e.g. according to specialty or degree of urgency.

Figure 11.8 A double-headed microscope allows a consultant histopathologist and a trainee to view a slide simultaneously.

Frozen section specimen

Frozen section diagnosis is useful when a very rapid answer is necessary. Surgeons are the main users. The surgeon supplies a small representative fresh tissue sample of the area of interest. A BMS freezes the tissue quickly in the pathology laboratory and can produce sections for microscopic examination within several minutes. There are a few disadvantages in comparison with routine processing: fresh tissue carries a higher risk of infection; the quality is inferior to that of routine material, resulting in a potential reduction in diagnostic accuracy and precision; small but representative samples are necessary; certain types of tissue (e.g. fat) are difficult to process; and the process is time-consuming and disruptive (***Summary box 11.4***).

Summary box 11.4

Frozen section: advantages and disadvantages

Advantages

- Quick diagnosis

Disadvantages

- Poorer quality sections
- Potential reduction in accuracy and precision of histological diagnosis
- Labour intensive
- Disruptive
- Risk of infection
- Small sample required
- Some tissue types difficult to process

Cytology specimen

Samples for cytology can be smeared immediately onto glass slides, fixed (usually in alcohol) or air dried and stained immediately or later. The process usually produces several slides, some of which are stained with a Papanicolaou (Pap) stain and some with another method such as May–Grünwald–Giemsa (MGG), H&E or Romanowsky (***Figure 11.9***). Liquid-based thin-layer technology is now replacing older methods. For liquid-based cytology, the sampling device is usually washed in a liquid medium and the material obtained is then processed in the laboratory using purpose-built equipment.

Storage

Resection specimens are generally stored for about 4–6 weeks. Tissue blocks and slides are retained for as long as space permits. Fresh tissue can be frozen for future clinical review, teaching, audit or research. Many countries now have formal tissue-banking processes that allow construction of an archive of cases. In many countries, the storage, transport and subsequent use of tissue is subject to many legal constraints.

PRINCIPLES OF MICROSCOPIC DIAGNOSIS

Diagnosis of malignancy

Neoplasia is a broad term that includes benign and malignant tumours and precursors of malignancy. The word 'cancer' is not precise, derives from observations of the similarities between crabs and tumours by ancient Greek physicians such as Hippocrates and usually refers to all malignancies (rather than carcinoma alone). Classification of a tumour as malignant implies that it can behave aggressively. The main features of malignancy are metastasis and invasion and there are characteristic architectural and cytological abnormalities. However, the criteria for a diagnosis of malignancy differ between anatomical sites and between tumour types. Sometimes, the traditional concept of benign and malignant is not applicable and instead there is a classification that identifies a spectrum of tumours from well differentiated to poorly differentiated or from low grade to high grade depending on known clinical behaviour.

Gustav Giemsa, 1867–1948, chemist and bacteriologist, Hamburg, Germany.
Dmitri Leonidovich Romanowsky, 1861–1921, Professor of Medicine, St Petersburg, Russia.
Hippocrates of Kos, Greek physician and surgeon, and by common consent 'the father of medicine', was born on the island of Kos, off Turkey, about 460 BCE and probably died in 375 BCE.

Summary box 11.5

Microscopic features of malignancy

- Metastasis
- Invasion
  - Of surrounding tissue
  - Vascular (intraluminal tumour and/or tumour in blood vessel wall)
  - Perineural
- Architectural abnormalities
- Necrosis
- Numerous mitotic figures
- Atypical mitotic figures
- Nuclear abnormalities
  - Pleomorphism
  - Enlargement
  - Hyperchromaticity
  - Chromatin clumping
- Nucleolar enlargement and multiplicity

Microscopic evidence of aggressive behaviour by the tumour is usually sufficient for a malignant label. For example, metastasis to another organ such as lymph nodes or liver is diagnostic of malignancy. Invasion of surrounding structures, perineural invasion (***Figure 11.10***) and vascular spread or invasion (***Figure 11.11***) strongly suggest malignancy.

Other microscopic features that are typical of malignancy include derangement of the usual tissue architecture, an increase in the number of mitotic figures, atypical mitotic figures and necrosis (tissue death) (***Figure 11.12***). Changes in the appearances of individual cells, i.e. cytological changes, include nuclear enlargement, an increase in the nuclear: cytoplasmic ratio, nuclear pleomorphism (variation in nuclear appearance) and nuclear hyperchromasia (dark colour) (***Figure 11.13a***). Multiplicity, irregularity and enlargement of nucleoli may also be apparent (***Figure 11.13b***). However, none of these features is diagnostic of malignancy in isolation.

The criteria for a histological diagnosis of malignancy vary according to the site and type of tissue. Carcinoma is by far the most common type of malignancy, and in many settings is diagnosable when epithelial cells invade beyond their normal boundaries. However, the categorisation of some types of non-epithelial proliferations (e.g. lymphoid or mesenchymal) as malignant may rely on cytological and/or architectural features rather than on invasiveness. In some cases, e.g. phaeochromocytoma, reliable histological distinction between benign and malignant is not possible. In other cases, e.g. gastrointestinal stromal tumours (GISTs), there are risk categories based on combinations of histological features that help to predict the likelihood of aggressive behaviour rather than benign or malignant designations. Additional techniques such as immunohistochemistry and clonality studies occasionally help to confirm or support a diagnosis of neoplasia or malignancy (see ***Immunohistochemistry: tumour pathology*** and ***Diagnostic molecular pathology***).

The term 'dysplasia' usually indicates that microscopic features similar to those of carcinoma are present but that there is no invasion. The term 'intraepithelial neoplasia' is analogous to dysplasia. Examples include cervical intraepithelial neoplasia (CIN) and gastrointestinal dysplasia (***Figure 11.14***). Grading of dysplasia may be as low grade/high grade or as mild/moderate/severe while grading of intraepithelial neoplasia may be numerical (e.g. CIN 1, CIN 2 and CIN 3).

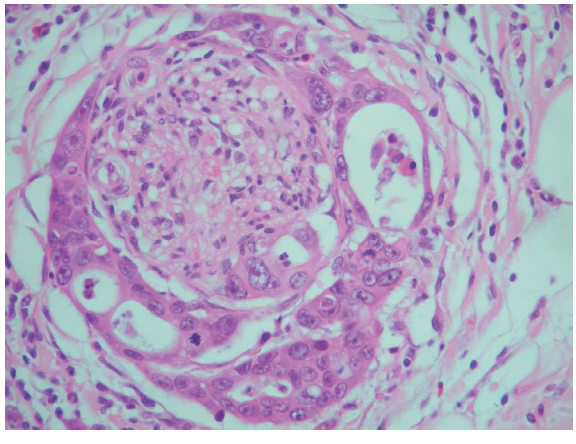

Figure 11.10 Perineural invasion. A nerve is almost surrounded by adenocarcinoma.

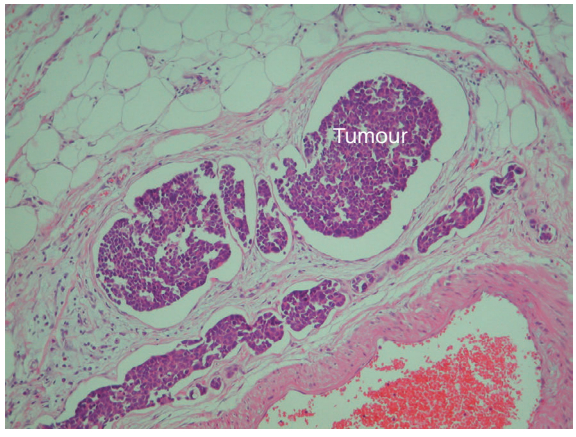

Figure 11.11 Vascular invasion. Aggregates of carcinoma cells are present within blood vessels. The tumour is poorly differentiated.

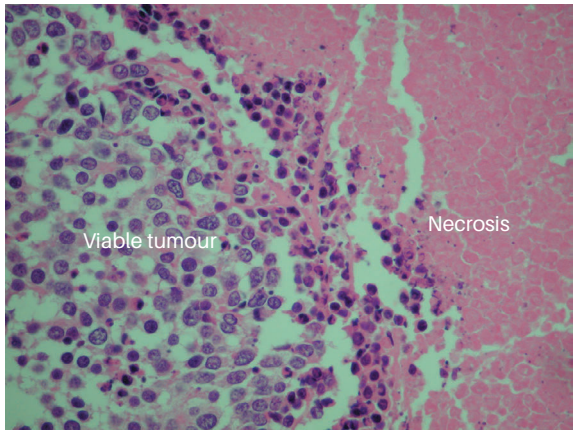

Figure 11.12 An area of necrosis in a poorly differentiated carcinoma.

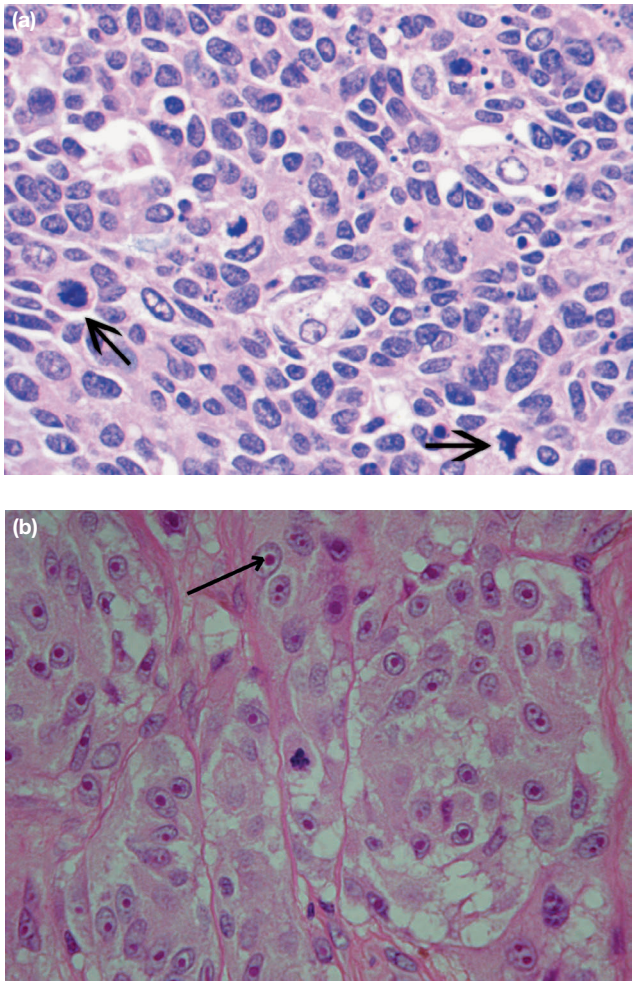

Figure 11.13 Cellular features of malignancy. **(a)** A neuroendocrine carcinoma showing nuclear pleomorphism (variation in shape) and variation in nuclear size. There are several mitotic figures (arrows). **(b)** A malignant melanoma showing nuclear pleomorphism and prominent nucleoli (arrow) (courtesy of Dr E Husain, Aberdeen Royal Infirmary, Aberdeen, UK).

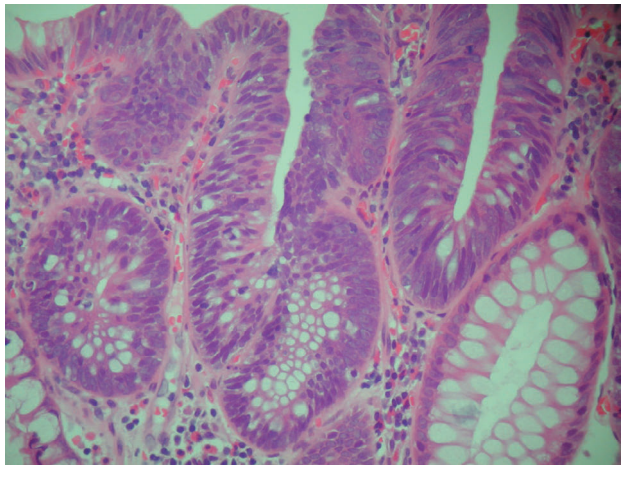

Figure 11.14 A colonic biopsy from a tubular adenoma with low-grade dysplasia. A non-dysplastic crypt is apparent at lower right. The remaining crypts mostly show features of dysplasia, including nuclear stratification (multilayering), nuclear enlargement and nuclear hyperchromaticity (dark colour).

There are various causes of a false-positive diagnosis of malignancy. These include contamination of a specimen with tumour from elsewhere, interchanging of specimens, observer error and histological mimicry. A false-negative diagnosis, i.e. a failure to diagnose malignancy when present, may reflect absence of tumour in the specimen or failure of the pathologist to recognise the changes as neoplastic.

Several conditions can resemble malignancy histologically. For example, radiation effect can produce cytological atypia that mimics malignancy, and the epithelial changes in regenerating tissue adjacent to a mucosal ulcer may show features reminiscent of neoplasia. The risk of interpretative error by the histopathologist is likely to be lower if there is thorough training of pathologists, regular updating of knowledge, discussion of difficult cases with colleagues and avoidance of excessive workloads. The surgeon also helps to minimise errors by supplying good clinical details.

Summary box 11.6

Causes of false-positive diagnoses of malignancy

- Interchanged samples
- Contamination
- Interpretative error
- Treatment-induced change, e.g. radiotherapy
- Ulceration

Histological types of malignancy

A malignant tumour showing features of epithelial differentiation, and typically arising in an epithelial layer, is a carcinoma. Other important types of malignancy include malignant melanoma (melanocytes) (***Figure 11.13b***), lymphoma (lymphoid cells) and sarcoma (mesenchymal cells). Further subclassification is often appropriate and necessary. For example, categories of carcinoma include squamous cell carcinoma (with evidence of keratinisation) (***Figure 11.15***), adenocarcinoma (with evidence of glandular differentiation and/or mucin production) (***Figure 11.16***) or neuroendocrine carcinoma (***Figure 11.13a***) (usually requiring immunohistochemical confirmation of neuroendocrine differentiation). Some carcinomas have a pattern that raises a certain differential diagnosis, e.g. clear cell carcinoma (***Figure 11.17***). There are many other morphological types of carcinoma.

Prognostic factors for malignant tumours

Tissue assessment is important for cancer prognosis. Stage is generally the most important prognostic factor for carcinomas. The internationally accepted Union for International Cancer Control (UICC)/American Joint Committee on Cancer (AJCC) staging schemes depend heavily on the histopathological TNM (Tumour Node Metastasis) category (pTNM), although the overall stage and in particular the M category are also evaluated clinically and on imaging and the final stage is derived from a combination of clinical, imaging, pathological and other assessments. The degree of differentiation may also be prognostic and is usually determined microscopically. As a

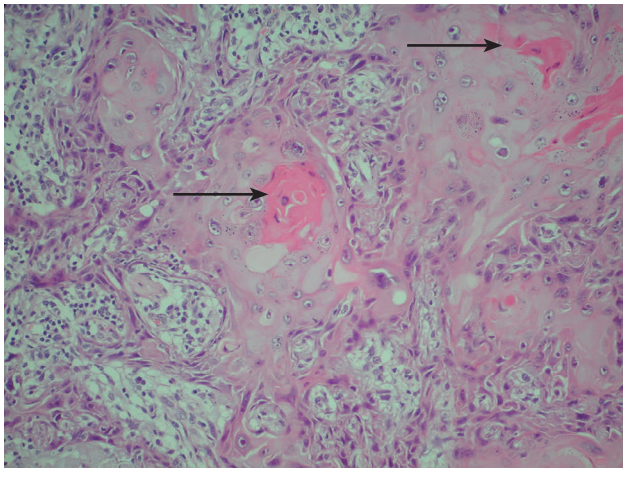

Figure 11.15 A well-differentiated squamous cell carcinoma. Irregular nests of squamous cells are present. They include foci of keratinisation (arrows).

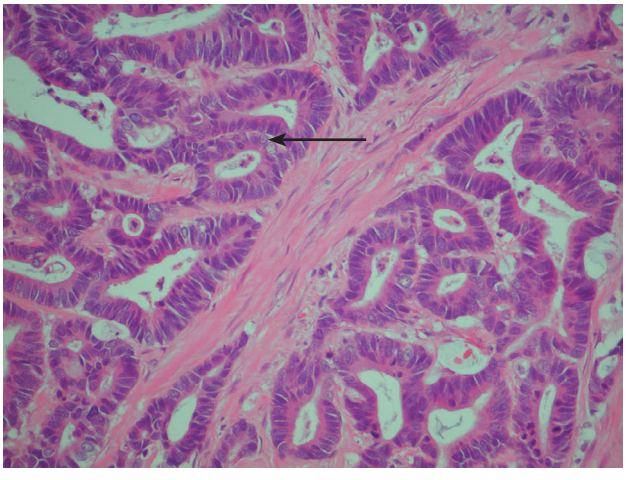

Figure 11.16 A well-differentiated adenocarcinoma. Gland formation (arrow) is obvious.

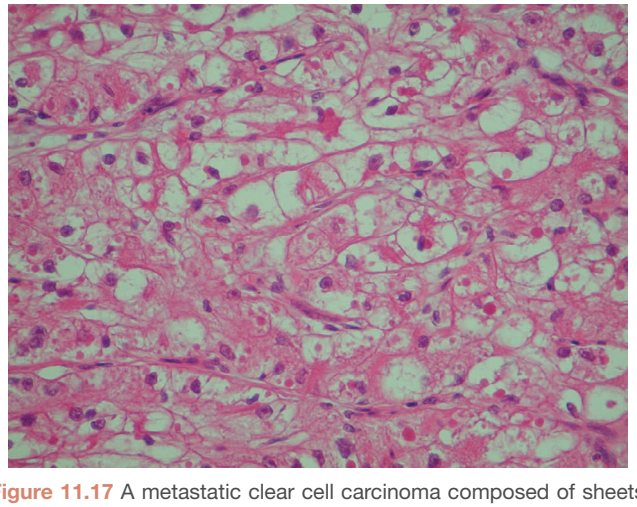

Figure 11.17 A metastatic clear cell carcinoma composed of sheets of cells with clear cytoplasm. A tumour with this appearance is most likely to be of renal origin but could have other sources such as liver, parathyroid gland, gynaecological tract and gastrointestinal tract.

rule, well-differentiated tumours recapitulate the appearances of their non-neoplastic tissue counterparts (***Figures 11.15 and 11.16***), whereas poorly differentiated tumours do not (***Figures 11.11 and 11.12***). Other histological features associated with a worse prognosis include vascular invasion (***Figure 11.11***), perineural invasion (***Figure 11.10***) and positive resection margins. The prognostic value of these factors differs between tumour types and sites.

There is an increasing number of potential prognostic factors for a wide range of malignancies and preneoplastic lesions. These include immunohistochemical tests and molecular tests that may aim to detect underlying genetic changes such as mutations or amplifications or may help to refine grading. For example, immunohistochemistry for the proliferation marker Ki67 is now essential for grading and prediction of behaviour of well-differentiated neuroendocrine neoplasms. Screening for mismatch repair (MMR) gene abnormalities using immunohistochemistry helps to predict response to therapy, outcome and the need for genetic testing for familial disease.

Although controversial, immunohistochemical staining might help to predict the behaviour of preneoplastic lesions such as Barrett's oesophagus (p53 staining) or cervical/anal intraepithelial neoplasia (p16 staining).

Non-neoplastic and inflammatory conditions

The diagnosis, assessment and management of non-neoplastic disease generates numerous pathology specimens. Examples include appendectomy for appendicitis, cholecystectomy for gallstone disease, hysterectomy for fibroids, skin excision for various lesions such as sebaceous cysts and prostatic chippings from glands with hyperplasia. Thorough histological examination helps to confirm or refute the provisional clinical diagnosis and also to exclude other conditions, some of which may be entirely incidental, e.g. neoplasia of the gallbladder, malignant change in uterine fibroids or carcinoma in prostatic chippings. Surgical and medical teams also generate a very large number of biopsies with the purpose of diagnosing and assessing non-neoplastic disease. In this setting, correlation with the clinical picture may be very important. For example, clinical details are essential for meaningful interpretation of inflammatory bowel disease biopsies, inflammatory skin biopsies, renal biopsies and medical liver biopsies.

Microscopic features of inflammation

Acute inflammation is characterised histologically by neutrophils (polymorphonuclear leukocytes), erosion or ulceration (***Figure 11.18***) and chronic inflammation by lymphocytes and plasma cells. Other inflammatory cells include eosinophils (***Figure 11.19***), mast cells and histiocytes. Granulomas (collections of epithelioid histiocytes) (***Figure 11.20a***) raise the possibility of mycobacterial infection (***Figure 11.20b***), fungal infection, parasites, sarcoidosis, Crohn's disease or a reaction to foreign material, among numerous other possible causes. Eosinophils in large numbers may reflect parasitic infection or allergy. Interpretation depends heavily on the site and clinical setting.

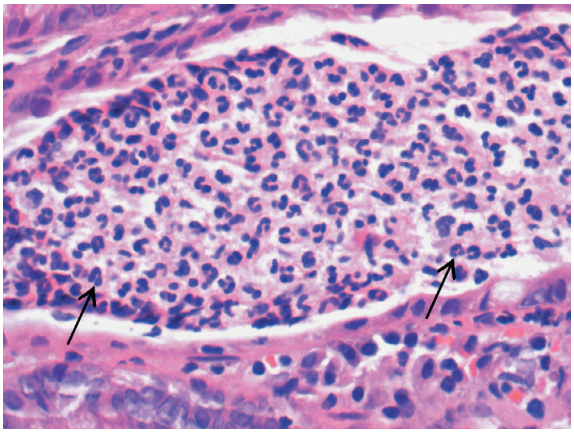

Figure 11.18 An acute inflammatory process characterised by numerous neutrophils. Note the typical multilobated nuclei (arrows).

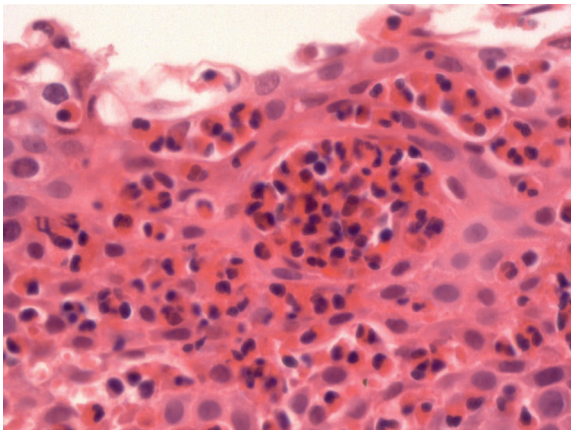

Figure 11.19 Oesophageal mucosa infiltrated by numerous eosinophils with bright red cytoplasm, many of which are forming clusters. Eosinophils may reflect allergy, parasitic infection or a wide variety of other causes. In this example, the clinicopathological diagnosis was eosinophilic oesophagitis.

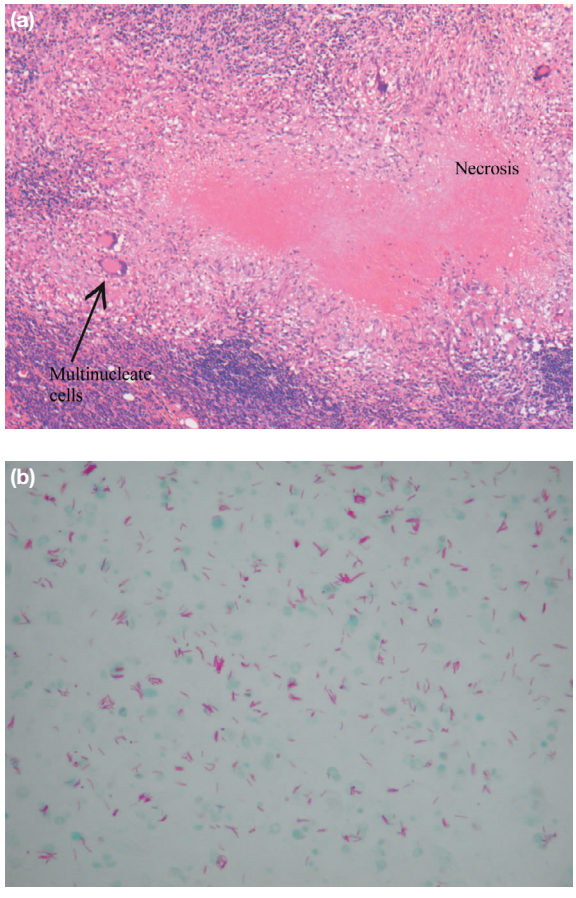

Figure 11.20 (a) A granuloma with necrosis, suggesting tuberculosis. Multinucleate giant cells of Langhans type are also present (arrow). (b) A Ziehl–Neelsen stain (from a different case) shows numerous pink acid-fast rod-shaped bacilli, confirming mycobacterial infection.

Other terms

Other specific tissue abnormalities are also detectable by microscopy. Histopathologists may use specific terms. Some examples are as follows.

- Hyperplasia: an increase in cell number.
- Hypertrophy: an increase in cell size.
- Atrophy: may refer to a reduction in cell number or cell size or a diminution in size of a structure (e.g. a duodenal villus undergoing atrophy in coeliac disease).
- Metaplasia: a change from one mature cell type to another, e.g. columnar metaplasia in the oesophagus (Barrett's oesophagus), whereby metaplastic gastric or intestinal-type epithelium replaces normal squamous epithelium.
- Necrosis: cell or tissue death, typically because of factors external to the cell, and associated with cell swelling, inflammation and eventual disappearance of cells (*Figure 11.20*).
- Apoptosis: a process of programmed cell death that occurs because of internal signals, and on histological examination typically manifests as cell shrinkage and nuclear chromatin condensation.

ASSESSMENT

Light microscopy

Most tissue assessment depends on conventional light microscopy. Microscopes have several lenses with various powers of magnification, typically ranging from ×20 to ×400 or more. A low-power lens allows scanning of a sample and assessment of overall architecture, while a higher power lens allows a

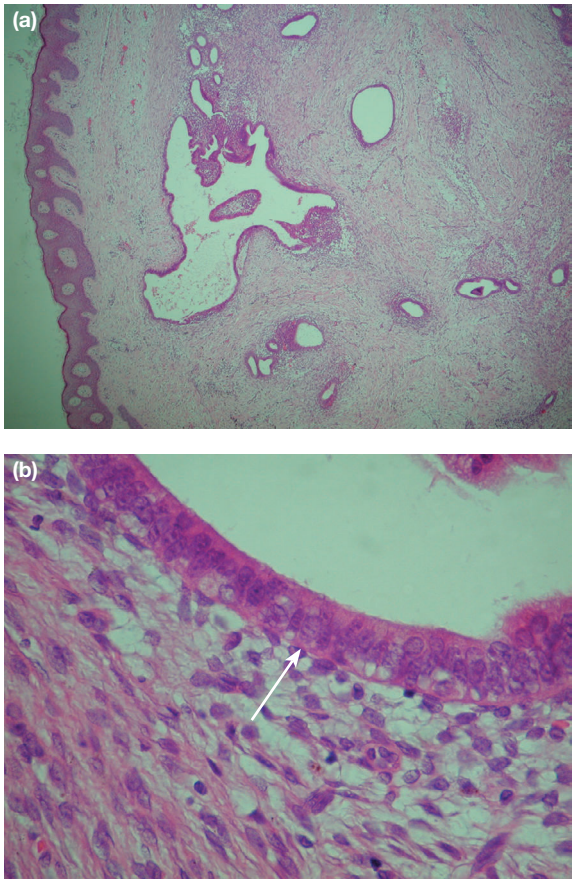

Figure 11.21 (a) Low-power view of an umbilical nodule. Glands are distributed irregularly through the tissue. (b) High-power view shows benign columnar epithelium lining the glands (arrow), indicating endometriosis rather than carcinoma.

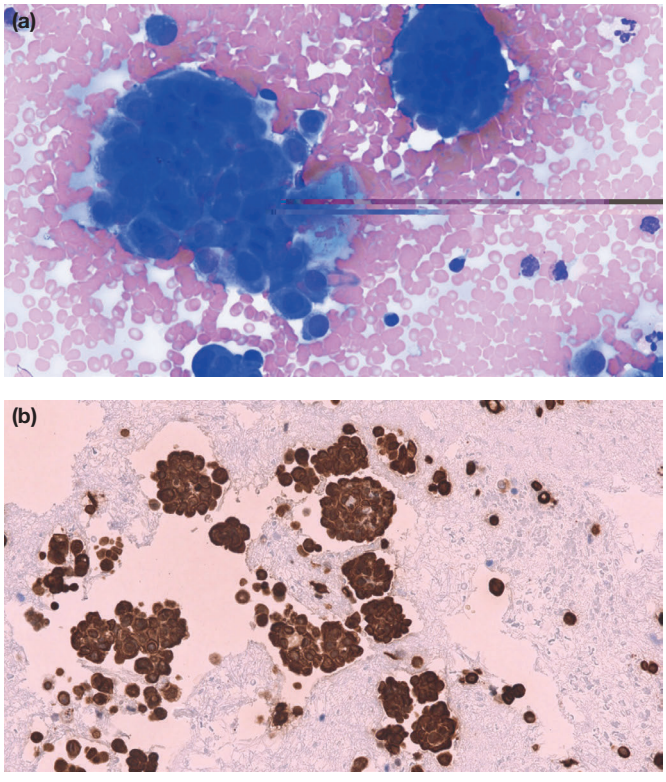

Figure 11.22 (a) A cytology preparation of a pleural effusion. Numerous cells with atypical features are present, forming closely packed groups of overlapping cells. (b) Immunohistochemistry shows positive staining for carcinoembryonic antigen, favouring carcinoma over mesothelioma.

closer view with more detail (*Figure 11.21*). Attachment of one or more teaching arms, a camera and other accessories are possible for many microscopes (*Figure 11.8*). Polarisation assists with detection of some types of foreign material (e.g. sutures) or to assess a special stain (e.g. Congo red for amyloid deposition).

Histological assessment

In a histological preparation, the microscopic structure of the tissue remains intact, allowing direct visualisation of tissue architecture. Accordingly, the pathologist can see not only the characteristics of the cells that form the tissue, but also the way in which these cells relate to one another and the structure and arrangement of the various tissue compartments.

Cytological assessment

A cytological preparation consists of a sample of cells only. Assessment of architecture is not usually possible because intact tissue is absent or sparse (*Figures 11.9 and 11.22*). Therefore, assessment relies on the characteristics of the individual cells. Accordingly, diagnosis of malignancy is often difficult because the pathologist cannot assess certain features that support a diagnosis of malignancy such as invasiveness. However, cytology has several potential advantages over a biopsy. Obtaining a specimen may be easier and less traumatic. The area of sampling may be wider. Processing times are usually shorter and costs lower. Also, the ability of non-medical staff to report a proportion of cases reduces costs.

Summary box 11.7

Cytology compared with histology

Advantages

- Wider area of sampling in some cases
- Often less invasive
- Fast
- Cheap

Disadvantages

- Cannot assess tissue architecture
- Less amenable to further tissue studies

Sodium diphenylbisazobisnaphthylamine sulphonate is a red dye marketed in 1884 by the AGFA company of Berlin, Germany, using the name '**Congo red**'. It is no longer used as a cloth dye owing to the carcinogenic risks of the benzidine moiety.

Screening

Screening programmes aim to detect and treat premalignant tissue changes (dysplasia/intraepithelial neoplasia) or early-stage malignancy for which treatment is likely to be curative. The programmes may rely on clinical assessment, imaging and/or pathological assessment. The cervical cancer programme traditionally relied on cytology, with biopsy and histology follow-up if appropriate, but the alternative of HPV testing is increasingly available. The breast cancer screening programme relies on imaging and may use cytology and/or histology to assess possible lesions. The bowel cancer screening programme relies initially on a non-tissue-based test followed, if appropriate, by lower gastrointestinal endoscopy with or without biopsy of abnormal areas. Screening for neoplasia in ulcerative colitis and in Barrett's oesophagus relies on endoscopic assessment and biopsy.

Specimen adequacy

There are many reasons for an inadequate specimen. The operator may fail to sample the target organ or lesion or may take a sample that is too small to include or reveal a heterogeneous abnormality. A sample from the centre of a necrotic or ulcerated lesion might include no viable tissue. Superficial biopsies from a carcinoma may fail to distinguish dysplasia (***Figure 11.14***) from invasive carcinoma. Cautery and crush artefact are sometimes severe enough to impede assessment. Suboptimal laboratory processing can also cause problems with interpretation.

Summary box 11.8

Reasons for an inadequate sample

Histology and cytology

- Failure or inability to sample the intended area
- Sample too small
- Sample unrepresentative
- Non-viable tissue, e.g. ulcer or necrosis

Histology

- Sample too superficial to detect deeper layers
- Cautery artefact
- Crush artefact

Deeper levels and extra blocks

The pathologist may request 'deeper levels', whereby the BMS cuts further into the paraffin block to obtain further sections that may provide more information. For example, deeper levels of an atypical but non-invasive epithelial lesion might show foci of invasion, allowing a definite diagnosis of carcinoma. Further sampling of tissue from a resection specimen (extra blocks) is sometimes necessary, e.g. if the number of lymph nodes in a cancer case is insufficient for accurate staging.

FURTHER WORK

Pathologists request further stains or other tests on a significant minority of histology specimens. This includes special stains, immunohistochemistry, *in situ* hybridisation and various molecular pathology techniques. Electron microscopy may assist with renal biopsy assessment. Some of these additional investigations are also applicable to cytology specimens (***Figure 11.22***). Sufficient tissue is again important for accurate interpretation of some tests, e.g. molecular testing and quantitative immunohistochemical methods.

Special stains

A 'special stain' is a stain that is not routine, i.e. not an H&E stain. Immunohistochemical stains are conventionally separate from this category. Some special stains demonstrate normal substances in increased quantities or in abnormal locations. The periodic acid–Schiff (PAS) stain demonstrates both glycogen and mucin, whereas a diastase PAS (D-PAS) stain demonstrates mucin, e.g. in an adenocarcinoma. Perls Prussian blue stain demonstrates iron accumulation (***Figure 11.23***), e.g. in haemochromatosis. A reticulin stain helps to demonstrate fibrosis (***Figure 11.24***). Elastic stains also show fibrosis and can highlight blood vessels by outlining their elastic laminae. Special stains can also reveal the accumulation of abnormal substances, e.g. a Congo red stain for amyloid.

Summary box 11.9

Additional techniques for assessing tissue

- Special stains
- Immunohistochemistry
- Electron microscopy
- *In situ* hybridisation, including fluorescence *in situ* hybridisation (FISH)
- Molecular pathology techniques (including single biomarker polymerase chain reaction [PCR] and next-generation sequencing [NGS])

Summary box 11.10

Common special stains

- PAS: glycogen, fungi
- D-PAS: mucin
- Perls Prussian blue: iron
- Reticulin: reticulin fibres, fibrosis
- van Gieson: collagen
- Congo red: amyloid
- Ziehl–Neelsen: mycobacteria

Hugo Schiff, 1834–1915, German biochemist who worked in Florence, Italy.
Max Perls, 1843–1881, pathologist, Giessen, Germany.
Ira Thompson van Gieson, 1866–1913, American neuropathologist, described this stain in 1889.

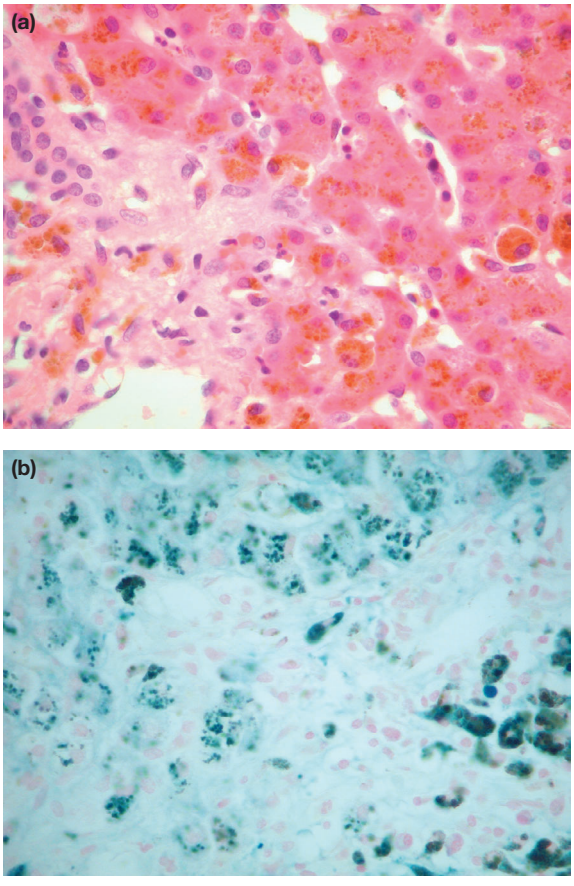

Figure 11.23 (a) Brown pigment in a biopsy. **(b)** A Perls stain is positive, indicating that the pigment is iron.

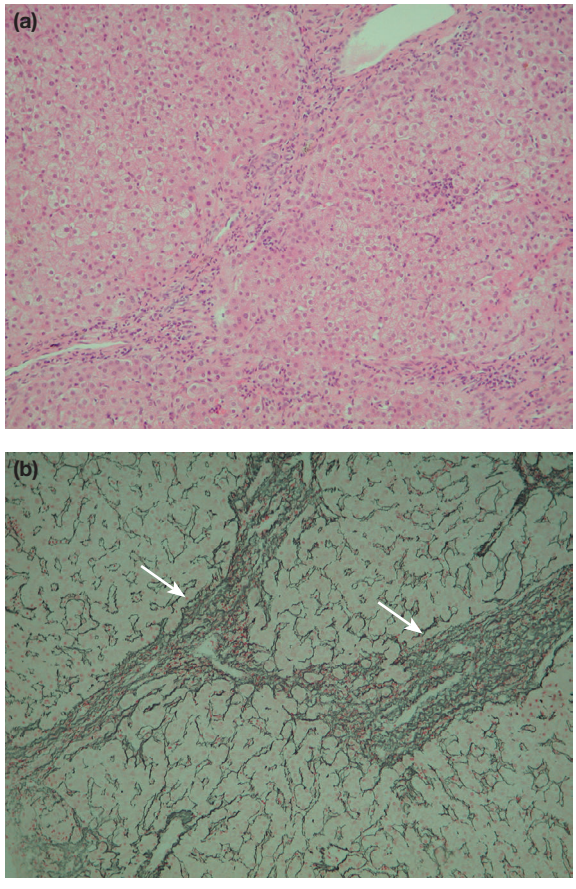

Figure 11.24 (a) A liver biopsy stained with haematoxylin and eosin in which the severity of fibrosis cannot be determined. **(b)** A reticulin stain demonstrates fibrous bridges (arrows).

Special stains are also useful for the diagnosis of infection. Some microorganisms are not visible on routine H&E slides but are demonstrable with a stain. For example, a Ziehl–Neelsen stain demonstrates acid-fast bacilli, particularly mycobacteria, by staining them bright red on a blue background (***Figure 11.20***). Other microorganisms may be detectable on H&E but are easier to see with a special stain, e.g. fungi (PAS or Grocott stain), protozoa (Giemsa stain) and spirochaetes (Warthin–Starry stain). Immunohistochemistry and *in situ* hybridisation also help to detect some microorganisms (see ***Immunohistochemistry: infections and other applications*** and ***In situ hybridisation***).

Electron microscopy

Electron microscopy allows visualisation of tissue at very high magnification, e.g. ×1000 to ×500 000. It may help to decide the lineage of a non-neoplastic or neoplastic cell and may help to determine the nature of abnormal deposits, e.g. in renal disease. However, it is time-consuming, labour intensive and expensive and consequently has limited applications.

Immunohistochemistry

Immunohistochemistry emerged in the 1970s and has had a major impact on histopathological diagnosis. The technique detects a specific antigen using an antibody. The antibody is labelled with a dye and after binding to its target antigen is visible in the tissue section as a coloured stain, often brown (***Figure 11.25***). This allows the pathologist to confirm or exclude the presence of an antigen as well as determine its tissue distribution and cellular localisation. Quantification may also be possible. For example, Ki67 is a cell cycle marker that allows the pathologist to calculate a proliferative index, which in turn has prognostic value for neuroendocrine neoplasms and other lesions. Immunohistochemistry is applicable to fixed and frozen tissue and to cytological preparations (***Figure 11.22b***). It is safe, quick and relatively inexpensive and is often specific. However, false-positive results can result from non-specific staining or from cross-reaction with similar antigens. Excessive reliance on immunohistochemistry can lead to errors.

Alfred Scott Warthin, 1866–1931, Professor of Pathology, The University of Michigan, Ann Arbor, MI, USA.
Allen Chronister Starry, 1890–1973, American pathologist.

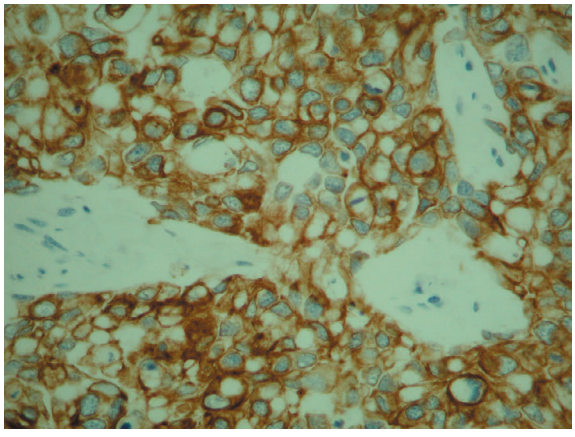

Figure 11.25 Diffuse immunohistochemical staining (brown) for a pancytokeratin marker in a malignancy, favouring carcinoma over other tumours.

Immunohistochemistry: tumour pathology

Immunohistochemistry has multiple applications in tumour pathology, including elucidation of site of origin and determination of cell type/direction of differentiation. Immunohistochemistry may also help to confirm neoplasia, determine the selection of treatment, refine prognostic predictions and screen for known underlying genetic changes.

Numerous immunohistochemical stains help to determine cell type in tumours. Epithelial cells express cytokeratins. Therefore, cytokeratin positivity, though not diagnostic, favours carcinoma (*Figure 11.25*) over other types of malignancy. Lymphoid markers include the panlymphoid marker CD45, the T-lymphocyte marker CD3 and the B-lymphocyte marker CD20. Markers of melanocytic differentiation include S100, MelanA and HMB45. Chromogranin, synaptophysin and CD56 help to confirm neuroendocrine neoplasia. A GIST typically expresses CD117 (*Figure 11.26*) and DOG-1. Endothelial cell markers include CD31, which may confirm a diagnosis of vascular neoplasia or highlight vascular invasion by tumours.

H&E appearances may indicate or suggest the anatomical site of origin of a metastatic tumour. For example, an adenocarcinoma has several possible sources such as gastrointestinal tract, pancreatobiliary system, bronchus, breast and gynaecological tract. A clear cell carcinoma (*Figure 11.17*) is often of renal origin but could be from the liver, pancreas, parathyroid or endometrium, among other sites. Immunohistochemical stains often provide valuable further information about anatomical origin. Some are highly specific for a particular site, e.g. prostate-specific antigen (PSA) and thyroglobulin. Others are somewhat less specific, e.g. thyroid transcription factor-1 (TTF-1), a marker of bronchogenic or thyroid origin; hepatocyte-specific antigen, suggesting hepatocellular origin; and cytokeratin 20, typically expressed by colorectal epithelium. Carcinoembryonic antigen (CEA) is present in several types of carcinoma (*Figure 11.22b*). In practice, pathologists encountering a neoplasm of uncertain origin or uncertain phenotype usually request a panel of markers relevant to the clinical setting and to the H&E appearances. Some malignancies, especially poorly differentiated examples, do not conform to the

Summary box 11.11

Some immunohistochemical stains used for tumours

- Cell type/site of origin
  - Epithelial (carcinoma): cytokeratins
  - Lymphoid (lymphoma): CD45, CD3 (T cells), CD20 (B cells)
  - Melanocytic (melanoma): S100, HMB45, Melan A
  - Neuroendocrine: synaptophysin, chromogranin
  - Vascular: CD31
  - Myoid: desmin, actin
- Site of origin/cell type
  - Prostate: prostate-specific antigen (PSA)
  - Lung: thyroid transcription factor-1 (TTF-1)
  - Thyroid: thyroglobulin
  - Colorectum: cytokeratin 20 (CK20), CDX2
  - Liver: hepatocyte-specific antigen (HSA)
  - Gastrointestinal stromal tumour (GIST): CD117, DOG-1
- Prognosis and treatment
  - Breast carcinoma and gastric carcinoma: HER-2
  - Neuroendocrine tumours: Ki67 proliferation index
- Screening for mutations
  - Colorectal carcinoma: mismatch repair proteins (MLH1, MSH2, MSH6, PMS2)

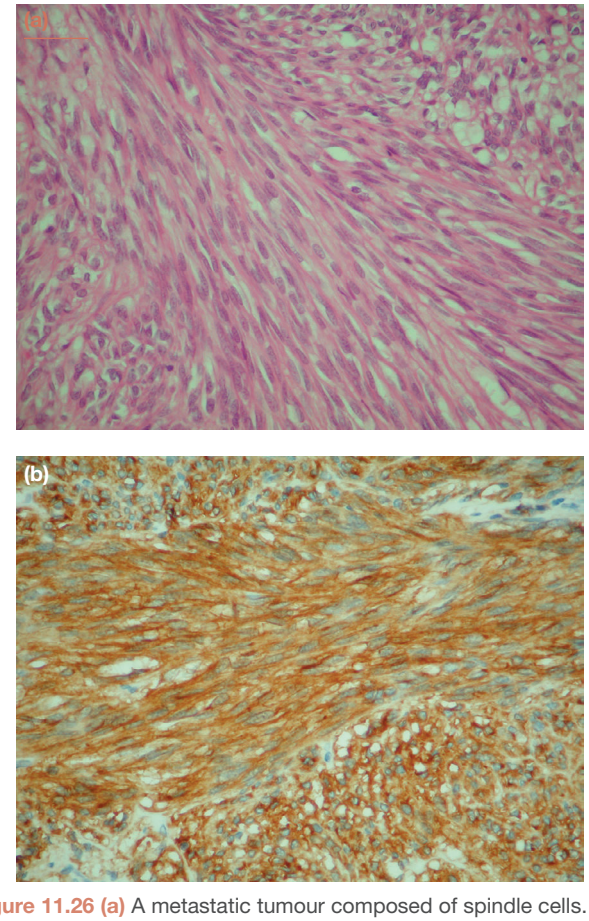

Figure 11.26 (a) A metastatic tumour composed of spindle cells. The clinical team suspected a diagnosis of gastrointestinal stromal tumour (GIST). (b) Positive immunohistochemistry for CD117, supporting a diagnosis of GIST.

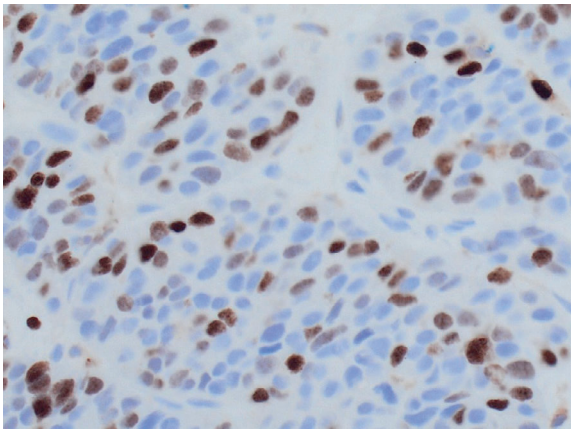

Figure 11.27 Immunohistochemistry for Ki67. The proliferative index is approximately 35% in this field.

typical immunohistochemical profiles. In all circumstances, interpretation takes place in the light of the clinical picture and imaging findings.

Less often, immunohistochemistry helps to confirm malignancy. For example, kappa or lambda light chain restriction (expression of only one immunoglobulin light chain) in lymphoid proliferations suggests clonality and, in turn, neoplasia rather than a reactive process. In general, immunohistochemistry does not distinguish well between benign and malignant.

Immunohistochemistry also plays a role in the selection of treatment and in predicting prognosis. For example, assessment of oestrogen receptor (ER) and human epidermal growth factor receptor-2 (HER2) status is routine for carcinomas of the breast (see ***Immunohistochemistry: tumour pathology***), while lymphomas are typically subjected to a comprehensive panel of markers that help determine treatment and prognosis. Ki67 proliferative index is an important prognostic factor for neuroendocrine neoplasms (***Figure 11.27***).

Immunohistochemistry: infections and other applications

There are antibodies to many infective agents, including cytomegalovirus (CMV), Epstein–Barr virus (EBV), herpes simplex virus, human herpes virus 8 (HHV8), hepatitis B virus and *Helicobacter pylori*. Some of these organisms, e.g. *H. pylori* and CMV, may be obvious or suspected on H&E examination, while others, e.g. EBV and HHV8, always require immunohistochemistry or other techniques for their detection.

Immunohistochemistry can also detect immunoglobulin and complement expression (e.g. in lymphomas or renal biopsies); confirm the abnormal accumulation of various proteins such as alpha-1-antitrypsin (A1AT); and help to characterise amyloid.

Newer immunohistochemical markers that detect specific gene mutations are appearing and may become useful in clinical practice in the future. An important example is screening for MMR gene mutations in most gastrointestinal carcinomas and endometrial carcinomas. Immunohistochemistry for *BRAF* V600E can replace mutational analysis in some settings. The major advantages of immunohistochemistry over other molecular tests for detecting genetic alterations are lower cost and faster turnaround.

Summary box 11.12

Uses of immunohistochemistry

- Cell type
- Neoplasia
  - Direction of differentiation/phenotype
  - Determination of anatomical site of origin
  - Confirmation of neoplasia
  - Grading
  - Selection of treatment
  - Detection of/screening for mutations
  - Prognosis
- Microorganisms – detection
- Other
  - Amyloid
  - Immunoglobulins
  - Complement

DIAGNOSTIC MOLECULAR PATHOLOGY

The broad heading of diagnostic molecular pathology refers to multiple tests that assess molecules (proteins, ribonucleic acid [RNA] and deoxyribonucleic acid [DNA]) in tissue. The information that they provide may be useful for diagnosis, classification of tumours, prognostic predictions, identifying patients with a hereditary cancer risk, determining treatment and identifying residual disease after treatment. Immunohistochemistry is conventionally separate from this category.

Basic methods in diagnostic molecular pathology

In situ hybridisation

In situ hybridisation (ISH) uses a labelled oligonucleotide probe that targets a specific sequence of RNA or DNA. It allows visualisation of the presence or absence and location of a particular RNA or DNA sequence *in situ* in tissue sections. Visualisation may depend on autoradiography, fluorescence microscopy or bright-field microscopy. Chromogenic *in situ* hybridisation (CISH) combines ISH and immunohistochemistry for the detection of specific nucleic acid sequences and is a common alternative to fluorescence *in situ* hybridisation (FISH) for the detection of *HER2* amplification. Viral genomes, e.g. EBV (***Figure 11.28***), CMV and high-risk HPV types are detectable using this approach. ISH plays an important role in tissue diagnostics and the management of tumours.

Sir Michael Anthony Epstein, b.1921, Professor of Pathology, University of Bristol, Bristol, UK.
Yvonne Barr, 1931–2016, Irish born virologist who emigrated to Australia. Epstein and Barr discovered this virus in 1964.

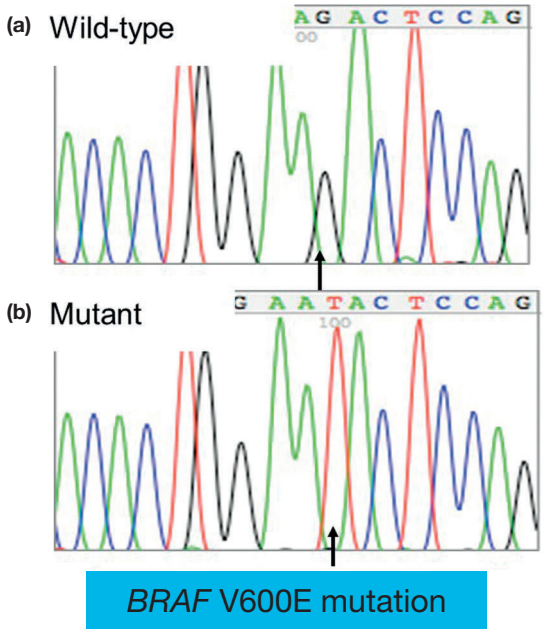

Figure 11.29 Sanger sequencing showing wild-type *BRAF* (a) and a *BRAF* V600E mutation (b) (courtesy of Dr M Rodriguez-Justo, UCL-AD, Cancer Institute, London, UK).

Polymerase chain reaction

The polymerase chain reaction (PCR) amplifies DNA, yielding millions of copies from a single copy of a selected target. Amplification of RNA is also possible, using the technique of reverse transcriptase PCR (RT-PCR). It is worth noting that real-time PCR (RTPCR) is a different method, typically used for quantification, with a very similar abbreviation. PCR is fast and safe and can be performed on homogenised fresh or formalin-fixed tissue. PCR-based methods have numerous applications in oncology (see ***Detection of clinically relevant abnormalities in genes***), including mutational analysis (***Figure 11.29***), testing for clonality, detection of fusion transcripts resulting from cytogenetic changes, detection of amplifications, demonstration of MSI and detection of gene hypermethylation. PCR-based methods can also detect microorganisms in tissue but this is not a common application because of the risk of false positives.

Cytogenetics and fluorescence in situ hybridisation

Conventional cytogenetics is the microscopic study of chromosomal changes in individual cells. Newer techniques, including FISH, array comparative genomic hybridisation, RT-PCR and next-generation sequencing (NGS) are increasingly replacing conventional cytogenetics. Cytogenetic tests seek alterations such as gene amplification, loss of segments of chromosomal material, loss of whole chromosomes (e.g. in renal cell carcinoma) and translocations with associated fusion genes (e.g. *EWSR1-FLI1* in Ewing's sarcoma).

Flow cytometry

Flow cytometry is a laser-based or impedance-based technique used for cell counting, cell sorting, biomarker detection and protein engineering. Cells are suspended in a stream of fluid and passed by an electronic detection apparatus. It is useful for detecting antigens in haematological neoplasms, usually in blood samples, and for determining ploidy, i.e. the number of sets of chromosomes in the nucleus of a cell. Although traditional flow cytometry is of limited value for tissue analysis, new applications of image cytometric DNA analysis allow detection of aneuploidy in tissue sections of gastrointestinal cancers.

Genomic changes in tumours

In normal circumstances, there is precise control of the division and proliferation of human cells. For example, various growth factors influence division by binding to specific cell surface tyrosine kinase receptors, resulting in the initiation of a complex intracellular cascade of changes. Damaged cells may undergo apoptosis, a carefully regulated process of programmed cell death.

Tumours require loss of control of cell proliferation. Abnormalities of numerous genes can affect proliferation and facilitate tumour development. The relevant genes fall into two main categories, i.e. proto-oncogenes (which stimulate cell proliferation) and tumour suppressor genes (which inhibit proliferation) but the picture is not always so straightforward. Activation of proto-oncogenes by genetic changes may induce or accelerate cell proliferation, while inhibition of tumour suppressor genes may remove the controls that normally prevent or retard proliferation. When a proto-oncogene contributes to cancer development, it is usually known as an oncogene. Other genetic changes can also facilitate tumorigenesis.

James Ewing, 1866–1943, Professor of Pathology, Cornell University Medical College, New York, NY, USA, described this type of sarcoma in 1921.
Frederick Sanger, 1918–2013, biochemist, Cambridge University, Cambridge, UK, awarded the Nobel Prize in Chemistry twice: once in 1958 for work on the structure of proteins and again in 1980 for work on base sequences of nucleic acids.

Abnormalities occur at various points during tumorigenesis. The classical model for this process is the 'adenoma–carcinoma sequence' of Fearon and Vogelstein, whereby the accumulation of mutations such as *APC*, *KRAS* and *TP53* in the colorectal mucosa corresponds broadly to the transformation of non-neoplastic mucosa into a colorectal adenoma and subsequently a carcinoma. Current models show that the picture is often very complex and differs between tumours and that a simple sequence does not operate consistently.

Several types of genetic abnormality can occur during tumorigenesis. The main categories of abnormalities are point mutations, fusion genes and copy number changes. Point mutations are single changes in the sequence of nucleotides in DNA and can be germline, i.e. inherited from a parent and accordingly present in every cell in the body, or somatic, i.e. acquired at some point during life and affecting only the tumour cells. Deletions and insertions (indels) of nucleotides result in a frameshift mutation. Examples include *TP53* tumour suppressor gene mutations, causing production of an abnormal p53 protein that lacks suppressor function; and mutation of the *KIT* gene, causing ligand-independent activation of a growth factor receptor.

Fusion genes may be formed by several mechanisms, including translocations and deletions. The translocation t(14:18) in follicular lymphoma results in juxtaposition of the anti-apoptotic *BCL2* to a regulatory region of an immunoglobulin heavy chain gene, with subsequent bcl-2 overexpression. Fusion genes can result from various chromosomal changes, e.g. *TMPRSS2-ERG* gene fusion in prostate adenocarcinoma can occur as a result of a chromosomal deletion and causes abnormal oncogenic activation of *ERG*.

Gene amplification refers to an increase in copy number, resulting in overexpression of the gene, and can variably result from abnormalities in DNA replication, chromosomal structure or telomeres. An example is *HER2* amplification, resulting in overexpression of the growth factor in carcinomas of breast and stomach.

These many types of abnormality in the genome may ultimately interfere with the function of proteins involved in regulatory processes: *TP53* and *KRAS* mutations are among the most common. Genetic changes can disrupt various pathways, including signal transduction (e.g. various growth factors and growth factor receptors, intracellular components such as *RAS* genes, *APC* gene), cell cycle regulators (e.g. *p16*, *RB*), DNA repair pathways (e.g. MMR genes, *BRCA1* mutations in breast carcinoma) and apoptosis (e.g. *BCL2*, an inhibitor of apoptosis).

DNA MMR genes play a vital role in correcting replication errors and other errors. Abnormalities of MMR genes cause instability of short tandem repeated sequences of DNA known as microsatellites, resulting in MSI. Tumours with this characteristic are MSI-H (high level of MSI). The relevant genes are *MLH1, MSH2, MSH6* and *PMS2*. MSI is a feature of around 15% of CRCs and can result either from a germline mutation in the MMR gene (Lynch syndrome) or, more often, from sporadic methylation of the *MLH1* gene (see ***Mismatch repair gene abnormalities in tumours***).

Epigenetic changes and methylation

Epigenetic factors are external to the gene sequence and can switch it on or off. The latter is known as epigenetic silencing and can result from DNA methylation (addition of a methyl group to DNA), modifications of histones and RNA-associated silencing. Loss of methylation with gene activation can occur in tumours. Conversely, hypermethylation of tumour suppressor genes or of the MMR gene *MLH1* can reduce or halt their activity, favouring malignancy.

Detection of clinically relevant abnormalities in genes

There are two broadly related areas of clinical practice that rely on molecular analysis. First, analysis of tumour DNA may improve diagnostic precision, enhance treatment plans and help predict clinical outcome. Second, it may suggest or detect germline mutations that are characteristic of an inherited disease. This can confirm non-neoplastic conditions, such as cystic fibrosis, or be used to diagnose a hereditary predisposition to cancer, e.g. Lynch syndrome.

Mutational analysis requires extraction of DNA from tissue (or from other sources such as blood) and often includes sequencing-based screening methods (e.g. Sanger sequencing, pyrosequencing) (***Figure 11.29***), screening methods comparing mutated with normal DNA and targeted mutation detection methods.

NGS (***Figure 11.30***) emerged relatively recently. The term NGS encompasses several platforms, each of which performs massively parallel sequencing, allowing simultaneous examination of millions of fragments of DNA for molecular alterations. It is applicable to formalin-fixed tissue, allows evaluation of many DNA regions in a single assay and displays increased analytical sensitivity (i.e. the ability to detect low-frequency alleles) compared with Sanger sequencing or conventional PCR. Widely clinically used targeted NGS panels can identify multiple known mutations and other variants in 20–500 genes of interest in a single test.

New powerful platforms can detect not only point mutations but also copy number variants and gene fusions in more than 100 genes involved in human oncogenesis with minimal nuclear acid (DNA and RNA) sample input.

Adequate amounts of good quality tumour DNA are necessary for the success of these techniques. Histology samples usually include both non-neoplastic tissue and tumour. The pathologist plays a crucial role in assessing the suitability of tissue samples for molecular analysis by analysing tumour cell content as a percentage of all cells, cellularity and degree of necrosis. Microdissection of the area of interest using conventional techniques or laser-assisted approaches improves yields of tumour-derived DNA.

Eric R Fearon, contemporary, Professor of Oncology, University of Michigan, Ann Arbor, MI, USA.
Bert Vogelstein, b. 1949, Professor of Oncology and Pathology, Johns Hopkins Medical School, Baltimore, MD, USA.
Henry Thompson Lynch, 1928–2019, Chair of Preventative Medicine, Creighton University, Omaha, NE, USA.

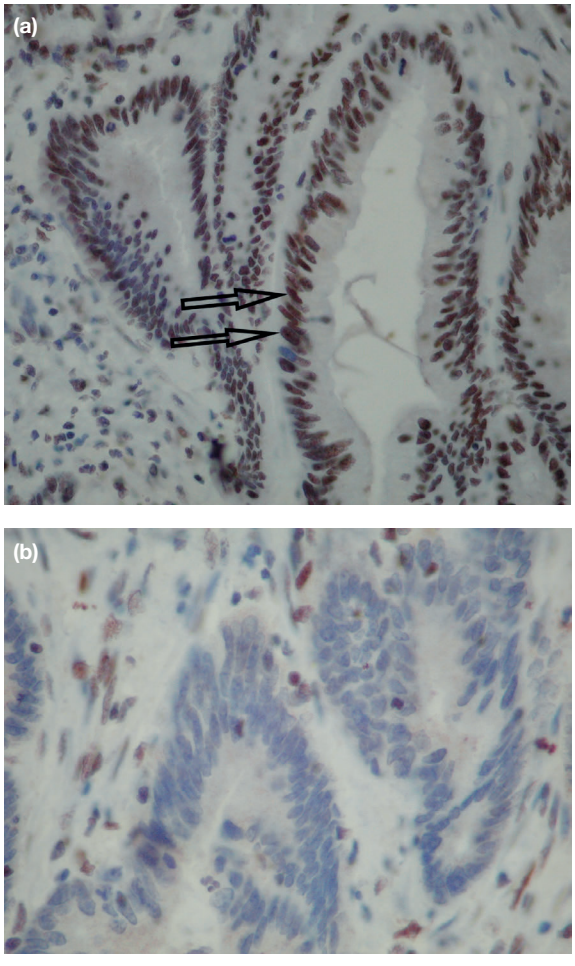

Figure 11.30 Immunohistochemical screening for mismatch repair gene abnormalities in a carcinoma. **(a)** There is retention of nuclear MLH1 expression (arrows showing positively staining brown neoplastic nuclei). **(b)** In contrast, there is loss of MSH2 expression (no staining in neoplastic nuclei), suggesting a mismatch repair gene abnormality.

- Fusions: FISH, NGS, PCR
- Amplifications: FISH, NGS
- Tumour mutation burden: NGS
- Immunohistochemistry may be a very useful initial test, and is often sufficient

Molecular changes and drug therapy

An increasingly common reason for molecular testing and related immunohistochemistry is the prediction of the response of advanced malignant tumours to specific drugs whose target is usually known ('theranostics'). For example, tumours with tyrosine kinase gene fusions that result in activation of the kinase are more likely than their counterparts to respond to tyrosine kinase inhibitors. A newer class of drugs known collectively as immune checkpoint inhibitors (ICIs) is highly successful for the treatment of a variety of advanced malignancies. Detection of any of several biomarkers may predict responsiveness to ICIs.

HER2 gene amplification

HER2 status influences the selection of therapy for breast cancer and metastatic gastric adenocarcinoma. Tumours with *HER2* amplification may be treated with the monoclonal antibodies trastuzumab or pertuzumab, often in combination with other drugs. Recent data suggest that *HER2* amplification may be a relevant therapeutic target in metastatic CRCs that are microsatellite stable.

Summary box 11.16

Tumour types that may respond to immune checkpoint inhibitor drugs

- Breast carcinoma
- Urothelial carcinoma
- Non-small cell lung cancer
- Small cell lung cancer
- Hepatocellular carcinoma
- Malignant melanoma

Translocations

Translocations can produce novel fusion genes that either produce a chimeric protein, e.g. *BCR-ABL* t(9:22) in chronic myeloid leukaemia, or may place an active promoter next to a proto-oncogene, causing its activation, e.g. t(14:18) *IGH-BCL2* in follicular lymphoma. Translocations that activate tyrosine kinases can result in drug responsiveness, e.g. *ALK, RET, NTRK, ROS* and *FGFR2*.

Tumour mutation burden

Tumour mutation burden (TMB) is a recently recognised biomarker. A higher number of mutations within the tumour corresponds to a higher TMB. High levels of TMB can predict response to ICIs. PD-L1 immunohistochemistry and detection of MSI-H are also used for this purpose.

Mismatch repair gene abnormalities in tumours

High levels of microsatellite instability (MSI-H), also known as deficient mismatch repair (D-MMR), occur as a result of germline mutations or acquired somatic events in the MMR genes (*MLH1, MSH2, MSH6* and *PMS2*). The former is referred to as Lynch syndrome (previously known as hereditary non-polyposis colorectal carcinoma) and is an autosomal dominant condition with predisposition to colorectal, gynaecological and other tumours (often at an early age).

Summary box 11.17

Microsatellite instability and mismatch repair genes

- Microsatellite instability (MSI)
  - Regulated by four main genes: *MLH1, PMS2, MSH2, MSH6*
- Genetic changes responsible for MSI
  - Sporadic hypermethylation of *MLH1* (more common; 85%)
  - Germline mutation, i.e. Lynch syndrome (less common)
- Microsatellite unstable (MSI-H) tumours
  - 15% of colorectal carcinoma (CRC)
  - 30% of endometrial carcinoma
- Tests
  - Immunohistochemistry
    - Recommended for all newly diagnosed CRCs
    - The preferred initial test in most centres
  - PCR-based microsatellite testing
  - NGS
- Clinicopathological correlation: MSI-H CRC
  - Typically right sided
  - More likely to have mucinous element histologically
  - Likely to have *BRAF* V600E mutation
- Clinical value
  - Phenotypic classification, e.g. medullary CRC is typically MSI-H
  - Prognosis, e.g. MSI-H better prognosis overall
  - Selection of drug therapy, e.g. MSI-H CRC responds better to ICIs and has no response to 5-fluorouracil
  - Screening for germline mutation, i.e. Lynch syndrome

Immunohistochemistry is the usual screening method for MMR mutations, although some centres use PCR-based microsatellite testing for screening. Loss of immunohistochemical staining by neoplastic cells is a marker for a gene defect, an indication for further testing and may lead to genetic testing for Lynch syndrome (***Figure 11.30***). In most patients, a detectable MMR abnormality is sporadic and does not represent Lynch syndrome.

MMR gene defects in CRC also identify sporadic tumours with different phenotypic and genetic characteristics. For example, *BRAF* V600E mutations are frequent in these cases and such cancers develop via the serrated polyp pathway rather than from adenomas (see ***Chapter 77***). MMR abnormalities generally predict lower recurrence rates, better survival rates and a lack of need for 5-fluorouracil.

Prognosis

Tests that help determine the selection of therapy for tumours may also have additional prognostic value. For example, a *BRAF* mutation in metastatic CRC is associated with a very poor prognosis. Commercially available multiple molecular marker tests may provide prognostic information (see ***Chapter 58***).

Cancer 'precision medicine'

This refers to the development of individualised cancer care plans, partly on the basis of molecular abnormalities in a tumour. Germline and somatic mutations may be taken into consideration, with the aim of tailoring treatments and targeting cancer cells precisely. With NGS, analysis of a single sample of tumour tissue for multiple known mutations that may predict treatment response is possible. In addition, many assays can detect mutations affecting as few as 5% of neoplastic cells. Other techniques may be used at the same time to detect abnormalities in the proteome (protein), transcriptome (mRNA), metabolome (metabolites) or epigenome, sometimes referred to as 'omics' assays. Such plans may, inevitably, be very complex (see ***Chapter 12***).

Molecular profile: examples of specific tumours

Colorectal carcinoma

In CRC, the anti-EGFR monoclonal antibodies cetuximab and panitumumab are used in combination with chemotherapy for metastatic disease. These drugs are less likely to be effective if *KRAS* or *NRAS* mutations are present than if a tumour is 'wild type' (i.e. has no *RAS* mutation). Various other genetic changes assist with selection of therapy and making prognostic predictions (***Summary boxes 11.17 and 11.18***).

Summary box 11.18

Molecular analysis in colorectal carcinoma

- Mismatch repair gene abnormalities
  - Multiple considerations (see *Summary box 11.17*)
- *KRAS or NRAS* mutation
  - Predicts resistance to EGFR inhibitors
- Tumour mutation burden
  - Predicts response to ICI therapy
- *BRAF* V600E mutation
  - Poor prognosis in metastatic CRC
  - Predictive of response to therapy
- *NTRK* fusion
  - Uncommon (<1% CRC)
  - Usually MSI-H
  - Poor prognosis
  - Specific therapy available: tyrosine kinase inhibitors

Bronchial (lung) carcinoma

In non-small cell lung cancer, specific *EGFR* mutations occur in a minority of lesions and identification predicts a response to the anti-EGFR tyrosine kinase inhibitor gefitinib, while *ALK* gene rearrangement predicts a response to the anaplastic lymphoma kinase (ALK) inhibitor crizotinib (see *Chapter 60*). *Summary box 11.19* shows other relevant molecular changes.

Summary box 11.19

Molecular and related changes in non-small cell lung carcinoma

Prediction of response to tyrosine kinase therapy

- Mutations
  - *EGFR*
  - *KRAS*
  - *BRAF* V600E
- Fusions
  - *ALK*
  - *RET*
  - *NTRK*

Prediction of response to immune checkpoint inhibitors

- PD-L1 expression (in a subgroup)

Gynaecological carcinoma

MMR status is increasingly important for the classification and management of ovarian and endometrial carcinomas. Other molecular changes that are important for prognosis and selection of therapy in endometrial cancer include polymerase ε (POLε) and *TP53* abnormalities. *HER2* amplification and PD-1 expression may be relevant in some settings. Classification into categories such as serous, mucinous and endometrioid influences prognostic predictions and now depends not only on traditional histology but also on a number of molecular changes (many of which are detectable using immunohistochemistry) (see *Chapter 87*).

Breast carcinoma

The most important ancillary tests for breast carcinoma remain ER immunohistochemistry and HER2 testing. As for many advanced malignancies, ICIs may be useful and accordingly PD-L1 immunostaining (with the appropriate antibody clone) may help predict outcome (see *Chapter 58*).

Lymphoma

The distinction between benign and malignant lymphoid proliferations is sometimes difficult. Clonal immunoglobulin heavy chain (IgH) gene rearrangements in B-cell proliferations and clonal T-cell receptor gene rearrangements in T-cell proliferations favour lymphoma over reactive proliferations. Identification of characteristic cytogenetic abnormalities plays an important role in diagnosis, classification and management of several haematological neoplasms. PCR-based tests help detect minimal residual disease after therapy.

Gastrointestinal stromal tumour, soft-tissue tumours and malignant melanoma

Most GISTs have either a *KIT* gene mutation or a *PDGFRA* gene mutation, more often the former. A few have defects in succinate dehydrogenase (*SDH*), *BRAF* or *NF1* genes. Identification of known mutations helps confirm the diagnosis. Mutational profile also helps predict clinical outcome and response to chemotherapy. For example, imatinib, a tyrosine kinase inhibitor, is a useful drug for advanced GIST but is ineffective in those with *SDH* mutations.

Molecular testing assists the diagnosis and classification of many types of soft-tissue tumour. Examples include Ewing's sarcoma and alveolar rhabdomyosarcoma, in which specific fusion genes are diagnostic. FISH testing detects characteristic cytogenetic changes.

In metastatic malignant melanoma, specific *BRAF* mutations predict response to the BRAF kinase inhibitor vemurafenib.

Table 11.1 outlines the clinical applications of some biomarkers in tumours.

DIGITAL PATHOLOGY AND ARTIFICAL INTELLIGENCE

The term 'digital pathology' usually refers to the examination of digitised slides on a workstation (computer) or another device. Uses include education, quality assurance, surveys, research and expert consults. With the development of high-quality scanners, histopathology departments can scan all slides and store them so that pathologists can access them anywhere.

Advantages include more flexible on-site and remote reporting, easy sharing, a reduction in costs and better recruitment. Disadvantages include the expense of set-up, maintenance and IT and repetitive strain injury. Additionally, diagnostic

accuracy may be slightly lower than with glass slides. Some pathologists, particularly cytopathologists, dislike the loss of a three-dimensional image, and detection of very small items such as microorganisms can be difficult.

AUTOPSY

In the past, autopsies (postmortems) allowed physicians and scientists to improve their knowledge of the human body and various diseases. The main reason for an autopsy is to confirm the cause of death, but autopsies remain very useful for medical education and audit. In the UK there are two main types. The first is the coroner's autopsy, when the coroner decides that there is a legal requirement to establish the cause of death, e.g. unexpected death or death during surgery or soon afterwards. Consent from relatives is not necessary. The second type is the hospital autopsy, which requires relatives' consent. For various reasons hospital autopsies are considerably less common than in the past.

ACKNOWLEDGEMENTS

The authors are very grateful to the following contributors for assistance with previous versions of the chapter and for providing images: Professor Mike Sheaff, London, UK; Dr Manuel Rodriguez-Justo, London, UK.

PART 1 | Basic principles

CHAPTER 12

Principles of oncology

Learning objectives

To understand:
- The biological nature of cancer
- That curative treatment is only one component in the overall management of cancer
- The principles of cancer prevention, early detection and screening
- The principles underlying non-surgical treatments for cancer

To appreciate:
- The principles of cancer aetiology and the major causative factors
- The multidisciplinary management of cancer
- The distinction between palliative care and end-of-life care
- The principles of palliative care

WHAT IS CANCER?

History

The word 'cancer' is credited to Hippocrates (460 BCE–370 BCE), who is widely agreed to be the father of medicine, and comes from the Greek word for a crab, referring to the finger-like projections of a cancer from a central mass, which have similarities to a crab's claws and legs.

The study of cancer has long been a part of clinical medicine: theories have moved from divine intervention and are now firmly based on the molecular origins of cancer. Rudolf Virchow was the first to demonstrate that cancer is a disease of cells and that the disease progresses as a result of abnormal proliferation, encapsulated by his dictum *omnes cellula e cellula* (every cell from a cell). In 1914, Theodor Boveri pointed out the importance of chromosomal abnormalities in cancer cells and, in the 1940s, Oswald Avery demonstrated that DNA was the genetic material within the chromosomes. In 1953, Watson and Crick described the structure of DNA, which was the key discovery leading to the understanding of the molecular biology of cancer. This understanding has allowed the investigation and understanding of the molecular mechanisms whereby cancer cells are formed and their abnormal behaviours are mediated; in turn, this has allowed modern molecular-based therapies to be developed.

The hallmarks of cancer

Cancer cells are able to proliferate in an uncontrolled fashion; their ability to divide and spread is unbounded. Cancer cell growth destroys first the tissue from which they arise and eventually the person in which they are present.

In order to survive, divide, invade and spread, cancer cells have to acquire a number of characteristics. No one characteristic is sufficient and not all characteristics are absolutely necessary. These features, based on articles by Hanahan and Weinberg, are given in ***Summary box 12.1***.

Establish an autonomous lineage

Cells develop independence from the normal signals that control supply and demand. The healing of a wound is a physiological process; the cellular response is exquisitely coordinated so that proliferation occurs when it is needed and ceases when it is no longer required. The whole process is controlled by a series of

Hippocrates, 460 BCE–375 BCE, was a Greek Physician and, by common consent, 'the father of medicine'.
Rudolf Ludwig Carl Virchow, 1821–1902, Professor of Pathology, Berlin, Germany.
Theodor Heinrich Boveri, 1862–1913, Professor of Zoology and Comparative Anatomy, Würzburg, Germany.
Oswald Theodore Avery, 1877–1955, bacteriologist, Rockefeller Institute, New York, NY, USA.

Robert Allan Weinberg, b.1942, The Whitehead Institute of Biomedical Research and Department of Biology, The Massachusetts Institute of Technology, Cambridge, MA, USA.

Summary box 12.1

Features of malignant transformation

- Establish an autonomous lineage
  - Resist signals that inhibit growth
  - Sustain proliferative signalling
- Obtain replicative immortality
- Evade apoptosis
- Acquire angiogenic competence
- Acquire ability to invade, disseminate and implant
- Evocation of inflammation
- Evade detection/elimination
- Loss of specialist cell function
- Develop ability to change energy metabolism

signals telling cells when, and when not, to divide. Cancer cells escape from this normal system of checks and balances: they grow and proliferate in the absence of external stimuli and regardless of signals telling them to desist.

Oncogenes are genes with the potential to cause cancer if mutated and expressed at high levels; they are key factors in carcinogenesis. Most oncogenes are normally involved in physiological processes, i.e. cell growth, but if mutated they can predispose a cell to cancer and in concert with other oncogenes can enable cancer cell survival and development of an established tumour. The implication is that we all carry the seeds of our own destruction: genetic sequences that, through mutation, can turn into active oncogenes and thereby cause malignant transformation. Indeed, through study of the timing of key genetic events in adult cancer development, a handful of cells develop the founder mutations of cancer development several decades prior to diagnosis. If the individual is unfortunate enough to accumulate further mutations in key driver genes, that cell becomes malignant and, if it proliferates, a cancer may develop. Only very rarely is a single mutation sufficient to cause cancer; multiple mutations are usually required. Colorectal cancer provides the classical example of how multiple mutations are necessary for the complete transformation from normal cell to malignant cell. Vogelstein and his colleagues identified the genes implicated and also postulated that it is necessary to have mutations in all the relevant genes; they also noted that these mutations must be acquired in a specific sequence for malignant transformation to occur.

Obtain replicative immortality

According to the Hayflick hypothesis, normal cells are permitted to undergo only a finite number of divisions. For humans this number is between 40 and 60. The limitation is imposed by the progressive shortening of the end of the chromosome (the telomere) that occurs each time a cell divides; eventually the lineage will die out. Cancer cells utilise the enzyme telomerase to rebuild the telomere at each cell division, such that there is no telomeric shortening, and the lineage will never die out. The cancer cell hence develops immortality.

Evade apoptosis

Apoptosis, taken from the Greek for 'leaf fall', is a form of programmed cell death that occurs as the direct result of internal cellular events instructing the cell to die. Unlike necrosis, which is a form of traumatic cell death resulting from acute cellular injury, apoptosis is an orderly and internally driven process. The cell dismantles itself neatly for disposal (***Figure 12.1***). There is minimal inflammatory response. Apoptosis is a physiological process. Cells that are redundant normally die by apoptosis and this is an important self-regulatory mechanism in growth and development, i.e. cells in the web space of the embryo die by apoptosis, or lymphocytes that could react to self. Genes, such as *p53*, that can activate apoptosis function as tumour suppressor genes. Mutation in such genes causes a loss of this inhibitory function, which will contribute to malignant transformation as apoptosis is evaded; this means that the wrong cells can be in the wrong places at the wrong times.

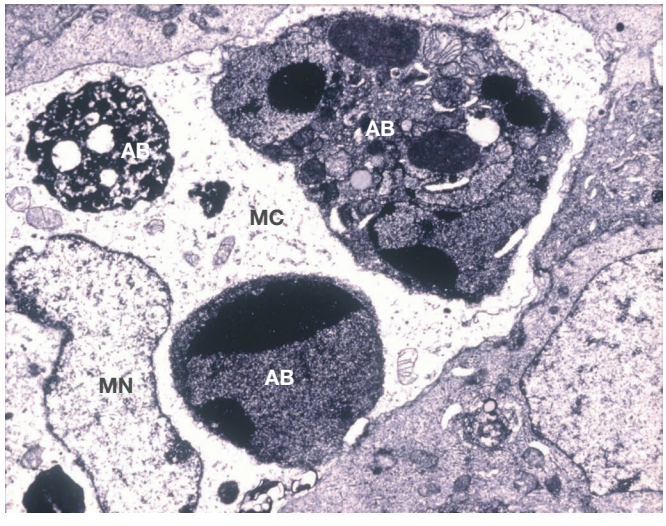

Figure 12.1 Electron micrograph of apoptotic bodies (AB) engulfed by a macrophage. Note the macrophage nucleus (MN) and macrophage cytoplasm (MC).

Acquire angiogenic competence

A mass of cancer cells cannot, in the absence of a blood supply, grow beyond a diameter of about 1 mm. This places a severe restriction on the capabilities of the tumour (note that the word tumour means swelling and does not mean the lesion is malignant, although 'tumour' is often taken by patients to be synonymous with cancer). It cannot grow much larger or spread widely within the body. If, however, the mass of cancer cells is able to attract or to construct a blood supply then it is able to quit its dormant state and behave in a far

Bert Vogelstein, b.1949, molecular biologist, Johns Hopkins Hospital, Baltimore, MD, USA.
Leonard Hayflick, b.1928, while working at the Wistar Institute in Philadelphia in 1962, he noted that normal mammalian cells growing in culture had a limited, rather than an indefinite, capacity for self-replication.

more aggressive fashion. The ability of a cancer to form blood vessels is termed angiogenesis and is a key feature of malignant transformation.

Acquire ability to invade

Cancer cells have no respect for the structure of normal tissues. They acquire the ability to breach the basement membrane and gain direct access to blood and lymph vessels. Cancer cells use three main mechanisms to facilitate invasion: (i) cause a rise in the interstitial pressure within a tissue; (ii) secrete enzymes that dissolve extracellular matrix; and (iii) become mobile. Unrestrained proliferation and a lack of contact inhibition enable cancer cells to exert pressure directly on the surrounding tissue and push beyond the normal limits. They secrete collagenases and proteases that chemically dissolve any extracellular boundaries that would otherwise limit their spread through tissues and, by modulating the expression of cell surface molecules called integrins, are able to detach themselves from the extracellular matrix. The abnormal integrins associated with malignancy can also transmit signals from the environment to the cytoplasm and nucleus of the cancer cells ('outside-in signalling') and these signals can induce increased motility. These processes are similar to those involved in normal development, i.e. in the migration of the neural crest or the formation of the heart. Epithelial cells behave as if they were mesenchymal cells and the process is termed epithelial–mesenchymal transition (EMT). EMT is a crucial step in malignant transformation and many of the genes and proteins implicated in the formation of cancer control processes are involved in EMT, e.g. *Src*, *Ras*, integrins, *Wnt*/β-catenin, Notch.

Acquire ability to disseminate and implant

Once cancer cells gain access to vascular and lymphovascular spaces, they can be readily distributed systemically throughout the body. This is not, of itself, sufficient to cause tumours to develop at distant sites. The cells also need to acquire the ability to implant. As Paget pointed out over a century ago, there is a crucial relationship here between the seed (the tumour cell) and the soil (the distant tissue). Most of the cancer cells discharged into the circulation probably do not form viable metastases. Circulating cancer cells can be identified in patients who never develop clinical evidence of metastatic disease; presumably these cells die if they cannot implant or they are destroyed by the patient's immune system.

Cancer can spread as individual cells or cell clumps that migrate and implant. Whether spread occurs in groups or as individual cells there is still the problem of crossing the vascular endothelium (and basement membrane) to gain access to the tissue itself. Cancer cells probably implant themselves in distant tissues by exploiting, and subverting, the normal inflammatory response. By expressing inflammatory cytokines, cancer cells can deceive the endothelium of the host tissue into becoming activated and allowing cancer cells access to the extravascular space. Activated endothelium expresses receptors that bind to integrins and selectins on the surface of cells, allowing the cancer cells to move across the endothelial barrier.

Tumour-related inflammation

A malignancy can provoke an inflammatory response and the cytokines and other factors produced as a result of that response may act to promote and sustain malignant transformation. Growth factors, mutagenic reactive oxygen species, angiogenic factors and anti-apoptotic factors may all be produced as part of an inflammatory process and all may contribute to the progression of a cancer.

Evade detection/elimination

Although derived from normal cells ('self') cancer cells are, in terms of their genetic make-up, behaviour and characteristics, foreign ('not self'). As such, they ought to provoke an immune response and be eliminated. It is entirely possible that malignant transformation is a more frequent event than the emergence of clinical cancer. The possible role of the immune system in eliminating nascent cancers was proposed by Paul Ehrlich in 1909 and revisited by both Sir Frank McFarlane Burnet and Lewis Thomas in the late 1950s. Cancer cells, or at least those that give rise to clinical disease, appear to gain the ability to escape detection by the immune system. This may be through suppressing expression of tumour-associated antigens or it may be through actively co-opting one part of the immune system to help the tumour escape detection by other parts of the immune surveillance system. This hallmark has been exploited in recent years in the development of T-cell checkpoint inhibitors, which 'take the brakes' off the immune system to re-enable T-cell killing of cancer cells, e.g. in renal cell carcinoma, lung cancer and melanoma.

Loss of specialist cell function

Cancer cells are geared to excessive proliferation. They do not need to develop or retain those specialised functions that prior to malignant transformation were their physiological function. These cells can therefore afford to repress or permanently lose those genes that control such functions. The longer term disadvantage to this process is that cancer cells are vulnerable to external stressors, which may, in part, explain why some cancer treatments work.

Stephen Paget, 1855–1926, surgeon, The West London Hospital, London, UK. Paget's 'seed and soil' hypothesis is contained in his paper 'The distribution of secondary growths in cancer of the breast', published in the *Lancet* in 1889.

Paul Ehrlich, 1854–1915, Professor of Hygiene, the University of Berlin, and later Director of the Institute for Infectious Diseases, Berlin, Germany. In 1908, he shared the Nobel Prize in Physiology or Medicine with **Elie Metchnikoff**, 1845–1916, 'in recognition of his work on immunity'. Metchnikoff was Professor of Zoology at Odessa in Russia, and later worked at the Pasteur Institute in Paris, France.

Sir Frank McFarlane Burnet, 1899–1985, Australian virologist, Walter and Eliza Hall Institute, Melbourne, Australia. Burnett shared the 1960 Nobel Prize in Physiology or Medicine with **Sir Peter Brian Medawar**, 1915–1987, Jodrell Professor of Zoology, University College, London, UK, 'for their discovery of acquired immunological tolerance'.

Lewis Thomas, 1913–1993, American pathologist and immunologist, who became President of the Sloan Kettering Memorial Institute, New York, NY, USA.

Develop ability to change energy metabolism

Blood flow in malignant tumours is often sporadic and unreliable. As a result, cancer cells may have to spend prolonged periods in low-oxygen states (i.e. relative hypoxia). Compared with the corresponding normal cells, some cancer cells may be better able to survive in hypoxic conditions. This ability may enable tumours to grow and develop despite an impoverished blood supply. Cancer cells can alter their metabolism even when oxygen is abundant; they break down glucose but do not, as normal cells would do, send the resulting pyruvate to the mitochondria for conversion, in an oxygen-dependent process, to carbon dioxide. This is the phenomenon of aerobic glycolysis, or the Warburg effect, and leads to the production of lactate. In an act of symbiosis, lactate-producing cancer cells may provide lactate for adjacent cancer cells, which are then able to use it, via the citric acid cycle, for energy production. This cooperation is similar to that which occurs in skeletal muscle during exercise.

The growth of a cancer

If it is accepted that a cancer starts from a single transformed cell then it is possible, using straightforward arithmetic, to describe the progression from a single cell to a mass of cells large enough to kill the host. The division of a cell produces two daughter cells. The relationship $2n$ will describe the number of cells produced after n generations of division. There are between 10^{13} and 10^{14} cells in a typical human being. A tumour 10 mm in diameter will contain about 10^9 cells. Since $2^{30} = 10^9$ this implies that it would take 30 generations to reach the threshold of clinical detectability and, as $2^{45} = 3 \times 10^{13}$, it will take fewer than 15 subsequent generations to produce a tumour that, through sheer bulk alone, would be fatal. This is an oversimplification because cell loss is a feature of many cancers: for squamous cancers as many as 99% of the cells produced may be lost, mainly by exfoliation. It will, in the presence of cell loss, take many cellular divisions to produce a clinically evident tumour. The growth of a typical human tumour can be described by an exponential relationship, the doubling time of which increases exponentially – so-called Gompertzian growth (***Figure 12.2***).

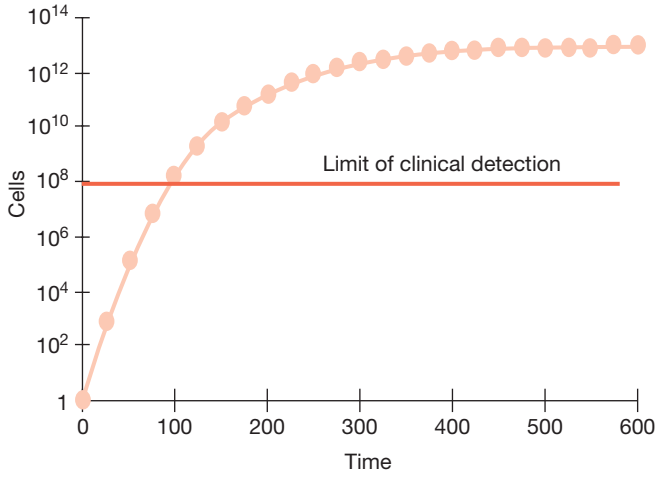

Figure 12.2 The Gompertzian curve describing the growth of a typical tumour. In its early stages, growth is exponential but, as the tumour grows, the growth rate slows. This decrease in growth rate probably arises because of difficulties with nutrition and oxygenation. The tumour cells are in competition: not only with the tissues of the host, but also with each other.

THE CAUSES OF CANCER

The interplay between nature and nurture

Both inheritance and environment are important determinants of cancer development. Neither influence is completely dominant. The balance between genes and the environment is context specific and not consistent. Two contrasting examples are breast and lung cancer. Although not all smokers develop lung cancer and lung cancer can occur in people who have never smoked, non-small cell lung cancer is much more common in smokers and is such a powerful risk factor that it accounts for approximately 80% of the disease. Conversely, germline *BRCA* gene mutations are highly penetrant and women with a *BRCA1* mutation can have a 60–90% lifetime risk of being diagnosed with breast cancer and 40–60% will develop ovarian cancer.

Knowledge about the causes of cancer can be used to design appropriate strategies for prevention or earlier diagnosis. As we find out more about the genes associated with cancer, genetic testing and counselling play increasingly important roles in the prevention of cancer. These considerations are incorporated into ***Table 12.1***, on the inherited cancer syndromes, and into ***Table 12.2***, on the environmental contribution to cancer.

THE MANAGEMENT OF CANCER

Management is more than treatment

The traditional approach to cancer concentrates on diagnosis and active treatment. This is a very limited view that, in terms of public health, may not have served society well. It implies a fatalistic attitude to the occurrence of cancer and an assumption that, once active treatment is complete, there is little more to be done. Prevention was forgotten and rehabilitation was ignored.

Otto Warburg, 1883–1970, chemist, Director of the Kaiser Wilhelm Institute for Cell Physiology, Berlin-Dahlem, Germany. Awarded the Nobel Prize in Physiology or Medicine in 1931 for 'his discovery of the nature and mode of action of the respiratory enzyme'.

Benjamin Gompertz, 1779–1865, an insurance actuary who described mathematically the relationship between life expectancy and age. The Gompertzian function provides an excellent fit to data points plotting tumour size against time.

TABLE 12.1 Examples of inherited syndromes associated with cancer.

Syndrome	Gene(s) implicated	Inheritance	Associated tumours and abnormalities	Strategies for prevention/ early diagnosis
Familial adenomatous polyposis (FAP)	*APC* gene	D	Colorectal cancer under the age of 25 Papillary carcinoma of the thyroid Cancer of the ampulla of Vater Hepatoblastomas Primary brain tumours (Turcot syndrome) Osteomas of the jaw CHRPE (congenital hypertrophy of the retinal pigment epithelium)	Prophylactic panproctocolectomy
Hereditary non-polyposis colorectal cancer (HNPCC1), Lynch syndrome 1	DNA mismatch repair genes (*MLH1; MSH2; MSH6*)	D	Colorectal cancer (typically in forties and fifties)	Surveillance colonoscopies/ polypectomies Non-steroidal anti-inflammatory drugs
HNPCC2	DNA mismatch repair genes *(MLH1; MSH2; MSH6)*	D	HNPCC associated with other cancers of the gastrointestinal or reproductive system	
Peutz–Jeghers syndrome	*STK11*	D	Bowel cancer; breast cancer; freckles round the mouth	Surveillance colonoscopy; mammography
Cowden[a] syndrome	*PTEN*	D	Multiple hamartomas of skin, breast and mucous membranes Breast cancer Neuroendocrine tumours Endometrial cancer Thyroid cancer	Active surveillance
Retinoblastoma	*RB*	D	Retinoblastoma Pinealoma Osteosarcoma	Surveillance of uninvolved eye
Multiple endocrine neoplasia (MEN) type 1	*Menin*	D	Parathyroid tumours Islet cell tumours Pituitary tumours	Awareness of associations and paying attention to relevant symptoms
MEN type 2A	*RET*	D	Medullary carcinoma of the thyroid Phaeochromocytoma Parathyroid tumours	Regular screening of blood pressure, serum calcitonin and urinary catecholamines Prophylactic thyroidectomy
MEN type 2B	*RET*	D	Medullary carcinoma of the thyroid Phaeochromocytoma Mucosal neuromas Ganglioneuromas of the gut	Regular screening of blood pressure, serum calcitonin and urinary catecholamines Prophylactic thyroidectomy
Li–Fraumeni	*P53*	D	Sarcomas Leukaemia Osteosarcomas Brain tumours Adrenocortical carcinomas	Very difficult, since pattern of tumours is so heterogeneous and varies between patients
Familial breast cancer	*BRCA1; BRCA2*	D	Breast cancer Ovarian cancer Papillary serous carcinoma of the peritoneum Prostate cancer	Screening mammography; pelvic ultrasound PSA (in males) Prophylactic mastectomy; prophylactic oophorectomy
Familial cutaneous malignant melanoma	*CDNK2A; CDK4*	D	Cutaneous malignant melanoma	Avoid exposure to sunlight, careful surveillance

Arvid Lindau, 1892–1958, Professor of Pathology, Lund, Sweden.
David Bloom, 1892–1985, dermatologist at the Skin and Cancer Clinic, New York University, New York, NY, USA, described the syndrome in 1954.

Viral infections – *continued*	Human immunodeficiency virus		Kaposi's sarcoma Lymphomas Germ cell tumours Anal cancer	Avoid unprotected sex
	Hepatitis B		Hepatocellular carcinoma	Avoid contaminated injections/ infusions Vaccination
Other infections	Schistosomiasis		Bladder cancer	Treatment of infection
	Helicobacter pylori		Stomach cancer	Eradication therapy
Inhaled particles	Asbestos		Mesothelioma	Protect workers from inhaled dusts and fibres
	Wood dust		Paranasal sinus cancers	
Chemicals	Environmental pollutants/chemicals used in industry		Angiosarcoma (vinyl chloride) Bladder cancer (aniline dyes, vulcanisation of rubber) Lung, nasal cavity (nickel) Skin (arsenic) Lung (beryllium, cadmium, chromium) All sites (dioxins)	Protection of exposed workers; avoid chemical discharge and spillages
	Medical	Alkylating agents used in cytotoxic chemotherapy	Leukaemia Lymphoma Lung cancer	Avoid over-treatment; only combine drugs with ionising radiation when absolutely necessary
		Immunosuppressive treatment	Kaposi's sarcoma	As low a dose as possible, for as short a period as possible
		Tamoxifen	Endometrial cancer	Biopsy if patient on tamoxifen develops uterine bleeding
Fungal and plant toxins	Aflatoxins		Hepatocellular carcinoma	Appropriate food storage, screen for fungal contamination of foodstuffs
Obesity/lack of physical exercise			Breast Endometrium Kidney Colon Oesophagus	Maintain ideal body weight, regular exercise

A more comprehensive view considers the management of cancer as taking place along two axes: one is an axis of scale, from the individual to the world population; the other is an axis based on the development of the disease, from prevention through to rehabilitation or palliative care (***Figure 12.3***).

Prevention

There is much written on the evidence on the preventable causes of cancer. It is concluded that many cancers could be prevented if people ate sensibly, exercised more and avoided carcinogens such as cigarette smoke. Early identification of premalignant conditions may also prevent certain malignancies developing, e.g. Barrett's oesophagus as a premalignant condition in oesophageal cancer. This advice supplements the preventative measures outlined in ***Table 12.2***.

Screening

Screening involves the detection of disease in an asymptomatic population in order to improve outcomes by early diagnosis of cancer at a curable stage. It follows that a successful screening programme must achieve early diagnosis and that the disease in question has a better outcome when treated at an early stage. The criteria that must be fulfilled for the disease, screening test and the screening programme itself are given in ***Summary box 12.2***. Merely to prove that screening picks up disease at an early stage, and that the outcome is better for patients with screen-detected disease than for those who present with symptoms, is an insufficient criterion for the success of a screening programme. This is because of potential inherent biases of screening (lead time bias, selection bias and length bias), which make screen-detected disease appear to be associated with better outcomes than symptomatic disease.

Moritz Kaposi (originally Kohn), 1837–1902, Professor of Dermatology, Vienna, Austria, described pigmented sarcoma of the skin in 1872.
Norman Rupert Barrett, 1903–1979, surgeon, St Thomas' Hospital, London, UK.

Figure 12.3 The management of cancer spans the natural history of the disease and all humankind, from the individual to the population of the world.

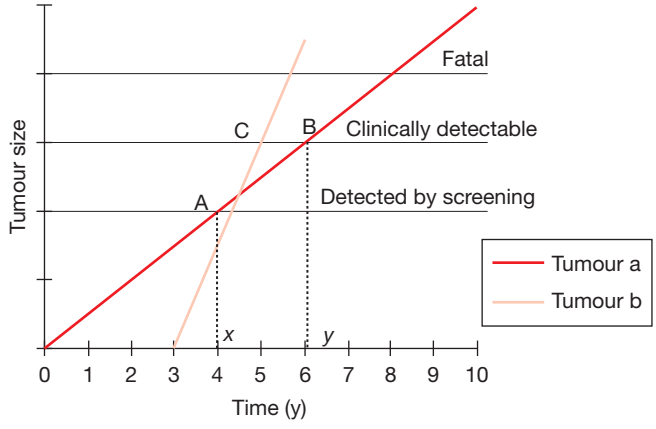

Figure 12.4 An illustration of lead time and length bias. ***Tumour a*** is a steadily growing tumour; its progress is uninfluenced by any treatment. Point A indicates the time at which the tumour would be diagnosed in a screening programme, and point B indicates the time at which the tumour would be diagnosed clinically, i.e. in the absence of any screening programme. If the date of diagnosis is used as the start time for measuring survival, then, in the absence of any effect from treatment, the screening programme will, artefactually, add to the survival time. The amount of 'increased' survival is equal to $y - x$ years, in this example just over 2 years. This artefactual inflation of survival time is referred to as lead time bias. ***Tumour b*** is a rapidly growing tumour; again its progress is uninfluenced by treatment. It grows so rapidly that, in the interval between two screening tests, it can cross both the threshold for detectability by screening and that of clinical detectability (at point C). It will continue to progress rapidly after diagnosis and the measured survival time will be short. This phenomenon, whereby those tumours that are 'missed' by the screening programme are associated with decreased survival, is called length time bias.

Summary box 12.2

Criteria for screening (based on Wilson–Junger criteria for a screening programme)

The disease:

- Recognisable early stage
- Treatment at early stage more effective than at later stage
- Sufficiently common to warrant screening

The test:

- Sensitive and specific
- Acceptable to the screened population
- Safe
- Inexpensive

The programme:

- Adequate diagnostic facilities for those with a positive test
- High-quality treatment for screen-detected disease to minimise morbidity and mortality
- Screening repeated at intervals if disease of insidious onset
- Benefit must outweigh physical and psychological harm

Lead time bias describes the phenomenon whereby early detection of a disease will always prolong survival from the time of diagnosis when compared with disease picked up at a later stage in its development whether or not detection in the screening process has altered the progression of the cancer (***Figure 12.4***). Selection bias describes the finding that individuals who accept an invitation for screening are, in general, healthier than those who do not. It follows that individuals with screen-detected disease will tend to live longer, independently of the condition for which screening is being performed. Length bias occurs because small, slow-growing tumours are likely to be picked up by screening whereas larger, fast-growing tumours are likely to arise and produce symptoms in between screening rounds. Screen-detected tumours will therefore tend to be less aggressive than symptomatic tumours. Because of these biases it is essential to carry out population-based randomised controlled trials and to compare the mortality rate in a whole population offered screening (including those who refuse to be screened and those who develop cancer after a negative test) with the mortality rate in a population that has not been offered screening. This research design has been applied to both breast cancer and colorectal cancer: in both cases there was a reduction in disease-specific mortality. However, in general, clinical trials of screening with the gold-standard endpoint of overall survival have not been undertaken because of the very large number of participants required with long study follow-up periods.

Cancer screening remains a controversial topic with advocates on both sides of the argument. Targeted, risk-based screening approaches, such as computed tomography (CT) scan-based screening of smokers and ex-smokers for lung cancer, are being evaluated as methods of developing more conclusive screening programmes.

James Maxwell Glover Wilson, 1913-2006, Principal Medical Officer at the Ministry of Health in London, England.

Diagnosis and classification

Accurate diagnosis is the key to successful management of cancer. Precise diagnosis is crucial to the choice of correct therapy; the wrong operation, no matter how well performed, is useless. An unequivocal diagnosis is also the key to an accurate prognosis. Only rarely can a diagnosis of cancer be confidently made in the absence of tissue for pathological or cytological examination. Cancer is a disease of cells and, for accurate diagnosis, the abnormal cells need to be obtained and visualised by a histopathologist. Different tumours are classified in different ways: most squamous epithelial tumours are classed as well (G1), moderate (G2) or poorly (G3) differentiated. Adenocarcinomas are also often classified as G1, G2 or G3 but prostate cancer is an exception, with widespread use of the Gleason system. The Gleason system grades prostate cancer according to the degree of differentiation of the two most prevalent architectural patterns. The final score is the sum of the two grades and can vary from 6 (3 + 3) to 10 (5 + 5) with the higher scores indicating poorer prognosis.

The ongoing development of molecular classifiers in many cancer types is beginning to profoundly alter our approach to treatment of these malignancies based on genetic mutations and other molecular features identified in individual patients, i.e. in melanoma where patients with *BRAF* gene mutations can be successfully treated with the *BRAF* inhibitors. Molecular characterisation of malignancies and identification of their vulnerabilities have already become standard of care in many cancers (i.e. breast, colorectal and lung cancer) and this list is likely to expand.

Cancer staging

It is not sufficient simply to know what and where a cancer is; its extent must also be known. If it is localised, then locoregional treatments such as surgery and radiation therapy may be curative. If the disease is widespread then, although such local interventions may contribute to cure, they will be insufficient and systemic treatment, for example with drugs or hormones, will also be required.

Staging is the process whereby the extent of disease is mapped out. Staging used to be a fairly crude process based on clinical examination, chest x-ray and occasionally ultrasound; it is now a sophisticated process, reliant on advanced imaging techniques such as CT, magnetic resonance imaging (MRI) and positron emission tomography (PET) scans. These technological advances bring with them the implication that patients staged as having localised disease today are not comparable to patients described in 1985 as having localised disease. Many of these latter patients would, had they been imaged using the technology of today, have had occult metastatic disease detected.

The Union for International Cancer Control (UICC) is responsible for the TNM (tumour, nodes, metastases) staging system for cancer. This system is compatible with, and relates to, the American Joint Committee on Cancer (AJCC) system

TABLE 12.3 Staging of colorectal cancer.

TNM		
TX,	Primary tumour cannot be assessed	
T0,	No evidence of primary tumour	
Tis,	Carcinoma *in situ* or intramucosal carcinoma	
T1,	Tumour invades submucosa	
T2,	Tumour invades muscularis propria	
T3,	The tumour has grown through the muscularis propria and into the subserosa, which is a thin layer of connective tissue beneath the outer layer of some parts of the large intestine, or it has grown into tissues surrounding the colon or rectum	
T4,	Tumour directly invades beyond bowel	a, The tumour has grown into the surface of the visceral peritoneum
		b, The tumour has grown into or has attached to other organs or structures
NX,	Regional lymph nodes cannot be assessed	
N0,	No metastases in regional nodes	
N1a,	Metastases in 1 regional lymph node	
N1b,	Metastases in 2 or 3 regional lymph nodes	
N1c,	There are nodules made up of tumour cells found in the structures near the colon that do not appear to be lymph nodes	
N2a,	Metastases in 4–6 regional lymph nodes	
N2a,	Metastases in ≥7 regional lymph nodes	
MX,	Not possible to assess the presence of distant metastases	
M0,	No distant metastases	
M1a,	The cancer has spread to 1 other part of the body beyond the colon or rectum	
M1b,	The cancer has spread to more than 1 part of the body other than the colon or rectum	
M1c,	The cancer has spread to the peritoneal surface	

Donald F Gleason, 1920–2008, pathologist, The University of Minnesota, Minneapolis, MN, USA.

for stage grouping of cancer. As an example, the TNM clinicopathological staging system for colorectal cancer is shown in *Table 12.3*.

The purpose of staging is twofold: to estimate prognosis and to help select appropriate treatment options. Anatomical staging provides important information as to the surgical resectability of disease and the risk of its recurrence. However, the risk assessment for most cancers is suboptimal and provides a wide confidence interval. Better staging techniques are entering care, such as the determination of circulating tumour DNA (ctDNA) in the blood of postoperative patients. Patients who demonstrate ctDNA postoperatively have a substantially higher risk of relapse than patients who do not. This information may be useful in the future to select patients who should be offered further treatment to eliminate residual tumour cells and, of equal importance, to identify patients with a low chance of relapse who can avoid further treatment.

Therapeutic decision making and the multidisciplinary team

As the management of cancer becomes more complex, it becomes impossible for an individual clinician to have the competence that is necessary to manage all patients presenting with a particular type of tumour. The formation of multidisciplinary teams represents an attempt to make certain that each and every patient with a particular type of cancer is managed appropriately. Teams should not only be multidisciplinary – they should also be multiprofessional. The advantages and disadvantages of multidisciplinary teams are summarised in *Table 12.4*.

The multidisciplinary team needs to answer three basic questions for every patient:

- What is the patient's diagnosis, stage and molecular characteristics of disease?
- What is the goal of treatment for the patient? In simple terms, this can be divided into cure, prolongation of life and palliation of symptoms.
- What treatment options are there to achieve these aims with the fewest possible side effects? Options may include surgery, radiotherapy, anti-cancer systemic (drug) treatment, symptom control measures, a combination of these options and, in some cases, observation.

It is important to realise that the multidisciplinary team makes recommendations, rather than definite treatment decisions. Several other factors must be considered, which can only be done by a clinician making a direct assessment of the patient's health and wishes. The clinician must ascertain the patient's fitness and hence their ability to tolerate treatment. This will be heavily influenced by comorbidities. Patients vary greatly in their willingness to tolerate treatment for a given benefit and particularly how they value quality of life compared with length of life or chance of cure.

There are often several possible treatment plans and the clinical team must take the time to explain the options carefully to the patient and the patient's supporters. In many cancer centres, there will be both standard-of-care and research options available for patients. Explanations should include what is involved in the treatment, what benefits may result and the chance of the patient receiving those benefits. The clinical team must also explain the possible downsides of treatment and the likelihood of experiencing them. Patients are often faced with a large amount of complex and difficult information at a time when they are extremely vulnerable. The clinical team must support patients to reach a decision and this may take time and repeated explanation.

Principles of cancer surgery

For most solid tumours, surgery remains the definitive treatment and the only realistic hope of cure. However, surgery has many roles in cancer treatment from diagnosis, prevention, removal of primary disease, removal of metastatic disease, reconstruction through to palliation of symptoms.

Role in diagnosis and staging

In most, but not all, patients the diagnosis of cancer has been confirmed by biopsy before definitive surgery is carried out; however, occasionally a surgical procedure is required to make the diagnosis, e.g. in renal cell cancer where not all patients with a renal mass will undergo a biopsy, prior to definitive surgery to remove and diagnose the tumour as either malignant or benign. Laparoscopic surgery is used as part of the staging of intra-abdominal malignancy, particularly oesophageal and gastric cancer. By this means it is often possible to diagnose widespread peritoneal disease and small liver metastases that may have been missed on cross-sectional imaging. Laparoscopic

TABLE 12.4 The advantages and disadvantages of the multidisciplinary team.

Advantages	Disadvantages
Open debate concerning management of complex patients with many specialists	Less confident and less articulate members of the team may not be able to express their views, even though their views may be extremely important
Decision making is open, transparent and explicit	May become a rubber-stamping exercise in which the class solutions implied by guidelines are applied to disparate individuals
Team members educate each other	Decisions are made in the absence of patients and their carers
A useful educational experience for trainees and students	Clinicians are able to avoid having to take responsibility for their decisions and their actions – 'corporate responsibility'
Performance can be monitored by managers	Time-consuming and resource intensive: takes multiple busy clinicians away from clinical practice for hours at a time

Summary box 12.3

Potential members of the cancer multidisciplinary team

- Site-specialist surgeon
- Surgical oncologist
- Plastic and reconstructive surgeon
- Clinical oncologist/radiotherapist
- Medical oncologist
- Diagnostic radiologist
- Interventional radiologist
- Palliative care physician
- Pathologist
- Speech therapist
- Physiotherapist
- Prosthetist
- Clinical nurse specialist (rehabilitation, supportive care)
- Clinical trial team representative
- Palliative care nurse
- Social worker/counsellor
- Medical secretary/administrator
- Multidisciplinary team coordinator

ultrasound is a particularly useful adjunct for the diagnosis of intrahepatic metastases. Other examples of when surgery is central to the diagnosis of cancer include orchidectomy, in a patient suspected of testicular cancer; lymph node biopsy in a patient with lymphoma; and sentinel node biopsy in melanoma and breast cancer.

Removal of primary disease

Radical surgery for cancer involves removal of the primary tumour and as much of the surrounding tissue and lymph node drainage as possible in order not only to ensure local control but also to prevent spread of tumour through the lymphatics. Although the principle of local control is still extremely important, it is now recognised that ultra-radical surgery probably has little effect on the development of metastatic disease, as evidenced by the randomised trials of radical versus simple mastectomy for breast cancer. It is important, however, to appreciate that high-quality, meticulous surgery taking care not to disrupt the primary tumour at the time of excision is of the utmost importance in obtaining a cure in localised disease and in preventing local recurrence.

Removal of metastatic disease

Under certain circumstances surgery for metastatic disease may be appropriate. This is particularly true for liver metastases arising from colorectal cancer where successful resection of all detectable disease can lead to long-term survival in about one-third of patients. With multiple liver metastases, it may still be possible to take a surgical approach by using *in situ* ablation with cryotherapy or radiofrequency energy. Another situation in which surgery may be curative in metastatic disease is that of pulmonary resection for isolated lung metastases, particularly from renal cell carcinoma.

Palliation

In many cases surgery is not appropriate for cure but may be valuable for palliation. A good example of this is the patient with a symptomatic primary tumour who also has distant metastases, e.g. a patient with a large, symptomatic renal cell cancer but diffuse metastatic disease. In this case, removal of the primary will increase the patient's quality of life but will have little effect on the ultimate outcome.

Principles underlying the non-surgical treatment of cancer

Medical and clinical (radiation) oncology are rapidly changing fields. Both understanding of cancer and the technology available are expanding at a rapid pace. Nevertheless, there are basic principles that remain constant. These are to ascertain as precisely as possible the diagnosis, stage of disease and molecular characteristics of the tumour and, from this information, assess via the multidisciplinary team the management options for the patient. In general terms, where a local treatment, i.e. surgery or ablation, is as effective as a systemic treatment, the local treatment will be preferred. The range of options will be specific to each tumour type and is constantly evolving. This is most true of the systemic therapy options available to patients.

The purposes of oncology treatment can be conveniently divided into:

- **curative primary**: the effect of non-surgical treatment alone is highly effective, e.g. head and neck cancers (*Table 12.5*);
- **neoadjuvant**: where non-surgical treatment prior to surgery can substantially reduce the morbidity of treatment and increase its chances of success, e.g. radiotherapy to downstage rectal carcinoma prior to surgery;
- **adjuvant**: where non-surgical treatment after surgery can increase the chance of cure, e.g. radiotherapy and chemotherapy after breast cancer;
- **life-prolonging/palliative**: these terms are better separated, especially in the case of life-prolonging treatments in a non-curative setting that may add years to life, e.g. use of olaparib in *BRCA*-mutated ovarian cancer.

Systemic therapies

In recent decades, drug development has evolved from screening large libraries of chemicals for their ability to interfere with cellular processes. Increased understanding of the molecular pathophysiology of cancers has identified key molecules essential to tumour function. Many of these molecules can be inhibited and are termed 'druggable targets'. Three-dimensional characterisation of these targets and synthesis of molecules to inhibit them has produced a large number of highly effective targeted therapies. The pace of change is sufficiently rapid that it is now only possible for an individual clinician to keep abreast of developments in a limited number of cancers.

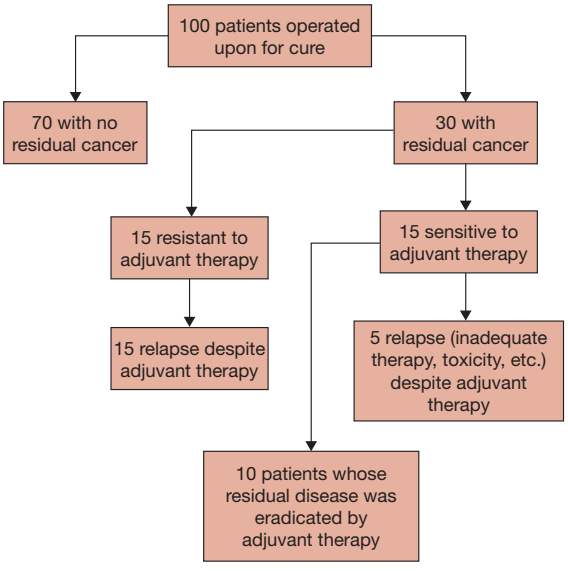
The following principles are key in decision making over systemic therapy administration to individual patients:

TABLE 12.5 Examples of malignancies that may be cured without the need for surgical excision.

Malignancy	Potentially curative treatment
Leukaemia	Chemotherapy (+/– radiotherapy)
Lymphoma	Chemotherapy (+/– radiotherapy)
Small cell lung cancer	Chemotherapy (+/– radiotherapy)
Tumours of childhood (rhabdomyosarcoma, Wilms' tumour)	Chemotherapy (+/– radiotherapy)
Early laryngeal cancer	Radiotherapy
Advanced head and neck cancer	Chemoradiation (synchronous chemotherapy and radiotherapy)
Oesophageal cancer	Chemoradiation (synchronous chemotherapy and radiotherapy)
Squamous cell cancer of the anus	Chemoradiation (synchronous chemotherapy and radiotherapy)
Advanced cancer of the cervix	Radiotherapy (+/– chemotherapy)
Medulloblastoma	Radiotherapy (+/– chemotherapy)
Skin tumours (BCC, SCC)	Radiotherapy

BCC, basal cell carcinoma; SCC, squamous cell carcinoma.

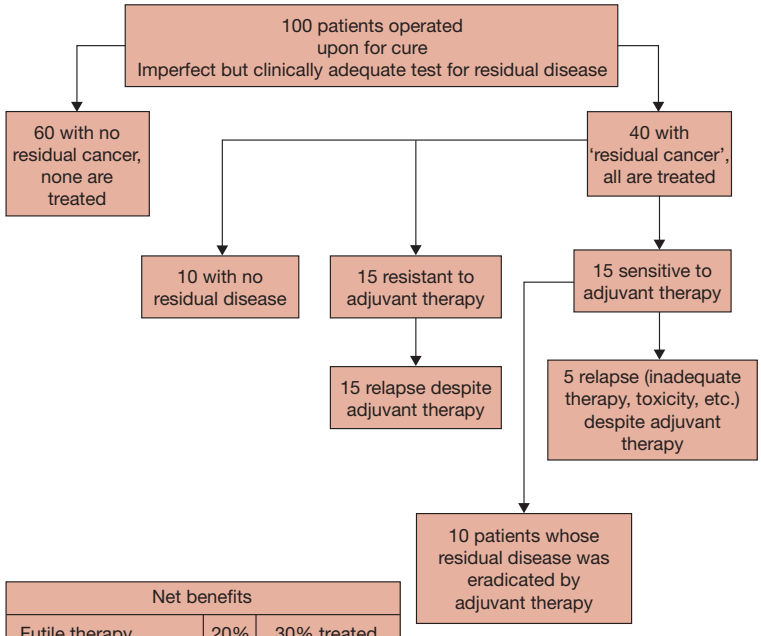
- Assess the fitness and willingness of the patient to tolerate each of these options.
  Most cancers occur in middle-aged or older patients. The older a patient is, the more likely they are to have comorbidities or be frail. It is important to note that middle-aged patients may be unfit or have serious comorbidities and that older patients may actually be very fit. Organ dysfunction and frailty may substantially increase the risks of treatment and reduce its chance of success. This must be assessed on an individual basis.
- Support the patient to understand the options and choose the most appropriate management approach.
  Discussions about prognosis and treatment options are complex, difficult and any decisions made are often irrevocable. They also take place when the patient and their family are at their most anxious and vulnerable. It is often necessary to provide information in digestible amounts and to do so repeatedly. There are few oncological situations where an immediate decision needs to be taken by the patient.
  The difficulties of drawing a balance between risk and benefit are illustrated by considering adjuvant therapy for a solid malignancy. In the absence of a good test to ascertain individual risk of relapse, it is necessary to treat large numbers of patients to benefit a small proportion, often around 10% (***Figure 12.5***). Although 10% is a small proportion, it represents a small chance of a major benefit, namely cure. If there were a test that could accurately determine patients with no residual disease after resection, then a lower proportion of patients would need to have adjuvant therapy, each of whom would have a higher chance of benefit (***Figures 12.5 and 12.6***).
- Frequently reassess the balance of risk and benefit during treatment.
  For patients receiving repeated cycles of treatment, there are three key questions to consider before proceeding with the next cycle of treatment:



1. **Is the treatment working**? Where there is measurable disease, this is usually assessed by radiological restaging at intervals of 6–12 weeks. The test for whether the treatment is working will depend on the goals of treatment: if the goal is stabilisation of disease then it may be sufficient that the tumour is not growing; if the goal is elimination of disease then progressive shrinkage of the radiological abnormalities will be necessary.
2. **Is the patient tolerating treatment?** This can only be discovered by asking the patient what side effects they are experiencing. Clinicians should be used to detecting and managing the side effects of the drugs they are prescribing. In addition to open questions, the clinician should enquire specifically about common or dangerous side effects. If the patient is not tolerating treatment, then it may be necessary to delay the next cycle or to reduce the dose, even though this may be at the expense of reducing the effectiveness of treatment.
3. **Is it safe to give the next cycle of treatment?** To answer this question, the clinician will have to assess what side effects the patient is experiencing and also ensure that laboratory measures are within acceptable limits. The necessary laboratory tests will commonly include full blood count, urea and electrolytes and liver function tests as well as other tests determined by which treatments are being used.

The range of non-surgical anti-cancer treatments

Radiotherapy



Half of all patients will receive radiotherapy during their cancer journey. The mechanism of action of radiotherapy is that ionising radiation causes single- and double-stranded DNA breaks. Cells most sensitive to radiotherapy are in mitosis or late G2 in the cell cycle. Damage may be caused by the direct effect of the ionising radiation on the DNA. However, the predominant therapeutic effect is indirect, and is achieved by ionising radiation causing the creation of oxygen free radicals, which then damage the DNA. The fact that the indirect damage is predominant explains why hypoxic cells are relatively resistant to radiotherapy. In practice, adequate

oxygenation of tissues is assisted by simple measures such as correcting anaemia prior to radiotherapy.

Cancer types differ greatly in their sensitivity to radiotherapy. Similarly, higher doses of radiotherapy are needed to control bulky disease (~70 Gy) than to eliminate residual tumour cells (~50 Gy) or to palliate symptoms (~30 Gy).

Radiotherapy is mainly used as a localised treatment (***Figure 12.7***). The target area is defined by imaging, which will include anatomical imaging, such as CT and MRI, to identify the tumour mass, neighbouring structures and landmarks for radiotherapy planning. Sometimes functional imaging, such as PET, is used to further define structures that should be included in the radiation field such as lymph nodes containing small volumes of tumour, whose metabolic signature is detected by PET. The planning and technical set-up of radiotherapy is a highly specialised subject. Planning can be extremely difficult and time-consuming, e.g. in the treatment of head and neck cancer, where the treatment intent is curative but there are multiple vital and highly sensitive structures close to the target area.

In general terms, the radiotherapy team will aim to provide a uniform therapeutic radiation dose to the target area, while sparing adjacent structures from significant damage. The most common form of treatment is external beam radiotherapy in which x-rays are aimed at the target volume from an external source. Where necessary, modern radiotherapy can employ sophisticated computer programs and algorithms to sculpt the shape of the treatment volume. It is now possible to irradiate irregularly shaped target volumes using techniques such as intensity-modulated radiation therapy (IMRT) and image-guided radiation therapy (IGRT). The ability to give high fractional doses in this way has led to the development of stereotactic ablative radiotherapy (SAbR), in which a small number of fractions can be used to treat primary tumours, or isolated metastases, to curative dose levels.

Other ways of targeting the tumour volume include brachytherapy, in which the radiation source is brought very close to the tumour by insertion of radioactive seeds, and radionuclide therapy, in which a radioactive source is concentrated at the tumour site.

One of the main problems in determining the optimal schedule of radiation is that there is a dissociation between the acute effects on normal tissues and the late damage. The acute reaction is not a reliable guide to the adverse consequences of treatment in the longer term. Since the late effects following irradiation can take over 20 years to develop, this poses an obvious difficulty: if a radiation schedule is changed it will be known within 2 or 3 years whether or not the new schedule has improved tumour control; it may, however, be two decades before it is known, with any degree of certainty, whether or not the new technique is safe.

Anti-cancer drugs

The classes of anti-cancer drugs, their modes of action and clinical indications are summarised in ***Table 12.6***.

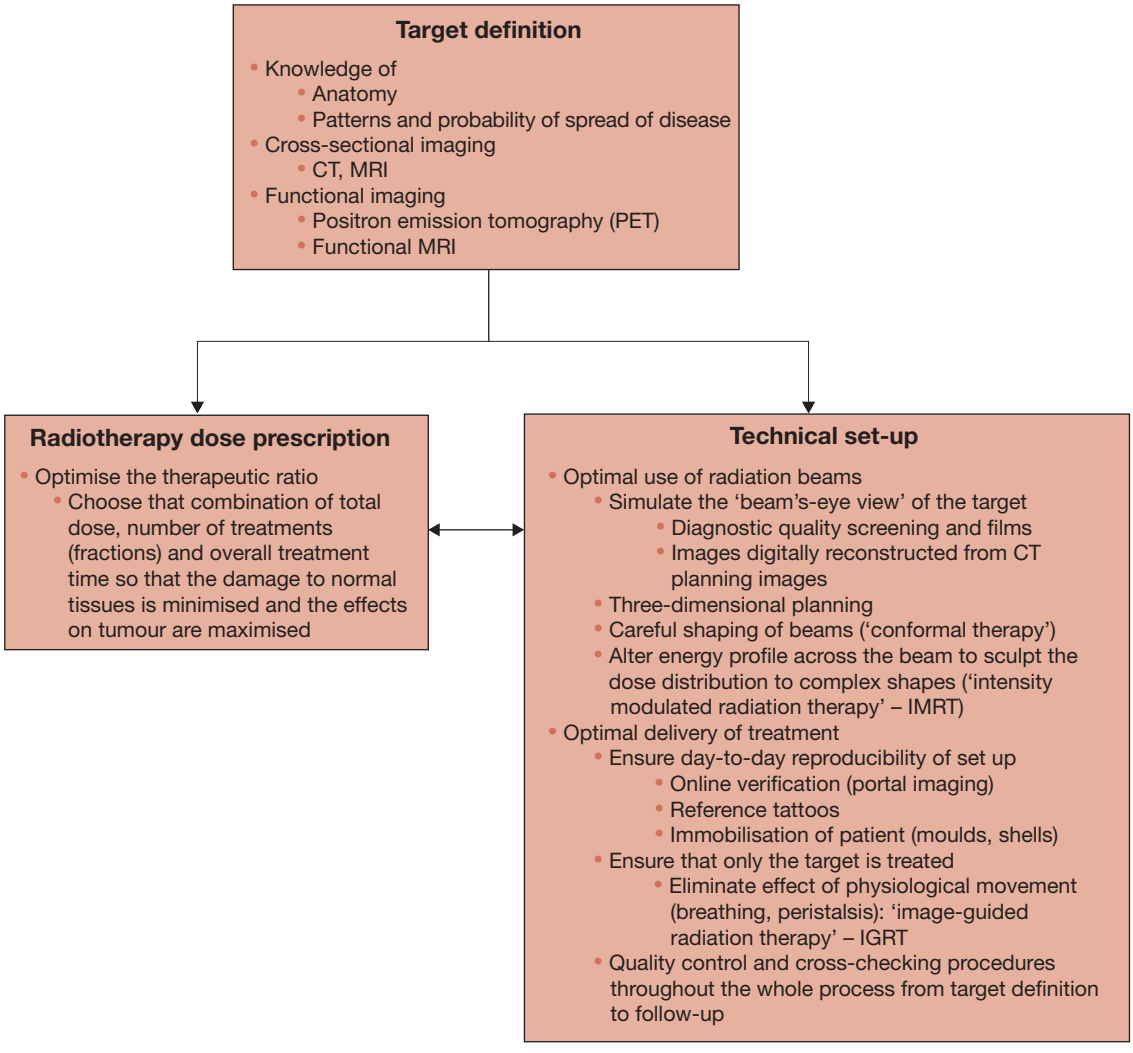

Figure 12.7 The processes involved in clinical radiotherapy. CT, computed tomography; MRI, magnetic resonance imaging.

TABLE 12.6 Examples of anti-cancer drugs currently in use.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Drugs that interfere with mitosis	Vincristine Vinblastine	Interfere with formation of microtubules: 'spindle poisons'	Lymphomas Leukaemias Brain tumours Sarcomas
	Taxanes: paclitaxel docetaxel cabazitaxel	Stabilise microtubules	Breast cancer Non-small cell lung cancer Ovarian cancer Prostate cancer Head and neck cancer
Drugs that interfere with DNA synthesis (antimetabolites)	5-Fluorouracil Capecitabine	Inhibition of thymidylate synthase, false substrate for both DNA and RNA synthesis	Breast cancer GI cancer
	Methotrexate	Inhibition of dihydrofolate reductase	Breast cancer Bladder cancer Lymphomas Cervical cancer
	6-Mercaptopurine 6-Thioguanine	Inhibit *de novo* purine synthesis	Leukaemias

Continued

TABLE 12.6 Examples of anti-cancer drugs currently in use – *continued*.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Drugs that interfere with DNA synthesis (antimetabolites) – *continued*	Cytosine arabinoside	False substrate in DNA synthesis	Leukaemias Lymphomas
	Gemcitabine	Inhibits ribonucleotide reductase	Non-small lung cancer Pancreatic cancer
Drugs that directly damage DNA or interfere with its function	Mitomycin C	DNA cross-linking, preferentially active at sites of low oxygen tension (a bioreductive drug)	Anal cancer Bladder cancer Gastric cancer Head and neck cancer Rectal cancer
	Cisplatin Carboplatin	Form adducts between DNA strands and interferes with replication	Germ cell tumours Ovarian cancer Non-small cell lung cancer Head and neck cancer Oesophageal cancer
	Oxaliplatin	Forms adducts between DNA strands and interferes with replication	Colorectal cancer
	Doxorubicin	Intercalates between DNA strands and interferes with replication	Breast cancer Lymphomas Sarcomas Kaposi's sarcoma
	Cyclophosphamide	A prodrug converted via hepatic cytochrome p450 to phosphoramide mustard. Causes DNA cross-links	Breast cancer Lymphomas Sarcomas
	Ifosfamide	Related to cyclophosphamide, causes DNA cross-links	Small cell lung cancer Sarcomas
	Bleomycin	DNA strand breakage via formation of metal complex	Germ cell tumours Lymphomas
	Irinotecan	Inhibits topoisomerase 1, prevents DNA from unwinding and repairing during replication	Colorectal cancer
	Etoposide	Inhibits topoisomerase 2, prevents DNA from unwinding and repairing during replication	Small cell lung cancer Germ cell tumours Lymphomas
	Dacarbazine	A nitrosourea that requires activation by hepatic cytochrome p450. Methylates guanine residues in DNA	Brain tumours Sarcoma
	Temozolomide	A nitrosourea but, unlike dacarbazine, does not require activation by hepatic cytochrome p450. Methylates guanine residues in DNA	Glioblastoma multiforme
	Actinomycin D	Intercalation between DNA strands, DNA strand breaks	Rhabdomyosarcoma Wilms' tumour
DNA damage response inhibitors	Olaparib Niraparib Rucaparib	Inhibit DNA repair by PARP, especially in *BRCA*-mutated cancers	Ovarian cancer Breast cancer Prostate cancer
Hormones	Tamoxifen	Blocks oestrogen receptors	Breast cancer
	Anastrozole Letrozole Exemestane	Aromatase inhibitors that block postmenopausal (non-ovarian) oestrogen production	Breast cancer
	Leuprolide Goserelin Buserelin	Analogues of gonadotropin-releasing hormone, continued use produces downregulation of the anterior pituitary with consequent fall in testosterone levels	Prostate cancer
	Cabergoline	Blocks prolactin release, a long-acting dopamine agonist	Prolactin-secreting pituitary tumours

Continued

TABLE 12.6 Examples of anti-cancer drugs currently in use – *continued*.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Hormones – *continued*	Bromocriptine	Dopamine agonist, blocks stimulation of anterior pituitary	Pituitary tumours
	Cyproterone acetate Flutamide Nilutamide Bicalutamide	Block the effect of androgens	Prostate cancer
	Abiraterone Cyproterone acetate	Block testosterone production	Prostate cancer
Inhibitors of receptor tyrosine kinases	Osimertinib Erlotinib Afatinib Gefitinib	Inhibit EGFR tyrosine kinase	Non-small cell lung cancer
	Imatinib	Blocks ability of mutant BCR-ABL fusion protein to bind ATP	Chronic myeloid leukaemia
	Imatinib	Inhibition of mutant c-KIT	GISTs
	Erlotinib	Inhibits EGFR tyrosine kinase	Non-small cell lung cancer Pancreatic cancer
	Sunitinib Regorafenib Lenvatinib	Promiscuous tyrosine kinase inhibitors (PDGFR, VEGFR, KIT, FLT)	Renal cancer GIST refractory to Imatinib Colorectal cancer Thyroid cancer
	Lapatinib	Inhibits tyrosine kinases associated with EGFR and HER2	Breast cancer
	Axitinib	Inhibits tyrosine kinase associated with VEGFR	Renal cancer
Cyclin-dependent kinase inhibitors	Palbociclib	Inhibits growth signal	Breast cancer
Protease inhibitors	Bortezomib	Interferes with proteasomal degradation of regulatory proteins, in particular stops NF-κB from preventing apoptosis	Multiple myeloma
Differentiating agents	All-*trans*-retinoic acid	Induces terminal differentiation	Acute promyelocytic leukaemia
Farnesyl transferase inhibitors	Lonafarnib	Inhibition of farnesyl transferase and consequent inactivation of *ras*-dependent signal transduction	Leukaemia
	Tipifarnib	Inhibition of farnesyl transferase and consequent inactivation of *ras*-dependent signal transduction	Acute leukaemia Myelodysplastic syndrome
Antibodies directed to cell surface antigens	Trastuzumab	Antibody directed against HER2 receptor	Breast cancer
	Cetuximab	Antibody directed against EGFR	Colorectal cancer Head and neck cancer
	Bevacizumab	Antibody directed against VEGFR	Colorectal cancer
	Rituximab	Antibody against CD20 antigen	Lymphomas
	Alemtuzumab	Antibody against CD52 antigen	Lymphomas
Antibody drug conjugates	Trastuzumab deruxtecan	Targets chemotherapy to *Her2* expressing tumour	Breast cancer
	Sacituzumab govitecan	Targets chemotherapy to *Trop2* expressing tumour	Breast cancer
	Enfortumab vedotin	Targets chemotherapy to *Nectin4* expressing tumour	Urothelial cancer
Inducers of apoptosis	Arsenic trioxide	Induces apoptosis by caspase inhibition Inhibition of nitric oxide	Acute promyelocytic leukaemia
	Venetoclax	BH3 mimetic	CML AML Lymphoma

Continued

TABLE 12.6 Examples of anti-cancer drugs currently in use – *continued*.

Class	Examples	Putative mode of action	Tumour types that may be sensitive to drug
Immunological mediators	Ipilimumab	Blocks CTLA-4 and thus releases the brakes on the activation of T cells	Melanoma Lung cancer Renal cancer
	Pembrolizumab Nivolumab Atezolizumab Durvalumab	Block the PD-1 signalling on T lymphocytes and thereby prevents the inhibition of T-cell activation	Melanoma Lung cancer Renal cancer Bladder cancer
	Interferon alpha-2b	Activates macrophages, increases the cytotoxicity of T lymphocytes, inhibits cell division (and viral replication)	Hairy-cell leukaemia
	Thalidomide	Anti-inflammatory, stimulates T cells, antiangiogenic	Myeloma
HDAC inhibitors	Panobinostat Vorinostat	Acetylation of histones is associated with increased transcription of genes; inhibiting deacetylation can decrease expression of mutated or dysregulated genes	Cutaneous T-cell lymphoma
	Entinostat	Acetylation of histones is associated with increased transcription of genes; inhibiting deacetylation can decrease expression of mutated or dysregulated genes	Melanoma
PI3K inhibitors	Idelalisib	Inhibits signalling via the PI3K/AKT/mTOR pathway and thereby switch off stimulus to cellular proliferation	B-cell lymphomas
mTOR inhibitors	Temsirolimus Everolimus	Inhibit mTOR, a key component in the PI3K/AKT/mTOR pathway	Renal cancer Neuroendocrine tumours
MEK inhibitors	Trametinib Selumetinib	Inhibit the MAPK pathway	Melanoma Neurofibroma
RAF inhibitors	Dabrafenib Vemurafenib	Inhibit the MAPK pathway	Melanoma

AML, acute myeloid leukaemia; ATP, adenosine triphosphate; CML, chronic myeloid leukaemia; CTLA-4, cytotoxic T-lymphocyte-associated protein 4; EGFR, epidermal growth factor receptor; FLT3, FMS-like tyrosine kinase; GI, gastrointestinal; GIST, gastrointestinal stromal tumour; HDAC, histone deacetylase; HER2, human epidermal growth factor receptor 2; MAPK, mitogen-activated protein kinase; mTOR, mammalian target of rapamycin; NF, nuclear factor; PARP, poly-ADP ribose polymerase; PD-1, programmed cell death protein 1; PDGFR, platelet-derived growth factor receptor; PI3K, phosphoinositide 3-kinase; RAF, rapidly accelerated fibrosarcoma; TKI, tyrosine kinase inhibitor; VEGFR, vascular endothelial growth factor receptor.

Cytotoxic chemotherapy

Selective toxicity is the fundamental principle underlying cytotoxic chemotherapy. Tumour types vary greatly in their sensitivity to cytotoxic chemotherapy and their vulnerability to drugs with specific mechanisms of action. Treatments are often given for a limited number of treatment days during a cycle of treatment lasting typically 3–4 weeks. This allows the tumour to receive an effective dose while providing sufficient time for the patient to recover in time for the next cycle. Many treatment regimens give a limited number of cycles, typically three to six in total. Other regimens are maintenance treatments, in which an unlimited number of cycles are given.

Hormonal treatments

Several tumour types, notably breast cancer and prostate cancer, are stimulated by endogenous hormones. Removal of this stimulus from sensitive tumours will result in their shrinkage. An understanding of the relevant endocrine pathways has identified several points for therapeutic intervention, including interference with hormone receptors and with hormone production.

Targeted treatments

The explosion of knowledge about the molecular biology of cancer has identified multiple therapeutic targets. This has ushered in an era of highly specific treatments that aim to inhibit a target essential for tumour survival while leaving other tissues unaffected. At present, most targeted therapies are not absolutely specific for their primary target and therefore do have unwanted or 'off-target' side effects. In addition, successful inhibition of the target may have inevitable undesirable consequences in addition to the desired effect, so-called 'on-target' side effects. Many targeted treatments are given in continuous cycles and the dosing and toxicity management strategies are therefore of particular importance.

These treatments will only work if a patient's tumour depends on a therapeutic target. The kinase inhibitor vemurafenib will only be effective in patients with melanoma whose

tumours have the V600E *BRAF* mutation; cetuximab is only effective in patients with colorectal cancer who have wild-type (non-mutated) *ras*; imatinib is particularly effective in patients with gastrointestinal stromal tumours who have mutations in exon 11 of the *Kit* gene – patients with mutations in exon 9 may still respond to imatinib but will require higher doses and patients without mutations in *Kit* are far less likely to respond to imatinib.

Treatment choice therefore requires a molecular analysis of the patient's tumour. It is this determination of treatment at the individual level that has led to the concept of 'personalised medicine'. Although major advances have been made, important targets such as *ras* remain elusive at present, although several *ras*-targeted molecules are in development.

Immunotherapy

Treatments to activate the immune system against cancer have a long history, stimulated by the observation that up to half of the volume of certain tumours was known to be made up of immune cells, which appeared to be inactive or dead. There is now an appreciation that multiple malignancies activate mechanisms whose normal purpose is to down-regulate the immune system after elimination of an infectious organism. These mechanisms are called T-cell checkpoints. Inhibition of these checkpoints can reactivate the immune cells and has had remarkable success in previously virtually untreatable diseases such as metastatic melanoma. This novel form of treatment is generally much better tolerated than cytotoxic chemotherapy but may result in side effects owing to the uncontrolled activation of the immune system. Side effects such as pneumonitis, colitis, adrenal failure and hypophysitis (pituitary inflammation) may be life-changing or life-threatening and are more common when using a combination of checkpoint inhibitors.

Immunotherapy is a very active field of research and it is likely that vaccines and engineered immune cells will increasingly enter treatment protocols in the coming years.

Principles of combined treatment

Non-surgical treatments are often used in combination. For example, radiotherapy and chemotherapy are often given together as an alternative to surgery, e.g. in the treatment of rectal, cervical, head and neck or brain cancers (***Table 12.5***). The rationale behind combination, as opposed to single-modality therapy, is straightforward and is somewhat analogous to that used for combined antibiotic therapy: it is a strategy designed to combat resistance. By the time of diagnosis many tumours will contain cancer cells that, through spontaneous mutation, have acquired resistance to individual modalities of treatment. Unlike antibiotic resistance, there is no need for previous exposure to the treatment. Spontaneous mutation rates are high enough to allow chance to permit the occurrence, and subsequent expansion, of clones of cells resistant to a treatment to which they have never been exposed. If only single-modality treatments were used, then the further expansion of these *de novo* resistant subclones would limit cure. The problem can be mitigated by, from the outset of treatment, combining treatment modalities.

There are three main principles upon which the choice of drugs for combination therapy is based: (i) use drugs active against the diseases in question; (ii) use drugs with distinct modes of action; (iii) use drugs with non-overlapping toxicities. By using drugs with different biological effects, for example by combining an antimetabolite with an agent that actively damages DNA, it may be possible to obtain a truly synergistic effect, i.e. where the effects of the two modalities together are superior to the additive effects of both separately. It is inadvisable to combine drugs with similar adverse effects: combining two highly myelosuppressive drugs may produce an unacceptably high risk of neutropenic sepsis. Where possible, combinations should be based upon a consideration of the toxicity profiles of the drugs concerned.

In considering the combination of radiotherapy and chemotherapy, radiation could be considered as just another drug. There is, in addition to synergy and toxicity, another factor to consider in the combination of drugs and radiation – the concept of spatial cooperation. Chemotherapy is a systemic treatment, radiotherapy is not. Radiotherapy is, however, able to reach sites, such as the central nervous system and testis, that drugs may not reach effectively. This is why, for example in patients treated primarily with chemotherapy for leukaemias, lymphomas and small cell lung cancer, prophylactic cranial irradiation may be part of the treatment protocol.

Summary box 12.4

Principles of combined treatment

- Use effective agents
- Use agents with different modes of action (synergy)
- Use agents with non-overlapping toxicities
- Consider spatial cooperation

Oncological emergencies

There are a limited number of true emergencies in oncology. Those that require immediate recognition and management are:

- **Cord compression**: rapid diagnosis and management to relieve pressure on the spinal cord is essential to obtain the best results for patients. Ideally, treatment should be instituted when cord compression is threatened rather than when it has already occurred. Management is likely to include steroids and either neurosurgery or radiotherapy.
- **Neutropenic sepsis**: rapid diagnosis and antibiotic therapy are essential. There is a strong inverse relationship between the time taken to start antibiotics and the chance of patient survival.
- **Immune side effects** including hypophysitis, adrenal failure and insulin-dependent diabetes.

In contrast, there are many urgent oncological situations that are very unpleasant for the patient or that can rapidly deteriorate if not recognised quickly. These include thrombosis, effusion, superior vena cava obstruction and pain, among many others.

Life after cancer

As early diagnosis becomes more common and treatment outcomes improve, so an increasing number of people are cured of cancer. However, the impact of a cancer diagnosis and its treatment is profound. Organisations such as UK-based Macmillan Cancer Support can provide information and support to patients facing the health, work and financial sequelae of cancer.

Symptom control and palliative care

The distinction between palliative and curative treatment is not always clear-cut and will become increasingly blurred as professional and public attitudes towards the management of cancer change. Twenty years ago cancer was perceived as a disease that was either cured or it was not; patients either lived or died. There was little appreciation that, for many patients, cancer might be a chronic disease. Nowadays, it is appreciated that many patients will have multiple different treatment options during their cancer journey. Five-year survival is not necessarily tantamount to cure. With the development of targeted therapies that regulate, rather than eradicate, cancer this state of affairs is likely to continue. The aim of treatment will be growth control rather than the extirpation of every last cancer cell. Patients will live with their cancers, perhaps for years. They will die with cancer, but not necessarily of cancer.

Patients fear the symptoms, distress and disruption associated with cancer almost as much as they fear the disease itself. Palliative treatment has as its goal the relief of symptoms. Sometimes this will involve treating the underlying problem, as with palliative radiotherapy for bone metastases; sometimes it will not. Sometimes it may be inappropriate to treat the cancer itself, but that does not imply that there is nothing more to be done – it simply means that there may be better ways to assuage the distress and discomfort caused by the tumour. Palliative medicine in the twenty-first century is about far more than optimal control of pain: its scope is wide and its impact immense (*Table 12.7*). The most important factor in the successful palliative management of a patient with cancer is early referral. Transition between curative and palliative modes of management should be seamless.

Common problems that may be effectively palliated include:

- **Cerebral metastases**: stereotactic radiosurgery for small lesions is highly effective, although limited to patients who are likely to survive long enough to benefit.
- **Effusions**: pleural and ascitic drains may control these chronic problems. In the case of pleural effusion pleurodesis may prevent reaccumulation.
- **Thrombosis**: increased coagulability and pressure on blood vessels make this a common problem in oncology.
- **Hypercalcaemia**: bisphosphonates may control the patient's calcium level and regular infusions will be necessary when the underlying tumour process is not controlled by other means.

TABLE 12.7 An outline of the domains and interventions included within palliative and supportive care.

Holistic needs assessment	Pain, anorexia, fatigue, dyspnoea, etc.	
	Treatment-related toxicity	
Symptom relief	Drugs	
	Surgery	
	Radiotherapy	
	Complementary therapies:	Acupuncture
		Homeopathy
		Aromatherapy, etc.
Psychosocial interventions	Psychological support Relaxation techniques Cognitive behavioural therapy Counselling Group therapy Music therapy Emotional support	
Physical and practical support	Physiotherapy Occupational therapy Speech therapy	
Information and knowledge	Macmillan	
	Maggie's centres	
Nutritional support	Dietary advice	
	Nutritional supplements	
Social support	Patients	
	Relatives and carers	
Financial support	Ensure uptake of entitlements	
	Grants from charities, e.g. Macmillan	
Spiritual support		

- **Fatigue**: this is often a difficult symptom, which is partly due to the tumour and partly due to its treatment. Encouraging aerobic exercise, even at a low level, can improve fatigue and also stimulate appetite.
- **Weight loss**: patients often lose their appetite and consequently lose weight. Eating little and often with food supplements as necessary may be effective in mitigating weight loss.
- **Fever**: recurrent fevers are a feature of certain tumours such as lymphoma and renal cell cancer. Tumour fever must be distinguished from infection and this can often only be done by exclusion.
- **Paraneoplastic syndromes**: these are varied and often difficult to recognise. Management of the underlying malignancy may not necessarily resolve the syndrome.

End-of-life care

End-of-life care is distinct from palliative care. Patients treated palliatively may survive for many years; end-of-life care concerns the last few months of a patient's life. Many issues, such as symptom control, are common to both palliative care

and end-of-life care but there are also problems that are specific to the sense of approaching death. These include a heightened sense of spiritual need, profound fear and the specific needs of those who are facing bereavement. The concept of a 'good death' has been embedded in many cultures over many centuries. Healthcare professionals deal with many deaths and sometimes forget that the patient who hopes for a good death has only one chance to get it right. This is why end-of-life care is worth considering in its own right and not as a mere appendage to palliative care.

Summary box 12.5

Issues at the end of life

- Appropriateness of active intervention
- Euthanasia
- Physician-assisted suicide
- Living wills
- Bereavement
- Spirituality
- Support to allow death at home
- The problem of the medicalisation of death

PART 1 | Basic principles

CHAPTER 13

Surgical audit and research

Learning objectives

To understand:

- The planning and conduct of surgical audit and research
- How to write up a project
- How to review a journal article and determine its value

INTRODUCTION

Surgeons are innovators and a key aspect of a surgical career is to constantly adapt, tweak and improve surgical techniques and treatments to provide the best outcomes for those under our care. In addition, few others in the hospital use more technology or devices on a day-to-day basis than surgeons. It is therefore beholden upon all surgeons to be able to critically evaluate both our individual performance and the impact of adaptations in techniques, devices and treatment pathways on the individual and collective outcomes of our patients.

Involvement in research and audit activities will form a stable cornerstone within a long and successful surgical career. The aim of this chapter is to outline both how to undertake a successful audit cycle and how to design and conduct a surgical research study. Key aspects associated with enhanced chances of a successful project are discussed, including how collaboration with others can be crucial.

Large numbers of clinical papers appear in the surgical literature every year. Many are flawed, and it is important that a surgeon has the skills to examine publications critically. The best way to develop a critical understanding of the research and audit undertaken by others is to perform studies of one's own. The hardest part of audit and research is writing it up, and the hardest article to write is the first. This chapter contains the information required to write a surgical paper and to evaluate the publications of others.

AUDIT OR RESEARCH?

Health professionals are expected to undertake audit and service evaluation as part of quality assurance. These usually involve minimal additional risk, burden or intrusion for participants. It is important to determine at an early stage whether a project is audit or research, and sometimes that is not as easy as it seems. The decision will determine the framework in which the study is undertaken. In the UK, the Health Research Authority (HRA) has developed a decision tool to help decide whether your project is classified as research (http://www.hra-decisiontools.org.uk/research/). This tool crystallises the differentiation between audit and research to three overarching questions:

1. Are the participants in your study randomised to different groups?
2. Does your study protocol demand changing treatment/care/services from accepted standards for any of the patients/service users involved?
3. Is your study designed to produce generalisable or transferable findings?

Although the first two questions are simple to comprehend, the third can create some confusion at times. The HRA states that, in this context, 'generalisable' means the findings can be reliably extrapolated from the study to a broader population of patients/service users and/or applied to settings or contexts other than those in which they were tested. The majority of audits can be assumed to be hypothesis generating as they would require subsequent prospective testing in a new population before findings could be considered as new 'evidence' – as such they do not fulfil this generalisability criterion. Finally, in this context, 'transferable' means that the findings of a qualitative study can be assumed to be applicable to a similar context or setting. Most qualitative studies are not usually generalisable but can quite often be considered to be transferable.

Further useful information on classifying your proposed project can be found in the HRA leaflet 'Differentiating clinical audit, service evaluation, research and usual practice/surveillance work in public health' (http://www.hra-decisiontools.org.uk/research/docs/DefiningResearchTable_Oct2017-1.pdf).

AUDIT AND SERVICE EVALUATION

Clinical audit is a process used by clinicians who seek to improve patient care. The process involves comparing aspects of care (structure, process and outcome) against explicit criteria and defined standards. Keeping track of personal

outcome data and contributing to a clinical database ensures that a surgeon's own performance is monitored continuously and can be compared with a national data set to ensure compliance with agreed standards. Involvement in active audit processes is also an essential component of revalidation for the individual surgeon in the UK. If care falls short of the guidance standard being compared against, some change in the way that care is organised should be proposed. This change may be required at one of many levels. It might be an individual who needs training or surgical equipment that needs replacing. At times, the change may need to take place at the team level. Sometimes, the only appropriate action is change at an institutional level (e.g. a new antibiotic policy), regional level (provision of a tertiary referral centre) or, indeed, national level (screening programmes and health education campaigns).

There are two main types of audit in common practice – single site/local audits and multisite regional, national or international audits. Both are designed to improve the quality of care. In an ideal world local audits might identify needs closest to the patient, which can then be further investigated in multisite larger scale audits. For example, hospital topics are often identified at departmental morbidity and mortality meetings, where issues relating to patient care are discussed. The reporting process might identify a possible national issue, and a national or international audit could be designed to be delivered by local surgical teams.

Audits are formal processes that require a structure. The following steps are essential to establish an audit cycle:

1. Define the audit question in a multidisciplinary team.
2. Identify the body of evidence and current standards.
3. Design the audit to measure performance against agreed standards based on strong evidence. Seek appropriate advice (local audit department in the UK) and ensure institutions have agreed to undertake the audit.
4. Measure over an agreed interval.
5. Analyse results and compare performance against agreed standards.
6. Undertake gap analysis:
    a. if all standards are reached, reaudit after an agreed interval;
    b. if there is a need for improvement, identify possible interventions such as training, and agree with the involved parties.
7. Reaudit.

A new type of audit that has developed significant traction in surgery over recent years is the 'multicentre snapshot audit', whereby many collaborators across multiple hospitals prospectively collate anonymised patient-level data for a specific condition, presentation or intervention over a short time period of normally around 6–8 weeks. This allows exploration of differences in patients, techniques and management across the cohort to identify areas of practice variability that may result in apparent differences in outcome. These studies generate hypotheses and identify areas where further prospective research is needed. Key advantages of these snapshot audits are their easy accessibility and the fact that they can be conducted at almost zero cost, so they can be an excellent means of bringing a new group together to collaborate and create contemporaneous and 'real-world' data together.

IDENTIFYING A RESEARCH TOPIC

Research is designed to generate new knowledge and might involve testing a new treatment or regimen. Once an idea has been formed, or a question asked, it needs to be transformed into a hypothesis. It is helpful to approach surgeons who regularly publish articles and who have a special interest in the subject area being considered. As ideas are suggested, it is important to consider whether the question posed really matters. Spending time refining the question (hypothesis) is probably the most important part of the process. Choosing the wrong topic can lead to many wasted hours. Once a topic has been identified, it is also important not rush into the study. The worst possible outcome is to find at the end of a long arduous study that the research has already been performed or that the chosen methodology did not support investigation of the primary/secondary outcomes.

The first port of call for information is the Internet (with assistance as needed from a medical librarian). Current articles about the proposed research should be retrieved; review articles and meta-analyses can be particularly helpful. It is very important to learn how to do an accurate and efficient search as early as possible. Collections of reviews are available – the Cochrane Collaboration brings together evidence-based medical information and is available in most libraries. Once information on the subject has been obtained and the relevant literature identified, it is important that these are carefully perused. It is not sufficient to just read the abstract! Further information is given in ***Table 13.1***.

An excellent source of ideas where research is needed can come from reviewing high-quality national guidelines such as those produced by the UK National Institute for Health and Care Excellence (NICE) on a particular area of interest, many of which include a section beneath the headline guidance being made on 'recommendations for research'. This section is populated after the currently available evidence for an intervention or treatment has been reviewed by the expert team and found lacking. Designing a research project to cover one or more of these agreed areas can be easily justified to both funders and clinicians alike.

Finally, there is an increased number of Priority Setting Partnerships across all aspects of surgery, including those formally undertaken by the James Lind Alliance and by others run by surgical associations and their patient–partner groups. These partnerships consist of patients, carers, healthcare professionals and organisations or charities representing people with the particular condition. They focus on identifying and prioritising research gaps or important specific questions for

Archibald Leman Cochrane, 1909–1988, Director of the UK Medical Research Council Epidemiology Unit, Cardiff, UK, after whom the Cochrane Collaboration is named.

which additional new research is needed to answer them. Again, creating research projects in these areas is likely to be well received; sometimes such studies are also prioritised for funding support.

It is also helpful to seek support from specific networks set up to support health research. In the UK, the National Institute for Health Research (NIHR) runs the Research Design Service (RDS), which provides free and confidential advice on research design, writing funding applications and obtaining public engagement in research for all researchers. There are also a number of training courses available in research methodology and application.

FORMING A TEAM

One of the most common reasons for the failure of an otherwise good research project is failure to involve others. Only the smallest single-centre project can be delivered by an individual researcher working alone; almost any project worth doing will need a team to deliver it. This team can bring the necessary skills and experience to help bring the project to fruition but also, and perhaps more importantly, it can provide the momentum required to keep pushing a project through to completion when the inevitable hurdles are met.

There may be local colleagues who form a natural team for a project, perhaps with the oversight of an experienced trainer or mentor. Another solution can be to get involved in a collaborative research group. Surgery has led the way with collaborative research working over recent years.

The first trainee-level research collaborative in the UK was formed in 2008 when a group of surgical trainees who shared the same frustrations around the challenges of conducting high-quality research while engaged in a full-time training programme came together to create the West Midlands Research Collaborative (WMRC). The premise was simple: to create and conduct prospective research projects that simultaneously collate data from across all of the members' units and to take advantage of the rotation of trainees' postings between units to ensure project longevity and thus enable longer term outcome collection. By achieving a critical mass of engaged members in these projects, the collective momentum ensured completion even if individuals were unable to personally contribute in a consistent manner because of examinations, family life or busy clinical periods. Such research collaboratives can be most effective in undertaking two key types of study: (i) simple randomised controlled trials (RCTs) and (ii) multicentre snapshot audits (see ***Audit and service evaluation***).

The first RCT undertaken by the WMRC was the ROSSINI trial, which explored the clinical effectiveness of a simple wound-edge protection device in reducing wound infections after abdominal surgery. A network of trainees mobilised 21 units for the trial and together they completed the trial 2 months ahead of schedule, having randomised 760 patients over a 23-month period, completing in January 2013. This achievement galvanised the research collaborative model and stimulated other new groups to form.

There are now general surgical research collaboratives in every region of the UK and national collaboratives for each surgical subspeciality area such as neurosurgery and cardiothoracic surgery. Many other countries with rotational surgical training programmes have also formed their own parallel collaboratives, including Australia, Portugal, Italy, The Netherlands and Canada. The collaborative movement has

established a new paradigm for evidence-based surgical practice, engaged thousands of surgical trainees and their consultant mentors and created an active network of research active clinicians at many hospitals across the world.

In the UK, trainee collaboratives have, to date, developed at least 10 RCTs and been awarded competitive grant funding worth over £8 million. The model has also extended to medical student collaboratives (STARSurg), and all 42 medical schools in the UK now have an active network student research collaborative. More recently, similar research collaboratives have also formed, utilising the established core principles, in non-surgical specialities such as anaesthetics, gastroenterology and elderly care.

All of these collaborative groups work on a principle of complete inclusivity – any interested person is very welcome to get involved in the collaborative; both in existing projects and in suggesting new ideas. People can join at any stage from medical student to consultant. Anyone interested in surgical research should seek out their local or national surgical research collaborative group and get involved.

PROJECT DESIGN

During the first phase, it is important to keep in the mind some important questions (***Summary box 13.1***).

Summary box 13.1

Questions to answer before undertaking research

- Why do the study?
- Will it answer a useful question?
- Is it practical?
- Can it be accomplished in the available time and with the available resources?
- Will the project benefit from collaboration to increase numbers or make best use of high-technology equipment?
- What findings are expected?
- What are the research governance requirements?
- What are the ethical issues?
- What impact could it have?

There are many different types of scientific study. The design used depends on the study. Time spent carefully designing a potential project is never wasted. An RCT is regarded as one of the best methods of scientific research; however, much surgical practice has been advanced through other different types of study such as those listed in ***Table 13.2***. For example, testing a new type of operation often requires a pilot study to assess feasibility, which is then followed by a formal RCT. The introduction of innovative surgical techniques may require novel handling, and recommendations have been made by the IDEAL collaborators (see ***Further reading***).

Research can be qualitative or quantitative. Quantitative research allows hard facts to speak for themselves. A medical condition is analysed systematically using hard, objective end points such as death or major complications, which should be clearly defined. For example, surgical complications are now classified using the Clavien–Dindo system. In qualitative research, data often come from patient narratives, and the psychosocial impact of the disease and its treatment are analysed; for example, narratives from patients with breast cancer. These kinds of data are often collected using quality-of-life measurements. A variety of different quality-of-life questionnaires exist to suit several different clinical situations. Much of the best research is both quantitative and qualitative. Recently, the importance of outcomes from the patient's perspective has been emphasised: patient-reported outcome measures (PROMs) are now an important component of the evaluation of surgical procedures.

TABLE 13.2 Types of study.

Type of study	Definition
Observational	Evaluation of condition or treatment in a defined population
	Retrospective: analysis of past events
	Prospective: contemporaneous collection of data
Case–control	Series of patients with a particular disease or condition compared with matched control patients
Cross-sectional	Measurements made on a single occasion, not looking at the whole population but selecting a small similar group and expanding results
Longitudinal	Measurements taken over a period of time, not looking at the whole population but selecting a small similar group and expanding results
Experimental	Two or more treatments are compared. Allocation to treatment groups is under the control of the researcher
Randomised	Two or more randomly allocated treatments
Randomised controlled	Includes a control group with standard treatment

Research should be focused according to institutional, national and international strategies. As finances for health care are always limited, it is important to consider including a cost–benefit analysis in any major area of research so that the value of the proposed intervention or change in treatment can be assessed. The NIHR provides the framework through which the Department of Health maintains and manages the research, research staff and research infrastructure of the National Health Service (NHS) in England.

Sample size

Calculating the number of patients required to perform a satisfactory investigation is an important prerequisite to any study. An incorrect sample size is probably the most frequent reason for research being invalid. Often, surgical trials are marred by the possibility of error caused by the inadequate number of patients investigated.

Pierre-Alain Clavien, contemporary, Professor of Surgery, Zurich, Switzerland.
Daniel Dindo, contemporary, surgeon, Zurich, Switzerland.

- **Type I error**. Benefit is perceived when really there is none (false positive).
- **Type II error**. Benefit is missed when it was there to be found (false negative).

Calculating the number of patients required in the study can overcome this bias. Unfortunately, it often reveals that a larger number of patients is needed for the study than can possibly be obtained from available local resources. This usually means expanding enrolment by running a multicentre study – which has the added benefit of improving the external validity of findings. More patients will need to be randomised than the final sample size to take into account patients who die, drop out or are lost to follow-up; this is known as the attrition rate. A longer time from trial entry to primary outcome assessment will result in an increased attrition rate of participants.

The following is an example calculation for a study to recruit patients into two groups. In order to calculate a sample size, it is now common practice to set the level of power for the study at 90% with a 5% significance level. This means that, if there is a difference between study groups, there is a 90% chance of detecting it. Based on previous studies, realistic expectations of differences between groups (i.e. the magnitude of the effect seen from utilising the intervention under study), according to the best available evidence, should be used to calculate the sample size. The formula below uses the results of a reduction in event rate from 30% to 20% (e.g. a new treatment expected to reduce the complication rate such as wound infection from 30% = r to 20% = s).

$$9 \times \frac{[r(100 - r) + s(100 - s)]}{(r - s)^2}$$

$$\text{e.g. } 9 \times \frac{[30(100 - 30) + 20(100 - 20)]}{(30 - 20)^2}$$

$$= 333 \text{ needed in each group}$$

Eliminating bias

It is important to imagine how a study could be invalidated by thinking of things that could go wrong. One way to eliminate any bias inherent in the data collection is to have observers or recorders who do not know which treatment has been used (blinded observer). It might also be possible to ensure that the patient is unaware of the treatment allocation (single blind). In the best randomised studies, neither patient nor researcher is aware of which therapy has been used until after the study has finished (double blind). Randomised trials are essential for testing new drugs. In practice, however, in some surgical trials, randomisation may not be possible or ethical.

Study protocol

Now that the research question has been decided, and it has been checked that sufficient patients should be available to enrol into the study, it is time to prepare the detail of the trial. At this stage, a study protocol should be constructed to define the research plan. It should contain the background of the proposed study, the aims and objectives, a clear methodology, definitions of population and sample sizes and methods of proposed analysis. It should include the patient numbers, inclusion and exclusion criteria and the timescale for the work. The protocol should be detailed enough for another party to come along in the future and theoretically replicate the study. It is useful to construct a flow diagram giving a clear summary of the research protocol and its requirements (***Figure 13.1***). It is helpful to imagine the paper that will be written about the study before the study is performed. This may prevent errors in data collection.

When a study is planned, sufficient time should be reserved at the beginning for fund-raising and obtaining ethical, regulatory and or other approvals (e.g. HRA). Time for data analysis and preparation of publication needs to be included in funding applications. The cost of any non-routine investigations and extra treatments should be identified and covered by the research grant in line with national guidance (in the UK, the Attributing the costs of health and social care Research and Development [AcoRD] guidance; https://www.gov.uk/government/publications/guidance-on-attributing-the-costs-of-health-and-social-care-research).

A data collection form should be designed or a computer collection package developed. If data are collected on a computer, appropriate safeguards for privacy, confidentiality and data quality will be necessary to comply with legislation. At this stage it is important to consider any validation requirements and needs for open access, either in a recognised archive (e.g. the UK Data Archive) or in an institutional repository. Any form of data collection needs to be quality assured. The quality assurance process will include training, standard operating procedures as well as monitoring and checking a certain sample of the data. At the end of data collection and analysis, a final database with all data should be locked and kept for future reference in a safe location. A data-archiving policy with a nominated data custodian should be in place.

Research is no longer confined by institutional or even geographical boundaries. Collaborative research groups in surgery at a national or international level have come together to undertake high-quality surgical research in recent years, aided by online communication and the availability of secure electronic databases such as REDCap™. The SUNRRISE trial shown in ***Figure 13.1*** was undertaken by researchers from two trainee-led research collaborative groups across the UK, in conjunction with a parallel collaborative group in Australia. All patients were included within the same study cohort in real time: the Australian sites were effectively identical to those in the UK because of online electronic randomisation systems and online live data capture via REDCap.

Some publishers require registration of a study at the time it is set up on a publicly available database (e.g. the World Health Organization's recognised registries such as ISRCTN, EudraCT and ClinicalTrials.gov). It is becoming increasingly popular to consider publication of a protocol paper.

Regulatory framework

In the UK, the implementation of the UK Policy Framework for Health and Social Care Research provides a framework

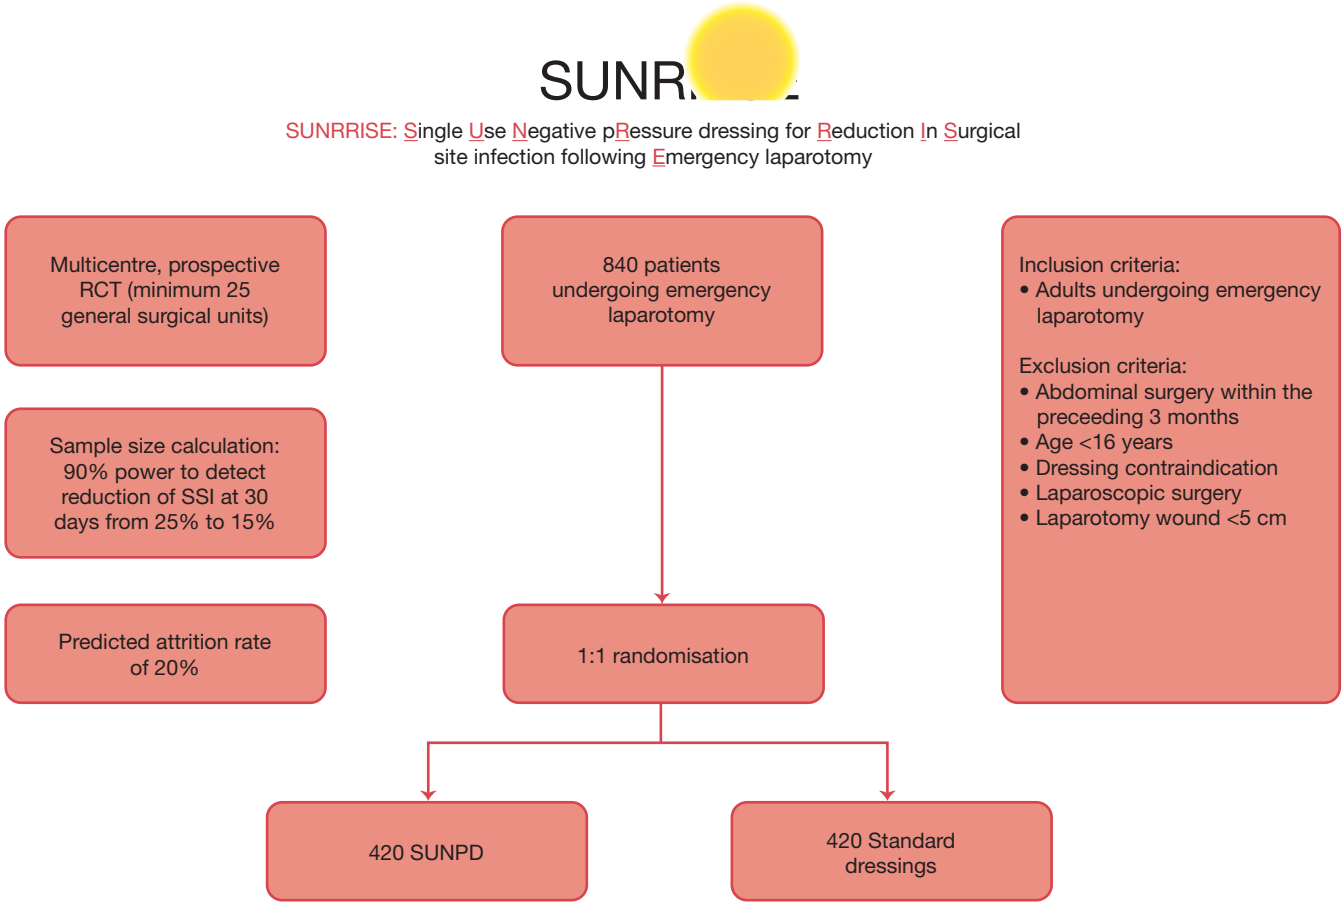

Figure 13.1 SUNRRISE trial: protocol summary and recruitment flowchart. Permission is granted by Birmingham Clinical Trials Unit, University of Birmingham, UK. RCT, randomised controlled trial; SSI, surgical site infection; SUNPD: single-use negative-pressure dressing.

that enhances the integrity of the study and includes requirements for sponsorship by an institution to ensure the following: peer review, independent ethics review, compliance with data protection principles, financial probity, dissemination and management of intellectual property.

Sponsorship is defined by the HRA as the individual, company, institution or organisation that takes on ultimate responsibility for the initiation, management (or arranging the initiation and management) of and/or financing (or arranging the financing) for that research. The sponsor takes primary responsibility for ensuring that the design of the study meets appropriate standards and that arrangements are in place to ensure appropriate conduct and reporting (https://www.hra.nhs.uk/planning-and-improving-research/research-planning/roles-and-responsibilities/#sponsor).

Peer review

Once the protocol is finalised, formal peer review is needed. In the UK, evidence of peer review will be needed before submitting an application to a research ethics committee and for HRA approval. Many funders of research will undertake their own independent peer review. There is usually feedback from this process that can provide valuable advice about the study.

Ethics

In the first instance, common sense is the best guide to whether or not a study is ethical. It is still important to seek advice from an independent research ethics committee whenever research is contemplated.

In the UK the requirement is that an NHS Research Ethics Committee (NHS REC) provides an independent ethical review of all health and social care research if it involves patients and/or carers. The Governance arrangements for Research Ethics Committees (GafREC) provides detailed guidance about NHS REC review requirements. The application for NHS REC review is made using the Integrated Research Application System (IRAS). IRAS enables entry of information about the project once, instead of duplicating information in separate application forms for regulators.

If the study does not require review by an NHS REC, the need for an independent ethical review should still be considered. Universities have developed their own ethical review infrastructure and this will be institute specific and location specific. For collaborative research, local ethical review should be obtained where possible, and developing a local ethics infrastructure should be considered if it does not already exist. Duplication of ethical review should be avoided.

Ethics committee forms may seem long and detailed, but it is important that these are filled in correctly as this helps to

prepare the investigators for all practical aspects of the project. All dealings with ethics committees should be intelligent and courteous. It is important to attend the meeting at which the study will be discussed, if invited, as it provides a forum for direct communication in relation to the study. It can save time as possible concerns of the ethics committee can be addressed at the time, avoiding lengthy correspondence.

Regulatory approvals

Interventional clinical or device trials are regulated by the Medicines and Healthcare products Regulatory Agency (MHRA) in the UK. Researchers are encouraged to use an existing and established international register such as ISRCTN or ClinicalTrials.gov to ensure that the public is aware of a trial before recruitment of the first participant. Trials involving sites specifically in EU countries must be registered in the EU Clinical Trials Register. Trials should be registered before applying to the MHRA for a clinical trial authorisation via the MHRA submissions portal and researchers must ensure that the registry is kept up to date and trial results are uploaded in the appropriate timeframe. This can be a complicated and trying process, and support should be sought from the investigators' employing institution. Editors of the major surgical journals now agree that all clinical trials should have been registered before an article relating to a trial can be published.

All studies undertaken with NHS patients and/or carers will need HRA Approval and confirmation of capacity and capability from NHS sites. Studies involving animals require approval from statutory licensing authorities. In the UK this is the Home Office. Animal research should be based on ARRIVE guidelines (Animal Research: Reporting of In Vivo Experiments).

Research integrity

In 2013, Universities UK, in collaboration with major funders of research, developed The Concordat to Support Research Integrity, which sets out key commitments to ensure a high standard in research. It highlights the principles and professional responsibilities of researchers and research institutions that are fundamental to the integrity of research wherever it is undertaken. These centre on:

- honesty in all aspects of research;
- accountability and transparency in the conduct of research;
- professional courtesy and fairness in working with others;
- good stewardship of research.

A study should not under any circumstances commence until appropriate approvals have been granted and compliance with the principles of research integrity is ensured. A helpful international summary of country-specific approval requirements is available from NIH (https://clinregs.niaid.nih.gov).

STATISTICAL ANALYSIS

Both audit and research commonly require statistical analysis. Many surgeons find the statistical analysis of a project the most difficult part. It is also the most commonly criticised part of papers written by clinicians. There are many useful books about statistics (see ***Further reading***); if in any doubt, a statistician will be pleased to give assistance. Statisticians should be consulted before research or audit has been conducted rather than being presented with the data at the end; they often give helpful advice over study design and can be an important part of the project team.

The following terms are frequently used when summarising statistical data:

- **Mean**: the result of dividing the total by the number of observations (the average).
- **Median**: the middle value with equal numbers of observations above and below – used for numerical or ranked data.
- **Mode**: the value with the highest frequency observed – used for nominal data collection.
- **Range**: the largest to the smallest value.

The most important decision for analysis is whether the distribution of the data is normal (i.e. parametric or non-parametric). Normally, distributed data have a symmetrical bell-shaped curve, and the mean, median and mode all lie at the same value. The type of data collected determines which statistical test should be used.

1. Numerical and normally distributed (e.g. blood pressure) – use an unpaired *t*-test to compare two groups or a paired *t*-test to assess whether a variable has changed between two time points.
2. Numerical but not normally distributed (e.g. tumour size) – use a Mann–Whitney *U*-test to compare two groups or a Wilcoxon signed rank test to assess whether a variable has increased/stayed the same/decreased between two time points.
3. Categorical (e.g. admitted or not admitted to an intensive care unit) – a chi-squared test can be used to compare two groups.

(**Note**: the use of these and any other statistical tests may benefit from professional advice.)

Confidence intervals are the best guide to the possible range in which the true differences are likely to lie. A confidence interval that includes zero usually implies a lack of statistical significance.

Scientists usually employ probability (*P*-values) to describe statistical chance. A *P*-value <0.05 is commonly taken to imply a true difference. It is important not to forget that $P = 0.05$ simply means that there is only a 1:20 chance that the differences between the variables would have happened by chance when in fact there is no real difference. If enough variables are examined in any study, significant differences will occur simply

Henry Berthold Mann, 1905–2000, and his student **Donald Ransom Whitney**, 1915–2007, Ohio State University, OH, USA, published their seminal paper 'On a test of whether one of two random variables is stochastically larger than the other' in 1947.
Frank Wilcoxon, 1892–1965, born County Cork, Ireland, American chemist and statistician.

by chance. Trials with multiple end points or variables require more sophisticated analysis to determine the significance of individual risk factors. Univariable or multivariable logistic regression analysis techniques may be appropriate.

Statistics simply deal with the chance that observations between populations are different and should be treated with caution. Clinical results should show clear differences. If statistics are required to demonstrate differences between results, it is likely that they are unlikely to have major clinical significance.

Computer software packages available

Statistical computer packages offer a quick way of analysing descriptive statistics such as mean, median and range, as well as the most commonly used statistical tests such as the chi-squared test. Various packages are available commercially and are useful tools in data analysis.

ANALYSING A SCIENTIFIC ARTICLE

The simplest way to analyse an article from a scientific journal is to look at the checklist of requirements for good scientific research. A group of scientists and editors developed the Consolidated Standards of Reporting Trials (CONSORT) statement to improve the quality of reporting of RCTs. Looking in detail at the study design is often the best way of deciding whether a trial is of value. The CONSORT document includes a checklist for the conduct of good RCTs (***Table 13.3***). Often clinicians overlook biases that others find obvious to detect, which can have a profound influence on the outcome of any study. Even the randomised design does not always guarantee quality, and a core component of systematic review is the grading of trial quality; several scoring systems have been developed (e.g. Jadad score). Recent guidelines have been published formalising the methods of systematic review and meta-analysis (Preferred Reporting Items for Systematic Reviews and Meta-Analyses [PRISMA] guidelines), and also many other types of article. These can be found in the instructions to authors of most surgical journals, which will now only accept articles that follow those rules.

PRESENTING AND PUBLISHING AN ARTICLE

There is no point in conducting a research or audit project and then leaving the results unreported. Even when results are negative, they are worth distributing; no project if properly conducted is worthless. Under-reporting of negative outcomes causes a systematic bias in the literature in favour of positive trials. Most studies do not provide dramatic results, and few surgeons publish seminal articles.

The key to both presentation and publication is to decide on the message and then aim for an appropriate forum. Big important randomised studies or national audits merit presentation at national or international meetings and publication in international journals. Small observational studies and audits are more often accepted for presentation at regional meetings and for publication in smaller specialist journals. Help and advice from clinicians familiar with presentation and publication are invaluable at this stage. The most important piece of advice is to follow accurately the instructions for journal submission. Most international meetings will accept presentations eagerly (especially by poster) as this increases the attendance at a conference.

Most surgeons publish research in peer-reviewed journals. The work that is submitted is checked anonymously by other surgeons before publication. If in doubt about whether to submit to a journal, many editors will give advice about the suitability of an article for submission to their journal. It is usually free to publish in surgical journals since the cost of refereeing and editing is borne by the journal subscriber. A second model of publication is becoming more prevalent: open access, in which the author pays. This ensures that all research is visible to anyone, by pushing the costs of the editorial process onto the study budget. It may well become standard in future.

Convention dictates that articles are submitted in IMRAD form: introduction, methods, results and discussion. Increas-

TABLE 13.3 Consolidated Standards of Reporting Trials (CONSORT) checklist for authors.

Heading	Subheading	Descriptor
Title		Identify as randomised trial
Abstract		Structured format
Introduction		Prospectively defined hypotheses, clinical objective
Methods	Protocol	Study population
		Intervention, timing
		Primary and secondary outcome
		Statistical rationale
		Stopping rules
	Assignment	Unit of randomisation
		Method: allocation schedule
	Masking (blinding)	
Results	Participant flow and follow-up	Trial profile, flow diagram
	Analysis	Estimated effect of intervention
		Summary data with appropriate inferential statistics
		Protocol deviation
Comment		Specific interpretation of study
		Sources of bias
		External validity
		General interpretation

ingly, electronic publication and the Internet is changing the face of scientific publication and, in the next decade, these restrictions on style may disappear. For now, the IMRAD format remains inviolable. The length of an article is important: a paper should be as long as the size of the message. Readers of large randomised multicentre trials need to know as much detail about the study as possible; reports on small and simple trials should be brief.

- **Introduction**. This should always be short. A brief background of the study should be presented and then the aims of the trial or audit outlined.
- **Methods**. The methodology and study design should be given in detail. It is important to identify potential biases. New techniques or investigations should be detailed in full; if they are common practice or have been described elsewhere, this should be referenced instead of described.
- **Results**. Results are almost always best shown diagrammatically using tables and figures. Results shown in the form of a diagram need not then be duplicated in the text.
- **Discussion**. It is important not to repeat the introduction or reiterate the results in this section. The study should be interpreted intelligently and any suggestions for future studies or changes in management should be made. It is prudent not to indulge in flights of fantasy or wild imagination about future possibilities; most journal editors will delete these. Recently, a standard format for the discussion section has been promoted, and journals such as the *BMJ* are keen that authors use it.
- **References**. This section should include all relevant papers recording previous studies on the subject in question. The reference section does not usually have to be exhaustive, but should include up-to-date articles. Remember to present the references in the style of the journal of submission.

EVIDENCE-BASED SURGERY

Surgical practice has been considered an art: ask 50 surgeons how to manage a patient and you will probably get 50 different answers. There is so much clinical information available that no surgeon can know it all. Evidence-based surgery is a move to find the best ways of managing patients using clinical evidence from collected studies. It was estimated that sufficient evidence to justify routine myocardial thrombolysis for heart attacks was available years before the randomised clinical studies that finally made it clinically acceptable; no one had gathered all the available information together.

Centres such as the Cochrane Collaboration have been collecting randomised trials and reviews to provide up-to-date information for clinicians. The Cochrane Library presently includes a database of systematic reviews, reviews of surgical effectiveness and a register of controlled trials. The *BJS* has been collecting surgical randomised trials on its website archive for 20 years (www.bjs.co.uk). As evidence accumulates, it is expected that this will gradually smooth out the differences between clinicians as the best way of managing patients becomes more obvious. Collecting published evidence together and analysing it often requires reviews of multiple randomised trials. These meta-analyses involve complex statistical analyses designed to interpret multiple findings and synthesise the results of multiple studies.

PART 1 | Basic principles

CHAPTER
14 Ethics and law in surgical practice

Learning objectives

To understand:

- The importance of autonomy in good surgical practice
- The necessity for reasonable disclosure prior to seeking consent for surgery
- Good practice in making decisions about withdrawal of life-sustaining treatment
- The primacy of confidentiality in surgical practice
- The importance of appropriate regulation in surgical research
- The importance of rigorous training and maintenance of good practice standards

INTRODUCTION

This chapter incorporates references to English common and statute law. Nevertheless, these legal and ethical principles have much in common with other jurisdictions across the world.

Surgery, ethics and law go hand in hand. In any other arena of public or private life, if someone deliberately cuts another person, draws blood, causes pain, leaves scars and disrupts everyday activity, then the likely result will be a criminal charge. If the person dies as a result, the charge could be manslaughter or even murder. Self-evidently, the difference between the criminal and the surgeon is that their intentions differ. While a criminal intentionally (or recklessly) inflicts harm, the surgeon's intention is limited to the treatment of illness. Any harm that ensues is either unintentional or is necessary (such as an incision) to facilitate treatment.

Patients submit to surgery because they trust their surgeons. What should 'consent' entail in practice and what should surgeons do when patients need help but are unable or unwilling to agree to it? When patients do consent to treatment, surgeons are provided with a wide discretion. The end result may be cure, but disfigurement, disability and death may also result. How should such surgical 'power' be regulated to reinforce the trust of patients and to ensure that surgeons practise to an acceptable professional standard? Are there circumstances, in the public interest, in which it is acceptable to sacrifice the trust of individual patients through revealing information that was communicated in what patients believed to be conditions of strict privacy?

These questions about what constitutes good professional practice concern medical ethics and law relating to consent, confidentiality and the underlying concept of personal autonomy.

In addition, these principles need to be applied to surgical activities, including professional matters relating to governance, regulation and the process of revalidation in its different guises around the world. Surgical training is starting to embrace the 'basic science' of surgical law to offer surgeons assistance in the resolution of such ethical dilemmas. This chapter is evidence of that process.

RESPECT FOR AUTONOMY

Surgeons have a duty of care towards their patients that goes beyond merely protecting life and health. Their additional duty of care is to respect the autonomy of their patients and their ability to make choices about their treatments, and to evaluate potential outcomes in light of other life plans. Such respect is particularly important for surgeons because, without it, the trust between them and their patients may be compromised, along with the success of the surgical care provided. We are careful enough in everyday life about whom we allow to touch us and to see us unclothed. It is hardly surprising that many people feel strongly about exercising the same control over a potentially hazardous activity, such as surgery.

For all these reasons, there is a wide moral and legal consensus that patients have the right to exercise choice over their surgical care. In this context, a right should be interpreted as a claim that can be made on the surgeon. The surgeon, therefore, accepts the strict duty to respect the patient's choice, regardless of personal preferences. Thus, to the degree that patients have a right to make choices about proposed surgical treatment, it then follows that they should be allowed to refuse treatments that they do not want, even when surgeons think that they are wrong. The right to make an unwise decision was exemplified in a case where a woman with capacity refused renal replacement therapy.[1] The court reminded doctors that, notwithstanding the fact that other citizens might consider her decision unreasonable, illogical or even immoral, none of these criticisms of the decision by themselves provide evidence of a lack of capacity. Patients can refuse surgical treatment that will save their lives, either at present or in the future. The latter, through the formulation of advance decisions or lasting powers of attorney, specify the types of life-saving treatments

that patients do not wish to have, notwithstanding that they may later become incompetent to refuse them.

DISCLOSURE PRIOR TO CONSENT

In surgical practice, respect for autonomy translates into the clinical duty to obtain informed consent before the commencement of treatment.

It is easy to underestimate the gap in understanding between a surgeon and his or her patient.[2] How many patients would recognise that unilateral eye surgery might lead to contralateral blindness? The risks and side effects of many operations are not intuitive, and the surgeon is not in a position to guess how the patient's plans for employment, leisure and family life may be inadvertently affected by a foreseeable complication. A budding Olympic gymnast might choose to forego surgery on a quiescent posterior triangle lesion if he or she knew the potential consequences of division of the accessory nerve. That is why patients need to be informed, beforehand, so they can choose whether or not to take the risk.

To establish valid consent to treatment, patients need to be given appropriate and accurate information. In England and Wales, the Department of Health's (DH) *Reference Guide to Consent for Examination or Treatment* (second edition) should be consulted, together with the General Medical Council's (GMC) most recent guidance *Decision Making and Consent* (GMC 2020).

Such information, disclosed during a formal and tangible discussion, must include:

- the condition and the reasons why it warrants surgery;
- the type of surgery proposed and how it might correct the condition;
- the anticipated prognosis and expected side effects of the proposed surgery;
- the unexpected hazards of the proposed surgery;
- any alternative and potentially successful treatments other than the proposed surgery;
- the consequences of no treatment at all.

With such information, patients can link their clinical prospects to the management of other aspects of their lives and the lives of others for whom they may be responsible. Good professional practice dictates that obtaining informed consent should occur in circumstances that are designed to maximise the chances of patients understanding what is said about their condition and the proposed treatment, as well as giving them an opportunity to ask questions and express anxieties.

Where possible:

- a quiet venue for discussion should be found;
- written material in the patient's preferred language should be provided to supplement verbal communication, together with diagrams where appropriate;
- patients should be given time and help to come to their own decision;
- the person obtaining the consent should ideally be the surgeon who will carry out the treatment. It should not be – as is sometimes the case – a junior member of staff who has never conducted such a procedure and thus may not have enough understanding to counsel the patient properly.

Good communication skills go hand in hand with properly obtaining informed consent for surgery. It is not good enough just to go through the motions of providing patients with the information required for considered choice. Attention must be paid to:

- whether or not the patient has understood what has been stated;
- avoiding overly technical language in descriptions and explanations;
- the provision of translators for patients whose first language is not English;
- asking patients if they have further questions.

When there is any doubt about their understanding, patients should be asked questions by their surgeon about what has supposedly been communicated to see if they can explain the information in question for themselves.

Surgeons have a legal as well as a moral obligation to obtain consent for treatment based on appropriate disclosure. Failure to do so could result in one of two civil proceedings, assuming the absence of criminal intent. First, in law, intentionally to touch another person without their consent is a battery, remembering that we are usually touched by strangers as a consequence of accidental contact. Surgeons have an obligation to give the conscious and capacitous patient sufficient information 'in broad terms' about the surgical treatment being proposed and why. If the patient agrees to proceed, no other treatment should ordinarily be administered without further explicit consent.

The second legal action that might be brought against a surgeon for not obtaining appropriate consent to treatment is in the tort (civil wrong) of negligence. Patients may have been given enough information about what is surgically proposed to agree to be touched in the ways suggested. However, surgeons may still be in breach of their professional duty if they do not provide sufficient information about the risks that patients will encounter through such treatment. Although standards of how much information should be provided about risks vary between nations, as a matter of good practice surgeons should inform patients of the hazards that any reasonable person in the position of the patient would wish to know. In UK law, this level and style of disclosure has been most recently reviewed in the case of *Montgomery v Lanarkshire Health Board*.[2]

Finally, surgeons now understand that, when they obtain consent to proceed with treatment, patients are expected to sign a consent form of some kind. The detail of such forms can differ, but they often contain very little of the information supposedly communicated to the patient who signed it. Partly for this reason, the process of formally obtaining consent can become overly focused on obtaining the signature of patients rather than ensuring that appropriate disclosure has been provided and understood.

It is important for surgeons to understand that a signed consent form is not proof that valid consent has been properly obtained. It is simply a piece of evidence that disclosure may have been attempted. Even when they have provided their signature, patients can and do deny that appropriate information has been communicated or that the communication was effective. Surgeons are therefore well advised to make brief notes

of what they have said to patients about their proposed treatments, especially information about significant risks. These notes should be placed in the patient's clinical record, perhaps by referring to the disclosure in the letter to the family doctor, copied to the patient. In addition, information sheets describing the generic risks, benefits, complications and alternatives associated with the proposed procedure can be provided. It seems that, soon, a record of dialogue will replace the consent form; see GMC (2020), para. 55.

DUTY OF CANDOUR

Equal consideration should be given to disclosure of information that was generated by the intervention, particularly where 'something went wrong' that caused (or had the potential to cause) harm or distress. The duty to disclose these matters is described as the duty of candour.

Surgeons are accustomed to disclosing to their patients that the proposed operation may go wrong. The disclosures of 'bleeding and infection' are ubiquitous across the land, together with the more specific foreseeable risks, such as damage to contiguous structures, recurrence of the original diagnosis or inadvertent exacerbation of disease. Failure to disclose these foreseeable complications prior to surgery, particularly if they then maim, paralyse or scar the patient, may lead to a claim that the consent was invalid and that the patient, had they known of the risk, either would have never had the operation or would have had it performed by somebody else at another time.

Since all of these misadventures are plainly caught by the GMC's threshold of 'something going wrong', they would need to be reported to the patient by the candid surgeon if they crystallise during surgery. Merely because the division of a ureter during hysterectomy appears as a foreseeable complication on a consent form cannot negate the duty to be candid should it occur; it is plainly an example of something going wrong.

This class of surgical complication must be starkly distinguished from the complications of the disease itself, since these are explicitly excluded from the duty of candour. The patient awaiting surgery for her rectal cancer might present with venous thromboembolism. This is a regrettable complication of her disease, but by itself cannot lead to the deduction that something has gone wrong with surgical management. Accordingly, there would be no duty to be candid.

By contrast, if the same patient, on arriving thrombus-free for her resection, then had a postoperative venous thromboembolism and if the unit's protocol of 28 days of low-molecular-weight heparin was not prescribed, a duty of candour would certainly be owed since something went wrong.

In clinical practice fault is **not** determinative when considering whether to be candid over the occurrence of a complication. Thus clinicians will wish to ensure that the patient is made aware of events to which she may otherwise remain oblivious, since this information may have an effect on her subsequent decision making. Accordingly, if something goes wrong that causes a complication, irrespective of whether the 'thing that went wrong' is indicative of substandard care, our obligation to be candid about the existence of the complication persists. The question of whether fault has occurred, and whether it has caused the complication, is likely to require careful consideration. Clinicians, and those in the hospital who advise them, need to be certain of the facts before being candid to ensure that they do not mislead the patient when fulfilling their duty of candour. It is likely that candour relating to fault and causation, while eventually necessary, may only be possible after an investigation of the event leading to the complication is concluded.

FURTHER PRACTICAL APPLICATIONS OF CLINICAL LAW IN SURGICAL PRACTICE

Thus far, the moral and legal reasons why the duty of surgeons to respect the autonomy of patients translates into the specific responsibility to obtain informed consent to treatment have been reviewed. For consent to be valid, adult patients must:

- have capacity to give it – be able to understand, remember and deliberate over the information disclosed to them about treatment choices, and to communicate those choices;
- not be coerced into decisions that reflect the preferences of others rather than themselves;
- have been given sufficient information for these choices to be based on an accurate understanding of reasons for and against proceeding with specific treatments.

Surgical care would grind to a halt if it were always necessary to obtain explicit informed consent every time a patient is touched in the context of their care. Fortunately, it is an elementary step merely to ask the patient whether they mind being examined – the usual response will be acceptance. This simple transaction illustrates that the legal and ethical 'rules' that govern a surgeon are often no more than an expression of good clinical practice; in this case, politeness.

Some patients will not be able to give consent because of temporary incapacity. This may result from their presenting illness or intoxication, or an unanticipated situation may be encountered midway through a general anaesthetic. The moral and legal rules that govern such situations are clear. The doctrine of medical necessity enables the surgeon, in an emergency, to save life and prevent permanent disability, operating without consent. This has historically been employed daily, where unconscious emergency patients undergo surgery to save 'life and limb'. No consent has been provided and none is required, providing the treatment is in the patient's best interests.

However, if the patient has made a legally valid advance decision refusing treatment of the specific kind required, their decision must be honoured, providing it is applicable to the current clinical situation. Wherever possible, surgery on patients who are temporarily incapacitated should be postponed until their capacity is restored and they are able to give informed consent or refusal for themselves.

Surgeons must take care to respect the distinction between procedures that are necessary to prevent death or irremediable harm and those that are done merely out of convenience. If the patient consents only to a dilatation and curettage, do

not consider performing instead a hysterectomy 'in her best interests', simply because she is anaesthetised.

CHILDREN AND YOUNG PEOPLE

In England and Wales, a person is a child until their 18th birthday; older children are distinguished from their younger counterparts, since 16- and 17-year-olds are additionally described as 'young people'. Citizens under 16 years are presumed incompetent, but they may rebut that presumption and establish their competence by demonstrating that they have sufficient maturity – intelligence to understand fully what is proposed – to make the relevant decision. Hence 'Gillick' competence. In the case of incompetent children (or competent children who choose to rely on a proxy), parents or someone with parental responsibility are ordinarily required to provide consent on their behalf. This said, surgeons should:

- take care to explain to children what is being surgically proposed, and why;
- always consult with children about their response;
- where possible, take the child's views into account and note that even young children can be competent to consent to treatment provided that they can 'pass' the Gillick test for the decision in question;
- it is almost always appropriate, in addition, to separately discuss the treatment with their parents, although it should be noted that, if a child is Gillick competent to defend their confidential information, it should not be assumed that they wish to share this with their parents.

When such Gillick competence is present, under English law, children can provide their own consent to surgical care, although they cannot unconditionally refuse it until they are 18 years old. These provisions illustrate the importance of respecting the autonomy of child patients and remembering that, for the purposes of consent to medical treatment, they may be just as capable as adults. If faced with a surgical emergency in a child of 15 for whom no consent is available for life- or limb-saving treatment, and there **really is no time** to seek authority from someone with parental responsibility, the child or the court, then proceed with the operation without consent. So far, in the English common law stretching back 800 years, no case has been brought to court complaining of a child's life being saved using this doctrine of necessity.

ADULTS: PEOPLE 18 AND ABOVE

Capacity in adults is presumed, but this may be challenged on the basis of a reasonable belief that they are incapacitated.

Incapacity in England and Wales is established (in those aged 16 years and over) by a two-stage test. First, the functional test for incapacity is employed: is the person unable to make the relevant decision? If they are **able** to make the decision, the presumption of capacity endures. If they are unable to make the decision, then the second (diagnostic) stage must be employed: is there an impairment or disturbance of the mind or the brain? If so, the two stages in combination result in a conclusion of incapacity. How this assessment is carried out and the entire structure of this area of law is set out in the Mental Capacity Act (MCA) 2005 Code of Practice. This is essential reading, and must be available to clinicians in all UK National Health Service (NHS) hospitals. Capacity is not synonymous with (Gillick) competence, but that is a topic for further reading. Capacity and incapacity are the significant binary measure by which the capability of young people and adults is judged, but be aware of the notion of the **vulnerable** patient, who may possess capacity but risks falling victim to predatory actors.

Capacity may be erased by psychiatric illness, but even in circumstances where patients have been legally detained for compulsory psychiatric care it **by no means** follows that such patients are unable to provide consent for surgical care. Their capacity should be presumed and consent should be sought. Only if it is established that such patients also (in addition to or as a consequence of their mental illness) lack capacity to provide consent for surgery can therapy then proceed in their best interests. However, if possible postpone treatment until, as a result of their psychiatric care, patients become able either to consent or to refuse. If this timely recovery is not predicted, then legal steps using the authority of the MCA 2005 must be taken to make elective surgery lawful. It would be unlikely that treatment for physical illness could be authorised under the Mental Health Act 1983. As with children, respect should always be shown for as much autonomy as is present.

INCAPACITY

Absence of capacity in adults does not vitiate the requirement, where possible, to take into account the patient's sentiments during clinical decision making. In one case, a judge declared that an elderly man with a septic leg, although incapacitated by his mental illness, had feelings, beliefs and values that weighed so heavily in the consideration of his best interests that they outweighed the clinical desire to save his life by amputation.[3] Although an unusual judgement in this context, it reflects the growing determination to give incapacitated adults an opportunity to influence their fate, as best they can.

Elective treatment for less grave complaints can also be provided; in England and Wales this is done under the auspices of the MCA 2005. The associated Code of Practice guides the surgeon in matters of capacity and disclosure, and in dealing with those who have taken steps to influence their treatment, anticipating the time that they will have lost their capacity. These arrangements may manifest either in documentary form, such as Advance Decisions, or in person, in the form of persons appointed with a Lasting Power of Attorney.

It is not possible for relatives of incapacitated adult patients to sign consent forms for surgery on their behalf unless the relative or friend has, very unusually, been appointed as a deputy by the Court of Protection. Indeed, to make such requests can be a disservice to relatives, who may feel an unjustified sense of responsibility if the surgery fails. This said, relatives play a vital role in providing background information about the patient, allowing the clinician to assess and then determine what treatment is in the best interests of the patient.

INCAPACITY IN AN EMERGENCY

It is not lawful to force a capacitous adult to have treatment without their consent.

Since the advent of the MCA 2005, the notion of acting based only on the common law 'doctrine of necessity' has largely become historical. This is because if an adult lacks capacity, and you are treating in their best interests, the Act authorises necessary and proportionate steps to save life and to prevent serious and permanent injury. It is difficult to envisage circumstances where the statute would not be engaged, but the common law doctrine has not been extinguished by the Act, so should give extra reassurance to surgeons acting in emergencies in the best interests of incapacitated patients. Bear in mind that the presently incapacitated patient may yet regain his or her capacity, so if an intervention can safely be deferred to await cognitive recovery it should be, provided that deferral is in your patient's best interests.

DECISIONS IN THE BEST INTERESTS OF INCAPACITATED PATIENTS

We are all well aware that adults with capacity must make their own treatment decisions. There is no justification or need to determine the best interests of such patients since they can (by definition) decide these matters for themselves. Accordingly, their 'best interests' are never explored. Naturally, clinicians will on occasion disagree with a capacitous patient's decision, and they are at liberty to try and persuade the patient to change his or her mind, but the patient with capacity has the last word. This is starkly exemplified by the adult with capacity who chooses to refuse the blood that would otherwise have saved his life. Or the capacitous woman who refuses the caesarean section that alone would allow her child to be born alive.

But for those who lack capacity to make decisions relating to their treatment, clinicians have become accustomed to acting in the patient's **best interests**. Meetings devoted to this subject are a ubiquitous daily occurrence in hospitals across the country. Again, we are all well aware of the general principle standing behind 'best interests'; the incapacitated patient's welfare must be viewed in its widest terms, not simply in the sense of medical but also social and psychological interests. The patient's previously expressed wishes, values, feelings and beliefs must be taken into account. This will involve consideration of the proposed medical treatment, the prospects of success and the likely outcome. That is all very well; how should we achieve this?

A case decided in 2017 provided us with clear, specific guidance concerning Mrs P, who was 72 years old when she suffered the intracranial bleed that left her in a minimally conscious state.[4] It was agreed that there was no prospect of her regaining the capacity to make decisions relating to her health, and it was speculated that her potential life expectancy was in the region of 3–5 years. Nonetheless, she was otherwise relatively healthy and the hospital wished to insert a gastrostomy for hydration and nourishment. She would not tolerate a nasogastric tube, the presence (and frequent replacement) of which distressed her. Mrs P's daughters disagreed with this proposal, explaining that their mother had previously expressed a wish not to be kept alive if severely handicapped, especially if her mental function was severely affected.

Because of this disagreement, the court was approached, the hospital seeking a declaration that the proposed treatment was lawful. The judgement was centred on the notion that, when considering best interests, those making the decisions must try and put themselves in the place of the individual patient and ask what her attitude to the proposed treatment is likely to be. And they must consult those who befriend or look after the patient, in particular to obtain a view on what her attitude to the treatment might be. Factors that should be taken into account would include the views of those who had a close relationship with the patient when she had capacity, and the impact of the patient's fate on those who were closest to her.

The court nevertheless made it crystal clear that what the patient would have done in the circumstances (if her capacity had been preserved) would not automatically be regarded as to be in her best interests. While courts (and clinical decision makers) will strive to recognise and comply with what the patient is likely to have wanted, acting in her best interests remains the paramount objective.

THE ROLE OF THE COURT

The question has arisen regarding the circumstances in England in which clinical decisions relating to withdrawal of treatment should be automatically referred to the court.[5]

Mr Y was an active man in his fifties when he had a cardiac arrest and consequent cerebral hypoxia. He never regained consciousness. He was fed through a gastrostomy, and over the following 3 months his doctors concluded that he had a 'prolonged disorder of consciousness' (a term that courts have accepted as encompassing persistent vegetative and minimally conscious states). It was also concluded that, if he were to regain consciousness, he would have profound disability, both physical and cognitive, and remain dependent on others to care for him. This prognosis was confirmed by a second opinion. His wife and children told the clinicians that Mr Y would not have wished to be kept alive if he had received that prognosis during the time preceding his loss of capacity. Accordingly, the family and clinicians all agreed that it would be in Mr Y's best interests to withdraw his clinically assisted nutrition and hydration (CANH).

The question for the court was whether a court order must **always** be obtained in such situations, or whether, under certain circumstances, these decisions can be taken without the involvement of a court.

Twenty-five years earlier, the courts had considered two very different clinical questions. In *re F* the question related to whether sterilisation to prevent pregnancy (rather than to treat disease) could be performed on an incapacitated woman.[6] In *Bland* it was proposed that CANH in a young man who had been in a persistent vegetative state for 3 years should be withdrawn.[7] The House of Lords had made it clear in both cases that, as a matter of good practice, a court declaration should be obtained (that the proposed treatment was in an incapacitated person's best interests) prior to the actions being taken.

In considering Mr Y's case, the Supreme Court noted that decisions on withdrawing CANH are frequent and ubiquitous,

taken consensually every day throughout the country in the best interests of patients with a wide range of neurodegenerative conditions, notably stroke and dementia. There could be no principled or logical reason to demand a court review of the tiny subset of patients with a 'prolonged disorder of consciousness' while blithely accepting the commonplace practice of withdrawal in other patients without recourse to the courts. Similarly, since CANH is seen as medical treatment, there can be no reason why its withdrawal should be seen as 'first among equals', there being no automatic recourse to declarations for withdrawal of antibiotics, ventilation or organ support.

For these and other reasons, the Supreme Court held that, provided the provisions and guidance of the MCA 2005 are followed, and that there is agreement as to what is in the patient's best interests, then life-sustaining treatment, whether this is CANH or any other form of life support, can be withdrawn or withheld without needing to make an application to the court.

Plainly, if there is any hint of lack of agreement or conflict of interest from any quarter, clinical or family, when the withdrawal of life-sustaining treatment is being considered, an application to court must be made. Equally, if in these circumstances at the end of the decision-making process the clinicians or family remain uncertain, because the conclusions on best interests are finely balanced, an application must be made.

This judgement marked a 'handing back' to clinicians of responsibility to make some decisions that for the last 25 years have been exclusively within the control of our courts. This redoubles the responsibility that clinicians bear to ensure that the MCA 2005 is understood and applied assiduously.

DO NOT ATTEMPT RESUSCITATION?

Furthermore, the decision to discontinue life-sustaining treatment may go hand in hand with a decision not to attempt cardiopulmonary resuscitation, in the event of cardiorespiratory arrest. In England, it is settled law that before finally making this 'DNACPR' decision, doctors must discuss it with patients or their relatives.[8] The reason for this insistence is that the patient may have personal circumstances, unbeknown to the surgeon, that might yet influence this final (and for the patient, portentous) decision. The only exclusion to this legal rule is where discussion of this matter with the patient may cause them not merely distress, but harm. The duty to consult a patient prior to deciding to withhold cardiopulmonary resuscitation was subsequently extended to a duty to consult those befriending an incapacitated adult.

DOCTRINE OF DOUBLE EFFECT

Surgeons could find themselves involved in the palliative care of patients whose pain is increasingly difficult to control. There may come a point in the management of such pain when effective palliation is possible only at the risk of shortening a patient's life because of the respiratory effects of the palliative drugs. In such circumstances, surgeons can, with legal justification, administer a dose that might be dangerous (although experts in palliative care are sceptical that this is ever necessary with appropriate training). In any case, the argument employed to justify such action refers to its 'double effect': that both the relief of pain and death might follow from such an action. Intentional killing (active euthanasia) is rejected as criminal malpractice throughout most of the world. A foreseeably lethal analgesic dose is thus regarded as lawful **only when it is solely motivated by palliative intent**, and this motivation has been documented. Recent authority from criminal law indicates that, if an analgesic injection is 'virtually certain' also to kill the patient, a court might deduce that the person giving the injection had an intention to kill. The key to the defence of double effect is the absolute absence of such an intention. It follows that if you are **virtually certain** that a palliative act will end the patient's life, consult widely before embarking upon it.

CONFIDENTIALITY BALANCED AGAINST THE RISK OF SERIOUS HARM

Respect for autonomy does not entail only the right of capacitous patients to consent to treatment. Their autonomous right extends to control over their confidential information, and surgeons must respect their patients' privacy, not communicating information revealed in the course of treatment to anyone else without consent. Generally speaking, such respect means that surgeons must not discuss clinical matters with relatives, friends, employers and other state actors unless the patient explicitly agrees. To do otherwise is regarded by all the regulatory bodies of medicine and surgery as a grave offence, incurring harsh penalties. Breaches of confidentiality are not only abuses of human dignity; they undermine the trust between surgeon and patient on which successful surgery and the professional reputations of surgeons depend. The delicacy of this situation was amply demonstrated in a recent case.

A woman (ABC) had a father (XX) who killed her mother, leading to his detention in a psychiatric facility.[9] His clinicians tested him for Huntington's disease, which proved positive. He had capacity, and agreed to the testing only on the basis that his results were not shared with his family.

In the meantime, ABC fell pregnant. Her father's doctors knew about the pregnancy and wanted to disclose XX's diagnosis to his daughter; from the time of his diagnosis there would have been a window of 2 months during which termination of her pregnancy was feasible. XX refused to disclose, aware that such knowledge might have an impact on his two daughters' reproductive decision making.

ABC discovered her father's diagnosis during a clinical visit when her baby was 4 months old. Shortly afterwards, she decided that her father's diagnosis should not be disclosed to her sister, now in the early stages of her own pregnancy.

Four years later, ABC tested positive for Huntington's. Feeling that it had been unfair to bring a child into the world in these tragic circumstances, she claimed that the doctors should have breached her father's confidentiality and told her of his diagnosis while she had a chance to choose whether she would undergo termination. In making this claim, she asserted that she was owed a duty of care by the doctors who also had a duty to respect her father's confidentiality.

The claimant told the court that the clinicians had a '…duty to balance the claimant's interest in being informed of her risk of a genetic disorder against her father's interest in having the confidentiality of that diagnosis preserved'. The court noted that if on that basis the clinicians properly considered and balanced the conflicting interests, but decided not to disclose, they would have fulfilled their obligation, provided their conclusion not to disclose the information was reasonable. The judge concluded that it was just, fair and reasonable to impose a legal duty to balance ABC's interest in being informed against XX's interest in maintaining his confidentiality relating to both his diagnosis (and the public interest in maintaining medical confidentiality generally).

The decision in ABC reveals that, important as respect for confidentiality is, it is not an absolute right. Surgeons are allowed to communicate private information to other professionals who are part of the healthcare team, provided that the information has a direct bearing on treatment. Here, it is argued that patients have given their 'implied' consent to such communication when they explicitly consent to a treatment plan. Whether implied consent can in any circumstances be valid is a matter for public debate, as government applies these words to tissue donation and access to electronic health records. Academic lawyers are sceptical that it is a species of consent at all, since there is no guarantee of the now-treasured disclosure prior to agreement. Such examples of 'implied' consent are better viewed as mere acquiescence on the behalf of patients, ignorant of and not objecting to decisions made about them, in the absence of personal consultation.

Patients cannot expect strict adherence to the principle of confidentiality if it poses a serious threat to the health and safety of others. There will be some circumstances in which confidentiality either must or may be breached in the public interest. For example, it must be breached as a result of court orders or in relation to the requirements of public health legislation.

SHARING INFORMATION WITH THE POLICE

It is not uncommon to receive a request from the police for patient data. Consider the patient admitted after a fall down the stairs; it is suggested that his partner had caused the fall. The partner is in police custody, awaiting a court's decision on bail the following day.

The patient, at the time of the police enquiry, was intubated and ventilated, lacking capacity to decide whether to consent to the disclosure of his clinical details. What should our position be in these circumstances? Sixty years ago Lord Denning made it clear that there is no general obligation for clinicians to disclose confidential information following a request from the police. Naturally, a constable can always approach a court in the face of clinical refusal; it would be most unlikely that an NHS trust would refuse to comply with a court order to disclose.

The DH suggests that doctors should consider disclosure if, among other considerations, the alleged offence is grave and the prevention or detection of crime would be prejudiced or delayed but for prompt disclosure.

Clinicians must disclose to the police any information identifying a driver alleged of committing a traffic offence; and even in the absence of a police request, their suspicions of a person's involvement in terrorist activities. Less specifically, doctors must disclose to the police the admission of a person wounded by knife or gun, so that at least the constabulary is made aware of an armed assailant in the neighbourhood. Whether the stabbed or shot person allows subsequent disclosure of their identity rather depends on their capacity at the time. Naturally, if the patient consents to disclosure no problem occurs. But some victims of assault may choose to remain silent, perhaps fearing more grievous injury if they become identified as an informer.

The patient who lacks capacity poses a more difficult problem. If it seems likely that they will soon regain the ability to make their own decision, it would be prudent to await that recovery. If there is evidential material that could be lost during the lapse of time, such as clear scars or bruises or footprints, by all means have these images recorded, but await the patient's capacitous consent before handing them to the police. At the other extreme, if the patient is unlikely to recover capacity after an assault, a grave offence may have transpired, making disclosure in the absence of consent more palatable.

If there is a simple stark binary choice between either respecting a person's confidentiality or protecting them from death or serious harm, most clinicians would likely value life and limb over a notion of confidences. Guidance from DH suggests that unlawful killing, rape, treason and child abuse could all cross the 'serious harm' threshold. By contrast, theft, fraud and criminal damage would not.

The leading case is of Dr Egdell, a psychiatrist instructed by W, who had killed five people with extreme violence.[10] W was seeking review of his secure hospital order and hoped that Dr Egdell would provide a favourable report of his mental health. On the contrary, Dr Egdell found that W was highly dangerous, fascinated by high explosives, and that the secure hospital's staff were oblivious to the threat W continued to pose.

Faced with the unhelpful report W's solicitors did not pursue the application to the Mental Health Tribunal, but Dr Egdell felt his report should nonetheless go to the Home Secretary and the medical director of the hospital. W disagreed. In subsequent litigation the Court of Appeal held that this disclosure in the teeth of W's capacitous opposition was justified and in the public interest. The breach in confidentiality was made lawful by the real risk of serious harm to others should W be released.

Frustratingly, the paucity of cases provides us with no further judicial gloss on this clinical dilemma.

TRANSPLANTATION

The law and ethics of organ transplantation require more space than this chapter allows. In common with other nations, the UK has a statutory framework for transplantation, but even among this small group of nations there is no unanimity of legislation, thus rules for deceased and live donor transplants

differ. In general, the rules for defining a dead donor, for compensating a living donor and for legitimising a market in organs differ widely. It is strongly recommended that you refer to the rules within your own jurisdiction.

RESEARCH

As part of their duty to protect life and health to an acceptable professional standard, surgeons have a subsidiary responsibility to strive to improve operative techniques through research to assure themselves and their patients that the care proposed is the best that is currently possible. Yet there is moral tension between the duty to act in the best interests of individual patients and the duty to improve surgical standards through exposing patients to the unknown risks that any form of research inevitably entails.

The willingness to expose patients to such risks may be further increased by the professional and academic pressures on many surgeons to maintain a high research profile in their work. For this reason, surgeons (and physicians, who face the same dilemmas) now accept that their research must be externally regulated to ensure that patients give their informed consent, that any known risks to patients are far outweighed by the potential benefits and that other forms of protection for the patient are in place (e.g. proper indemnity) in case they are unexpectedly harmed. The administration of such regulation is through research ethics committees, and surgeons should not participate in research that has not been approved by such bodies. Equally, special provisions will apply to research involving incompetent patients who cannot provide consent to participate, and research ethics committees will evaluate specific proposals with great care.

In practice, it is not always clear as to what constitutes 'research' that should be subjected to regulation, as compared with a minor innovation dictated by the contingencies of a particular clinical situation. Surgeons must always ask themselves in such circumstances whether or not the innovation in question falls within the boundaries of standard procedures in which they are trained. If so, what may be a new technique for them will count not as research but as an incremental improvement in personal practice. Nevertheless, major innovations in operative procedure are scrutinised by national regulatory authorities; in the UK by the National Institute for Health and Care Excellence (NICE). This process of scrutiny has been designed to ensure that the innovation is safe, efficacious and cost-effective. It is regarded (by the NHS) as a mandatory step when introducing a new interventional procedure.

Equally, surgeons know that exigencies of operative surgery sometimes demand a novel and hitherto undescribed manoeuvre to get the surgeon (and the patient) out of trouble. Providing your solution is necessary, proportionate to the circumstances, performed in good faith and would pass the scrutiny of your peers as reasonable, it is unlikely that any subsequent criticism of your actions could be sustained.

If a proposed innovation passes the criteria for research, it should be approved by a research ethics committee. Such surgical research should also be subject to a clinical trial designed to ensure that findings about outcomes are systematically compared with the best available treatment and that favourable results are not the result of arbitrary factors (e.g. unusual surgical skill among researchers) that cannot be replicated (see also *Chapter 12*).

STANDARDS OF EXCELLENCE

To optimise success in protecting life and health to an acceptable standard, surgeons must only offer specialised treatment in which they have been properly trained. To do so will entail sustained further education throughout a surgeon's career in the wake of new surgical procedures. While training, surgery should be practised only under appropriate supervision by someone who has appropriate levels of skill. Such skill can be demonstrated only through appropriate clinical audit, to which all surgeons should regularly submit their results. When these reveal unacceptable levels of success, no further surgical work of that kind should continue unless further training is undergone under the supervision of someone whose success rates are satisfactory. To do otherwise would be to place the interest of the surgeon above that of their patient, an imbalance that is never morally or professionally appropriate.

Surgeons also have a duty to monitor the performance of their colleagues. To know that a fellow surgeon is exposing patients to unacceptable levels of potential harm and to do nothing about it is to incur some responsibility for such harm when it occurs. Surgical teams and the institutions in which they function should have clear protocols for exposing unacceptable professional performance and helping colleagues to understand the danger to which they may expose patients. If necessary, offending surgeons must be stopped from practising until they can undergo further appropriate training and counselling. Too often, such danger has had to be reported by individuals whose anxieties have not been properly heeded and who have then been professionally pilloried rather than acknowledged for their contribution to patient safety. Those who participate in closing ranks, and ostracism, share the moral responsibility for any resulting harm to patients. If something goes wrong with surgical treatment, the UK health regulators unanimously insist that the patient should be told what has happened; in many senses, a similar disclosure to that which occurred during the consent process, but now with the benefit of hindsight. Again, this candid disclosure is designed to put the patient in the same position as the surgeon, with respect to information about their health.[11]

CONCLUSION

Surgeons have combined duties to their patients: to protect life and health and to respect autonomy, both to an acceptable professional standard. The specific duties of surgeons are shown to follow from these: reasonable practice concerning informed consent; confidentiality; decisions not to provide, or to omit, life-sustaining care; surgical research; and the maintenance of good professional standards. The final duty of surgical care is to exercise all these general and specific responsibilities with fairness and justice, and without arbitrary prejudice. Now, at least partly either enshrined in statute or echoed in the English common law, these duties closely reflect the guidance of the GMC.

The conduct of ethical surgery illustrates good citizenship: protecting the vulnerable and respecting human dignity; and equality. To the extent that the practice of individual surgeons is a reflection of such sustained conduct, they deserve the civil respect that they often receive. To the extent that it is not, they should not practise the honourable profession of surgery.

PART 1 | Basic principles

CHAPTER 15

Human factors, patient safety and quality improvement

Learning objectives

To learn:

- The importance of understanding human behaviour, quality and value in healthcare delivery
- The importance of human factors and teamworking in reducing and rectifying error
- Medical error and its definitions, including adverse events and near misses
- The importance of patient safety, strategies and application in clinical practice
- Quality improvement as an overarching activity
- The need for system thinking and leadership

INTRODUCTION

In recent years, increased emphasis has been placed on the study of healthcare systems to better understand the relationship of how management and administrative systems best support clinical practice and promote quality improvement and patient safety. To some extent this has come about as a consequence of the increasing complexity of healthcare delivery, which, although credited with dramatically improving public health over the last 50 years, has led to the realisation that patient satisfaction and safety is frequently compromised. This issue is multifactorial but includes poor integration of care pathways, poor planning and utilisation of resources and errors in management and clinical care. A disaffected healthcare workforce challenged with excessive administrative and governance workloads compounds these issues and leads to 'burnout', which contributes to poor clinical outcomes and further compounds societal and patient dissatisfaction with patient care.

Understanding healthcare systems, promoting 'value' for both healthcare providers and patients and supporting the healthcare workforce to deliver high-quality and safe care remains the biggest challenge for the healthcare industry in the current decade. This chapter addresses some of these important issues and provides a framework for surgeons to contribute to the design of safe and efficient surgical pathways of care.

Today's healthcare systems face two big challenges: increasing demand because of greater volumes of patients who are older, who often have comorbidities and who often require multidisciplinary care; and an increasing volume of treatment options, often of greater complexity and cost.

Despite the ability of medical science to manage and treat an increasing array of complex medical conditions, not all medical conditions are managed well. Implementing evidence-based care in complex health systems is challenging. Added to this, the financial cost of health care challenges both healthcare recipients and providers and questions how best to drive the 'quality' agenda in healthcare delivery.

According to the Institute of Medicine, patients do not always receive the most suitable care at the best time or in the best place. Its influential report, *Crossing the Quality Chasm: A New Health System for the 21st Century,* emphasises the need to redesign healthcare processes and systems in response to this quality gap.

The concept of 'value' in health care has been developed to provide a focus for both healthcare recipient and provider. Professor Michael Porter, director of the Harvard Business School's Institute for Strategy and Competitiveness, has advocated value-based health care as one of the most important topics in healthcare transformation. Porter proposed six principles that support a value-based approach to health care:

1. Organise care around medical conditions – care should be based upon the medical needs of a community.
2. Measure outcomes and costs for every patient.
3. Align reimbursement with value – to support better outcomes and more efficient care.
4. Systems integration – organise treatment around matching patient, treatment and location.
5. Geography of care – provide centres of excellence for complex care.
6. Information technology – provide integration of the healthcare system.

While value-based care has mainly gained traction within the USA and the private healthcare sector elsewhere, it is interesting to see its conceptual components being taken up by public health systems such as the National Health Service (NHS) in the UK, with an understanding of the need for a universal healthcare number and integrated healthcare information technology (IT) platforms and healthcare initiatives such as

Michael E Porter, b.1947, economist, Harvard Business School, Boston, MA, USA.

'Right care, right time, right place for carers' and 'Choosing Wisely UK', all of which are based on designing healthcare systems that are truly patient-centric and offer quality outcomes that matter to patients.

HUMAN FACTORS

The healthcare setting has become increasingly complex. Patient and societal demands for transparency in defining and justifying treatment decisions impact on all healthcare workers, who need to understand their professional responsibilities when working within complex social and work environments. Healthcare workers must understand that patients are increasingly better informed and wish to be included more fully within the decision-making processes regarding treatment options. Likewise, when performance and clinical outcomes are less than expected, patients and their supporters are entitled to timely and honest appraisal of 'what went wrong' and to be part of the discussion regarding ongoing care.

Therefore, increasingly, surgeons will need to integrate knowledge, technical skills and mastery of complex equipment while participating in a multidisciplinary healthcare setting, in order to deliver safe and effective care. The communication skills required to work in these complex environments and engage effectively with audit, management and quality improvement systems are all dependent on human behaviour.

These complex skill sets are set out in the study of human factors (HF), which examines the behavioural interrelationships between humans, the tools they work with and the environment in which they work. It is a complex area that incorporates knowledge derived from many disciplines. A better understanding of the effects of teamwork, tasks, equipment, workspace, culture and organisation on human behaviour will improve performance in clinical settings. A HF approach to patient safety differs from traditional safety training in that the focus is less with the technical knowledge and skills required to perform specific tasks, but rather with the cognitive and interpersonal skills needed to effectively manage team-based, high-risk activities. With time, HF training has evolved from models describing human interactions within complex environments to more nuanced programmes that modify workers' behaviour and improve patient safety.

HF was originally conceived in the 1940s in the aviation industry to better understand the relationship between a team's behaviour, its technical surroundings and a changing environment. The 'cognitive skills' of the aircraft crew refers to the mental processes used for gaining and maintaining situational awareness, for solving problems and for making decisions, whereas 'interpersonal skills' are the communications and behavioural activities associated with teamwork.

Crew resource management (CRM) training was developed to build effective communication skills and a cohesive environment among team members and to build an atmosphere in which all personnel feel empowered to speak up when they suspect a problem. Team members are trained to cross-check each other's actions, offer assistance when needed and address errors in a non-judgemental fashion. Debriefing and providing feedback are key components of CRM training. It also emphasises the roles of fatigue, perceptual errors (such as misreading monitors or mishearing instructions) and the impact of management styles and organisational cultures.

More recent developments in HF have looked more closely at designing systems better suited to minimising error. Studies examining the hierarchy of intervention effectiveness and concepts based on nudge theory allow for design of healthcare systems that increase safety and give a better understanding of how people make decisions and behave.

The nudge theory, introduced by Richard Thaler and Cass Sunstein, is based on shaping the environment to encourage choice selection along pathways deemed to be beneficial to the individual, an organisation or society. A key feature of nudge theory is to structure the selection of preferred options while allowing individuals to maintain freedom of choice within the decision-making process. One successful example is the adoption of generic medication brands on electronic medical records by the use of a simple opt-out checkbox if the prescriber wishes to use a non-generic medication.

It is now widely recognised that HF need to be considered in every aspect of surgical care if the highest standards in patient safety are to be achieved. However, safety is just one aspect of a wider HF systems approach to equipment, task, environment and organisational design. Better understanding of HF can also significantly contribute to the quality, accessibility and cost of healthcare services and to the recruitment and retention of healthcare staff.

Summary box 15.1

Acknowledging the gap between medical progress and delivery of quality patient care

- Health care is complex with many areas for improvement
- Understanding of the influence of HF among care givers can highlight areas of risk but also potential solutions
- The different factors that impact human behaviour can be identified and influenced in a way that improves health care
- Acknowledge the importance of 'value' for both healthcare provider and patient
- Training in human factors to enhance teamworking is a prerequisite of contemporary health care

PATIENT SAFETY

Medicine will never be risk-free. From the beginning of training, doctors are taught that errors are unacceptable and that the philosophy of *primum non nocere* (first, do no harm) should permeate all aspects of treatment. Yet, worldwide, despite all the improvements in treatment and investment in technologies,

Richard H. Thaler, b.1945, economist, University Chicago, IL, USA, winner of the Sveriges Riksbank Prize in Economic Sciences in Memory of Alfred Nobel 2017 for contributions to behavioural economics.

Cass R Sunstein, b.1954, lawyer, Harvard Law School, Boston, MA, USA, co-authored *Nudge: Improving Decisions about Health, Wealth, and Happiness* with Thaler in 2008.

training and services, there remains the challenge of dealing with unsafe practices, incompetent healthcare professionals, poor governance of healthcare service delivery, errors in diagnosis and treatment and non-compliance with accepted standards.

When errors occur, it is important that there are systems in place to ensure that all those affected are informed and cared for, and that there is a process of analysis and learning to uncover the causes and prevent recurrence of such events. It is equally important to learn more about the characteristics and facilitators of safe, high-quality care. The study of patient safety is now a healthcare discipline in its own right, encompassing patient safety methodologies, health service design, investigation of incidents and related research. The development of risk management strategies within the healthcare setting attempts to address these failings. Comprehensive risk management is not just an exercise in ligation avoidance but aims to develop a cultural awareness and support for all healthcare workers in defining and delivering high-quality clinical care.

A milestone report by the US Institute of Medicine of the National Academy of Sciences (now the National Academy of Medicine), *To Err is Human: Building a Safer Health System*, drew widespread attention to the impact of medical error on healthcare outcomes. The World Health Organization (WHO) estimates that, even in advanced hospital settings, one in 10 patients receiving health care will suffer preventable harm, although measurement of the incidence of suboptimal outcomes remains challenging. In addition to the potential for needless suffering, the financial burden of unsafe care globally is compelling, resulting as it does in prolonged hospitalisation, loss of income, disability and litigation costing many billions of dollars every year. In 2017 the Organisation for Economic Co-operation and Development (OECD) published *The Economics of Patient Safety*, which indicates that this is a problem faced in all healthcare systems, with iatrogenic patient harm being the 15th leading cause of the global disease burden and accounting for 15% of all OECD countries' hospital expenditure.

While the relationship between medical error and litigation is particularly complex, sophisticated healthcare systems understand that effective strategies to promote patient safety and quality improvement must include a whole organisational culture change with both central senior management involvement and active engagement by all those within the organisation. Furthermore, clinical audit, data management and incident reporting must be carried out in a 'blame-free' culture with an emphasis on education and the avoidance of an adversarial culture, which hinders active participation.

PATIENT SAFETY AND RISK MANAGEMENT

Patient safety can only be considered in a broader understanding of risk management. Healthcare risk management has traditionally focused on the important role of patient safety and the reduction of medical error. However, with the increasing complexity of the healthcare environment, which includes not only the increasing complexity of medical care but also the use of new and advanced technologies, IT and cybersecurity risks and the ever-changing legal and regulatory frameworks that health providers work in, a more comprehensive approach to risk management is required.

As comprehensive risk management will increasingly become central to the design and delivery of all aspects of health care, surgeons need to be not only aware of the developments in this area but also willing to contribute to the design, implementation and assessment of risk management systems.

Supporting a safety culture

Adverse events and near misses go unreported for many reasons, including a fear of blame and the potential for litigation. Clinical risk management is an integrated process, based on risk identification, analysis and control of events, carried out within a 'blame-free' environment. Data collected from these episodes should be collated and learnt both institutionally and by uploading to a national database. Doctors should be familiar with the systems that operate within their own working environment.

Complaints from a patient or carer often highlight a problem that, when analysed, provides opportunities for reducing adverse events. Knowing how to manage complaints is an important part of providing better health care. There is wide acceptance for the need for complaints to be made easily and effectively, such that now more and more patient advocacy units provide a range of options for resolving complaints, including the provision of information and mediation and the setting up of conciliation meetings between the parties. Such risk management is complex and involves multiple domains, including operational, legal and financial issues. For the purpose of this chapter the focus is on clinical risk, benchmarking and incident reporting.

Most medical care entails some level of risk to the patient, either from the underlying condition or comorbidity or from the treatment itself, each of which may lead to recognised complications or side effects. These episodes must be differentiated from patient safety incidents, which have been described as preventable events or circumstances that did or could result in unnecessary harm to a patient. These include adverse events that result in actual harm, near-miss events that by chance or intervention cause no harm and no-harm events that reach a patient but result in no harm because of chance or other mitigating circumstance.

The most frequent contributing factors that lead to patient safety incidents are listed in ***Table 15.1***. Of these, inadequate communication between healthcare staff, or between medical staff and their patients or family members, ranks highest in frequency.

UNDERSTANDING PATIENT SAFETY INCIDENTS

Understanding the concepts underlying patient safety incidents is useful because it helps to anticipate situations that are likely to lead to errors and highlights areas where preventative action can be taken. The problem of error can be viewed in two ways – from a person approach or from a system approach.

TABLE 15.1 Factors that contribute to patient safety incidents.

Human factors	• Inadequate patient assessment; delays or errors in diagnosis • Failure to use or interpret appropriate tests • Error in performance of an operation, treatment or test • Inadequate monitoring or follow-up of treatment • Deficiencies in training or experience • Fatigue, overwork, time pressures • Personal or psychological factors (e.g. depression or drug abuse) • Patient or working environment variation • Lack of recognition of the dangers of medical errors
System failures	• Poor communication between healthcare providers • Inadequate staffing levels • Disconnected reporting systems or over-reliance on automated systems • Lack of coordination at handovers • Drug similarities • Environment design, infrastructure • Equipment failure owing to lack of parts or skilled operators • Cost-cutting measures by hospitals • Poor governance structures and inadequate systems to report and review patient safety incidents
Medical complexity	• Advanced and new technologies • Potent drugs, their side effects and interactions • Working environments – intensive care, operating theatres

The person approach

Human performance principles tell us that humans are fallible and that errors can occur through doing the wrong thing – errors of commission; failure to act – errors of omission; or errors of execution – doing the right thing incorrectly. These principles also tell us that, by understanding the reasons why adverse events and near misses occur and by applying the lessons learnt from past events, future errors can be prevented. However, for most errors the person approach on its own tends to blame the individual and restricts learning. For this reason, individual performance may be best assessed by professional appraisal processes and clinical audit, which ensures that performance outcomes are benchmarked across institutional, national and international norms.

The system approach

Health systems add complex organisational structures to human fallibility, thus substantially increasing the potential for errors. A systems approach to error recognises that adverse events rarely have an isolated cause and that they are best addressed by examining why the system failed rather than who made the mistake. This is clearly outlined in the 2013 report by Professor Don Berwick called *A Promise to Learn – A Commitment to Act*, which looked into improving patient safety in the NHS, where the emphasis is on a system-wide approach to patient safety.

However, greater analysis of organisational safety needs to go beyond understanding not only why unanticipated events occur, which has been referred to as safety 1; it also needs to understand the robustness and resilience within systems due to human innovation and adaptability, which frequently prevents untoward events and is referred to as safety 2. Safety 1 places the emphasis on identifying errors after the event and aims to prevent them from occurring or recurring in the future, whereas safety 2 acknowledges that healthcare work is resilient and that everyday performance succeeds much more often than it fails. This is because clinicians constantly adjust what they do to match the conditions. Working flexibly, and actively trying to increase clinicians' capacity to deliver more care more effectively, is key to this new approach. At its heart, proactive safety management focuses on how everyday performance usually succeeds rather than why it occasionally fails, and it actively strives to improve the former rather than simply preventing the latter.

The publication 'From Safety-I to Safety-II: A White Paper' (2015) expands on this concept and stresses the importance of assimilation of these two ways of thinking. Sophisticated healthcare systems need not only to examine what works well but also to examine adverse events and understand and plan for adverse outcomes. Balancing these concepts should be considered an investment not only in safety but also in improving productivity and patient and staff well-being.

The underlying principles to these approaches to risk management stem from theories such as Heinrich's safety pyramid, which proposes that each major injury within a system masks a multiple of minor injuries and near misses. This model stresses the importance of near-miss reporting in order to fully understand the spectrum of patient safety and allow adequate risk management planning.

More recently James Reason proposed the 'Swiss cheese' model of causation to explain the consequences of multiple errors that result in harm, analogous to the holes in a Swiss cheese, which if aligned create a defect that has adverse consequences. For organisational safety to be effective each

Donald Berwick, b.1946, Professor of Pediatrics and Health Care Policy, Harvard Medical School, Boston, MA, USA.
Herbert W Heinrich, 1886–1962, engineer, Hartford, CT, USA, a pioneer in industrial safety.
James T Reason, b.1938, Professor Emeritus of Psychology, University of Manchester, Manchester, UK.

healthcare worker is required to take responsibility for their respective roles in order to avoid the summation of error and resultant harm. Consequently, the more layers of responsibility, the fewer the chances of adverse events occurring.

Summary box 15.2

Understanding patient safety incidents

- Errors can be viewed from a person-centred or a system approach
- The majority of near misses or adverse events are due to system factors
- Understanding why these errors occur and applying the lessons learnt will prevent future injuries to patients
- It is important to report all near misses or adverse events so that we can constantly learn from mistakes
- Error models can help us understand the factors that cause near misses and adverse events
- Examining what works well may be an additional constructive approach to defining safe patient pathways

STRATEGIES FOR PATIENT SAFETY

As safety is everybody's business, building and embedding a safety culture into surgical service delivery is the key to improving patient outcomes. At an institutional level, defining 'best practice' within a robust governance system and benchmarking against national and international norms is required prior to implementation of strategies for improvement. Clearly these strategies will vary depending on local requirements and resources.

International

Since 2009, WHO has embarked on a series of global and regional initiatives to improve surgical outcomes. Much of this work has stemmed from WHO's Second Global Patient Safety Challenge, *Safe Surgery Saves Lives*. One specific strategy that has been shown to be effective is the use of the surgical checklist, which, when properly implemented, has been shown to improve surgical outcomes in both low- and middle-income countries and in wealthier countries.

Checklists

Checklists in the operating theatre environment are now accepted as standard safety protocols since the *Safe Surgery Saves Lives* Study Group at WHO published its results. The use of a perioperative surgical safety checklist in eight hospitals around the world was associated with a reduction in perioperative mortality from 1.5% to 0.7% and major inpatient complications from 11.0% before to 7.0% after the introduction of the checklist. A more recent study from two hospitals in Norway (2015) showed a decrease in complications from 19.9% to 11.5%, a fall in mean length of stay of 2 days and a significant fall in hospital mortality from 1.9% to 0.2% in one hospital.

The surgical safety checklist identifies specific checks to be carried out at three obligatory time points (***Figure 15.1***). The checklist items are not intended to be comprehensive and additions and modifications are encouraged. For example, during the COVID-19 pandemic, the checklist lent itself to including COVID-19-specific checks within this pathway.

The benefits of standardisation of surgical processes need not be limited to the operating theatre. Several studies have shown that the majority of surgical errors (53–70%) occur outside the operating theatre, either before or after surgery, and that a more substantial improvement in safety can be achieved by targeting the entire surgical pathway.

There is no question that checklists are tools that improve outcomes, provided they are correctly implemented. However, there are some important considerations. Checklists are suited to solving specific kinds of problems, but not others. Even in comparison with aviation, managing patients involves an enormous amount of coordinated, time-pressured decision making and potential delays. Checklists are simple reminders of what to do; however, unless they are coupled with attitude change and efforts to remove barriers to actually using them, they will have limited impact. Simply put, if one begins to believe that safety is simple and that all it requires is a checklist, there is a danger of abandoning other important efforts to achieve safer, higher quality care.

Experience has shown, however, that for successful implementation of a checklist considerable attention is required to the following factors:

- early engagement of staff;
- active leadership and identification of local champions;
- extensive discussion, education and training;
- multidisciplinary involvement;
- coaching;
- ongoing feedback;
- local adaptation.

Resource-rich countries

Many countries and professional bodies in resource-rich countries have developed various strategies to improve outcomes in surgical practice. These include:

- regulatory systems for the licensing of physicians and healthcare institutions;
- national/statutory policies for patient safety;
- standard setting by surgical professional bodies;
- national clinical audits and quality improvement programmes;
- statutory reporting of adverse events.

Low- and middle-income countries

Resource-poor countries share many of the aspirations and challenges of resource-rich countries; however, they also face issues that require different strategies. The probability of a patient being harmed in hospital is greater with, for example, a greater risk of healthcare-associated infection and difficulty maintaining medical equipment because of lack of parts or necessary skills. In some countries, the proportion of injections

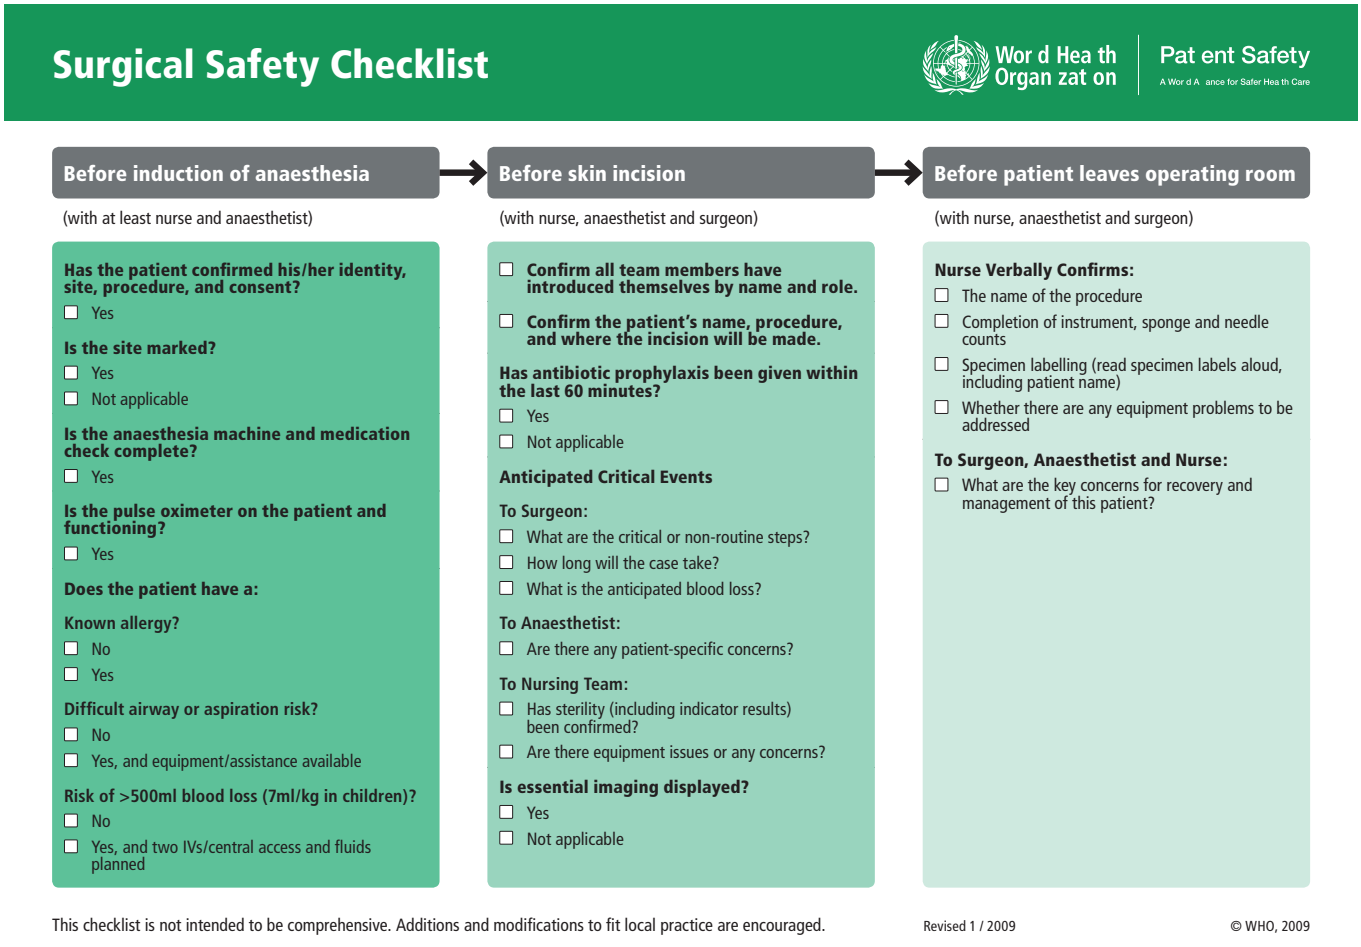

Figure 15.1 World Health Organization's surgical safety checklist (https://www.who.int/teams/integrated-health-services/patient-safety/research/safe-surgery/tool-and-resources).

given with syringes or needles reused without sterilisation is as high as 70%. Each year, unsafe injections cause 1.3 million deaths, primarily as a result of transmission of hepatitis viruses and human immunodeficiency virus.

Identifying and addressing patient safety risks in collaboration with colleagues across the world allows progress to be made on a number of important areas of surgical safety as well as supporting improvements in surgical training. International collaborations, often based on personal professional relationships, can be a catalyst to supporting surgical training and surgical safety initiatives worldwide. The WHO surgical safety checklist (***Figure 15.1***) demonstrates that many patient safety initiatives are not resource intensive but require attention to the details of process and care pathways commensurate with the local context.

Hospital level

Clinical governance

Patient safety requires a team approach. Many national and international bodies, professional organisations and medical and academic health centres now realise the importance of leadership training. Motivated and well-prepared healthcare workers trained to work together can reduce risks to patients, themselves and their colleagues, especially if incidents are managed positively and opportunities to learn from adverse events and near misses are used. High-performing institutions consistently develop transparent governance structures to provide robust oversight of not only risk management but also all aspects of business planning and outcome reporting in addition to workforce education and training.

Summary box 15.3

Strategies for patient safety

- WHO has established a number of international initiatives for patient safety, including the surgical safety checklist
- Seek opportunities for certification and accreditation from national and international healthcare quality improvement organisations
- Engage with available national and international audits
- Seek collaboration with recognised training bodies and quality improvement organisations
- Hospitals or institutions that offer the greatest patient safety systems develop clinical governance, leadership and team-building programmes and foster teamworking

SPECIFIC ISSUES IN COMMUNICATION

Professional behaviour and maintaining fitness to practice

Professionalism is an important component of patient safety. This embraces attitudes and behaviours that serve the patient's best interests above and beyond other considerations. Organisations responsible for maintaining ethical standards include professionalism as one of the standards by which healthcare workers are judged (see *Chapter 14*).

Fitness to work or practice – **competence** – refers not just to knowledge and skills but also to the attitudes required to be able to carry out one's duties. Monitoring their own fitness for work is the responsibility of each individual, their employer and professional organisations. Healthcare workers are required to have transparent systems in place to identify, monitor and assist them to maintain their competence. **Credentialing** is one way to ensure that clinicians are adequately prepared to safely treat patients with particular problems or to undertake defined procedures.

Communicating openly with patients and their carers and obtaining consent

A patient-centred approach by medical staff, with involvement of patients and their carers as partners, is now recognised as being of fundamental importance. There are better treatment outcomes and fewer errors when there is good communication, while poor communication is a common reason for patients taking legal actions.

Involving patients in and respecting their right to make decisions about their care and treatment is crucial. Explaining risk is a difficult but important part of good communication. It requires skill to explain the potential for harm of a procedure so that it is fully understood because patients vary in their perception and understanding and it is often difficult to assess the trade-offs between harm and benefit.

Obtaining consent for surgery requires that surgeons provide information to help patients to understand the positives and negatives of their various treatment options (*Table 15.2*). Patients should be allowed to make these informed decisions without coercion or manipulation. Consent should be obtained by someone who is capable of performing the surgery, and this should be taken when the patient is fully aware, especially in the non-urgent situation, well before the surgical procedure (see *Chapter 14*). A failure to provide adequate time for discussion regarding consent and also to understand that consent is a process that frequently requires multiple interactions with a patient are frequent causes of an unsatisfactory consent process.

TABLE 15.2 Information to be provided when seeking consent for surgery.

- The condition and the reasons why it warrants surgery.
- The type of surgery proposed and how it might correct the condition.
- The anticipated prognosis and expected side effects of the proposed surgery.
- The unexpected hazards of the proposed surgery.
- Any alternative and potentially successful treatments other than the proposed surgery.
- The consequences of no treatment at all.

When things go wrong: open disclosure

Communicating honestly with patients after an adverse event, or **open disclosure**, includes a full explanation of what happened, the potential consequences and what will be done to fix the problem. Safe care also involves taking care of the patient after the event, ensuring that the problem does not happen again and sincerely offering regret or an apology, as appropriate. These issues are increasingly reflected in open disclosure policies for healthcare workers; in the UK they are explicitly outlined in the General Medical Council's professional duty of candour and statements by many of the professional bodies. Since 2015, and as a consequence of the Francis report, a duty of candour has been placed on a statutory basis in the UK for all healthcare providers.

Situational awareness: understanding the work environment and working well within it

Nowhere is teamworking more important than in managing the flow of information within health care. Poor communication can lead to misinformation to patients and staff and delays in diagnosis, treatment and discharge as well as in failures to follow up on test results. On the other hand, good teamwork, good communication and continuity of care reduce errors and improve patient care and staff satisfaction within a team.

The nuances of good communication extend beyond the ability to converse with other members of the healthcare team and include specific competencies, namely situational awareness and emotional intelligence. Situational awareness describes an awareness of all individuals within the environment and an appreciation of the importance of change with time. Emotional intelligence, as defined by Peter Salovey and John Mayer, is 'the ability to monitor one's own and other people's emotions, to discriminate between different emotions and label them appropriately, and to use emotional information to guide thinking and behavior'. Experienced clinicians and clinical leaders understand that excellent communication skills are based on both situational awareness and emotional intelligence.

Sir Robert Anthony Francis, b.1950, British barrister, chaired the Stafford Hospital Inquiry.
Peter Salovey, b.1958, social psychologist, President of Yale University, New Haven, CT, USA.
John D Mayer, b. 1953, contemporary, psychologist, University of New Hampshire, NH, USA.

These features of situational awareness and emotional intelligence are important in identifying stress within oneself and other members of the healthcare team. **Stress, tiredness and mental fatigue** in the workplace are significant occupational health and safety risks in health care. There is good evidence linking tiredness with medical errors. Fatigue can also affect well-being by causing depression, anxiety and confusion, all of which negatively impact on clinicians' performance. Increasingly 'burnout' has been identified as a major cause of poor performance in the medical workforce. **Burnout** is characterised by a state of emotional, mental and physical exhaustion caused by prolonged stress. Burnout in the medical workforce has increased in recent years and has been attributed to lack of autonomy within the profession and increased administrative workloads; the latter is compounded by electronic record-keeping and working in an increasingly regulated environment. Doctors suffer from burnout to a greater extent than other professions.

Organisations and those in leadership positions bear responsibility for managing the working environment and work practices to minimise fatigue and stress. While this is widely reflected in legal restriction of working hours, much needs to be done to determine whether reducing resident or trainee hours of work leads to greater patient safety because of the 'trade-off' in requiring additional 'handovers' between clinical teams and subsequent loss of continuity of care.

Prescribing safely

Patients are vulnerable to mistakes made in any one of the many steps involved in the ordering, dispensing and administration of medications. Medication errors are one of the most common errors across all medical specialties. Accuracy requires that all steps are correctly executed. Common medication errors include:

- poor assessment or inadequate knowledge of patients and their clinical conditions;
- inadequate knowledge of the medications;
- dosage calculation errors;
- illegible handwriting;
- confusion regarding the name or the mixing up medications.

PATIENT SAFETY AND THE SURGEON: PROFESSIONAL RESPONSIBILITY

Among medical specialties, surgery is one of the most invasive healthcare interventions that a patient can experience. More than 100 million people worldwide undergo surgical treatment every year. Problems associated with surgical safety in resource-rich countries account for half of the avoidable adverse events that result in death or disability.

The 'more than one cause' theory of accident causation can be aptly applied to many aspects of surgical patient care during the perioperative period. However, irrespective of the safety event or issue, the surgeon as the likely senior team leader will play a key role in reporting and communicating these events with patients and carers, other team members and hospital administration. This is particularly so for those so-called '**coal-face**' errors where patients identify the surgeon as being responsible for a defined episode of care.

Summary box 15.4

Patient safety at the coal face

- Communicating well with patients and their carers
- Understanding situational awareness and emotional intelligence
- Effective teamworking
- Professionalism, as another essential component of patient safety
- System approach to clinical risk management events and patients' complaints

Cuschieri and others have described coal-face errors as those that can potentially be committed by surgeons during the care of their patients and include:

- diagnostic and management errors;
- resuscitation errors;
- prophylaxis errors;
- prescription/parenteral administration errors;
- situation awareness, identification and teamwork errors;
- technical and operative errors.

Situation awareness: identifying teamwork errors

Operating theatres have been described as 'among the most complex political, social and cultural structures that exist, full of ritual, drama, hierarchy and too often conflict'. In such an environment, systems should seek to prevent error by improving workplace preparedness and by incorporating defences that reduce human error or minimise its consequence. Well-recognised and potential errors include:

- the wrong patient in the operating theatre;
- surgery performed on the wrong side or site;
- the wrong procedure performed;
- failure to communicate changes in the patient's condition;
- disagreements about proceeding;
- retained instruments or swabs (*Figure 15.2*).

All these events are catastrophic for the patient and almost invariably occur through a lack of communication (see *Never events*). This means that all theatre staff should follow protocols and be familiar with the underlying principles supporting a uniform approach to caring for patients.

Technical and operative errors

In surgery, the person rather than systems approach emphasises the accountability of the surgeon, who, unlike colleagues in other medical disciplines, when operating carries specific

Sir Alfred Cuschieri, b.1938, Maltese surgeon and Emeritus Professor of Surgery, Dundee, UK.

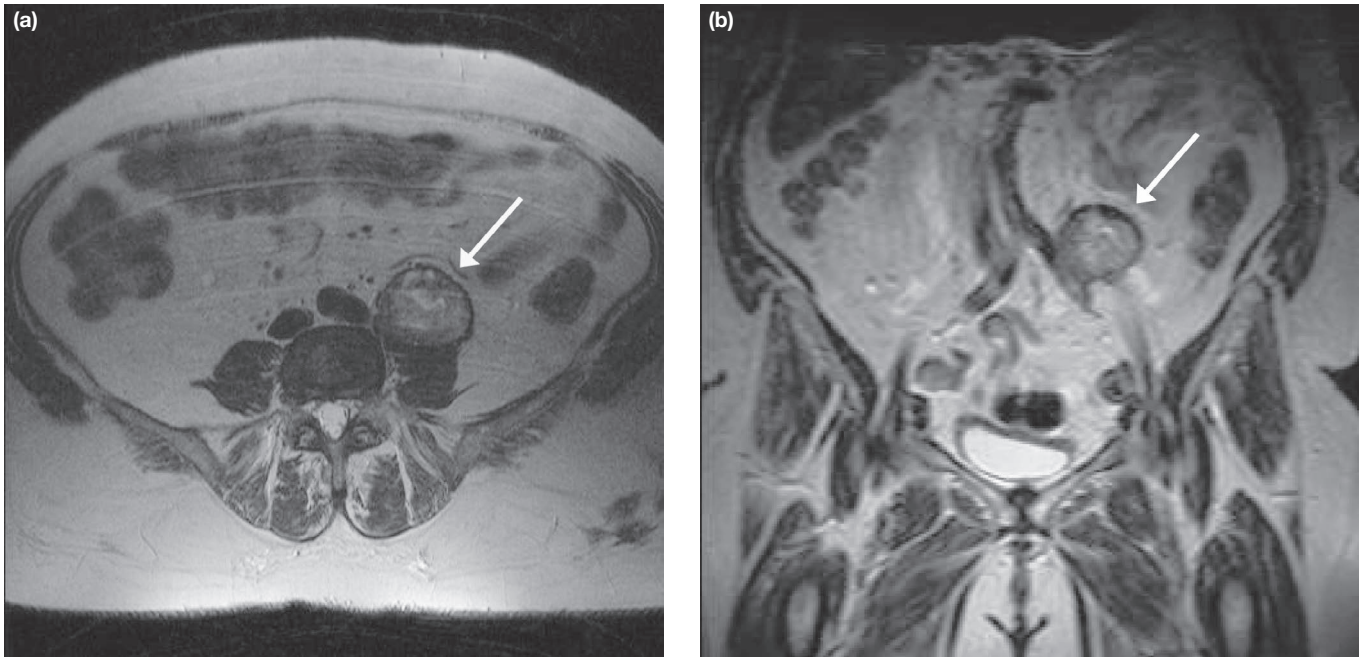

Figure 15.2 Axial (a) and coronal (b) magnetic resonance images demonstrating a well-defined abdominal mass with whorled stripes in a fluid-filled central cavity (arrows). This 60-year-old woman had had an abdominal hysterectomy 10 years previously and presented with pyrexia and flank pain. The cause was due to the late presentation of a retained surgical swab.

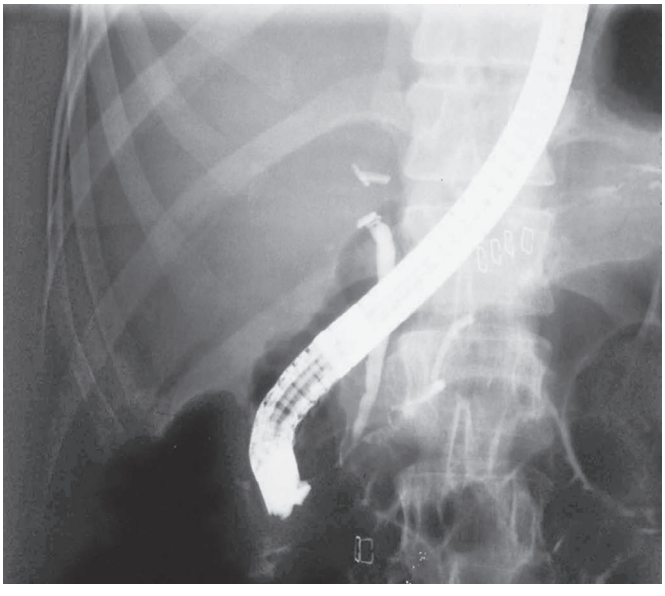

Figure 15.3 Endoscopic retrograde cholangiopancreatography radiograph showing an iatrogenic bile duct injury.

responsibilities. During a surgical procedure, for example, there may be a specific action that, of itself, may be the error, such as inadvertent injury to the common bile duct during a cholecystectomy (*Figure 15.3*). The practical value of this kind of interpretation is that, provided latent conditions are excluded, it gives a sense of responsibility to the surgeon and it may also help to point to the most effective pathway for remediation, by counselling or retraining, as against reassessing the system and putting in place further safeguards.

Central to operative performance is proficiency, an acquired state, honed by sound teaching, practice and repetition, by which a surgeon consistently performs operations with good outcomes. In cognitive psychology, high surgical proficiency is a state of automatic unconscious processing, with the execution being effortless, intuitive and untiring, as opposed to non-proficient execution, which is characterised by conscious control processing, requiring constant attention and resulting in slow, deliberate execution and inducing fatigue. The transition from one state to the other is better known as the 'learning curve' and is reflected in the hierarchal pyramid of competence (*Figure 15.4*). This should not carry negative connotations for trainee surgeons, who might be at the conscious processing stage but still perform a perfectly good operation, although it might take longer and be more tiring.

Failures in operative technique include:

- **cognitive** errors of judgement, such as late conversion of a difficult laparoscopic procedure into an open one;
- **procedural**, when the steps of an operation are not followed or are omitted;
- **executional**, when, for example, too much force is used, which may result in damage that may or may not have consequences;
- **misinterpretation** of anatomy/pathology, which is compounded by minimal access surgery with the limitations of a two-dimensional image;
- **misuse** of instrumentation, such as with energised dissection modalities (e.g. diathermy);
- **missed** iatrogenic injury either at the time of surgery or diagnosed late.

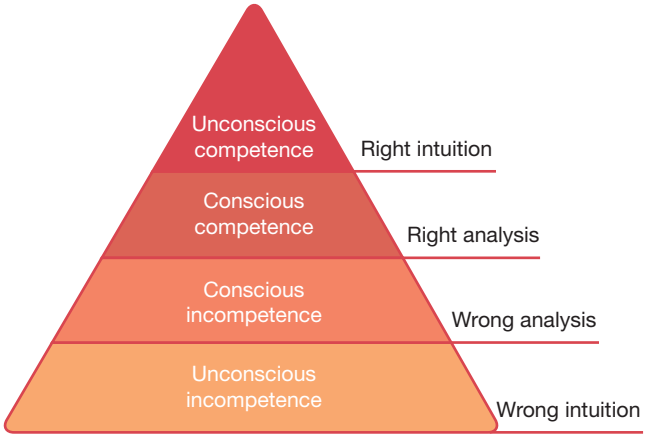

Figure 15.4 Hierarchy of competence.

Never events

Many national health services and institutions now require that all incidents are managed, reported and investigated. Incidents can be defined as events that could have or did result in unintended and/or unnecessary serious harm.

One subset of serious incidents is a **never or serious reportable event**. These events are considered to be wholly preventable; for example, a retained abdominal swab or instrument, where guidance providing strong systemic protective barriers should have been implemented, namely checklists. Each 'never event' type has the potential to cause serious harm to the patient or even death. However, serious harm or death is not required to have occurred for that incident to be categorised as a 'never or serious reportable event'. As previously described clinical incidents of this nature, by definition, mandate an open disclosure process with patients and their carers.

Shouldering the burden of adverse event

As primary care givers and clinical leaders, surgeons will not infrequently find themselves taking an active part in adverse event reporting. The professional responsibilities involved with managing adverse outcomes can be onerous, particularly understanding societal change and patients' expectations, in increasingly litigious societies. The administrative burden and responsibility associated with this need to be recognised. Issues relating to surgeons' well-being and burnout remain a cause for concern: supporting surgeons following adverse events has been increasingly recognised as a responsibility of all within the surgical community. The concept of the 'second victim' has been advanced to acknowledge the effects of adverse outcomes on surgeons' well-being. This is not to denigrate the undoubted harm caused to the 'first victim', or patient. Increasingly, however, comprehensive risk management systems will need not only to be patient-centric but also to acknowledge and support resilience of those working within our health services.

QUALITY IMPROVEMENT

In health care, quality improvement is defined as the continuous and combined efforts of people to make changes that will lead to better patient outcomes, enhanced healthcare system performance and better learning and professional development. Improvements come about through the intentional actions of staff equipped with the skills and data needed to bring about changes in patient care, either directly or indirectly. Such changes require substantial and sustained commitments of time and resources. The field of improvement science provides frameworks and methodologies that help when designing or redesigning healthcare processes and systems, especially when the aim is to ensure more efficient, safe, timely, effective, patient-centred and equitable care. The concept of value is an important adjunct to healthcare improvement. Value takes into account the total cost of health care as compared with the outcomes delivered to patients and helps to place emphasis on health, well-being and preventative care as opposed to exclusively focusing on treatment of illness.

There are large numbers of improvement activities that range from redesigning how teams deliver care in the multiple small clinical groupings (microsystems) that make up healthcare organisations to more large-scale reconfigurations of specialist services such as stroke care and cancer care. Other areas of healthcare improvement focus on areas as diverse as the redesign of training, budgeting processes and information systems. Common to all healthcare improvement is the necessity for doctors and other healthcare staff to reflect on and improve the way they work and to build a culture that both understands and values continuous improvement.

CLINICAL OUTCOMES, AUDIT AND IMPROVEMENT

Clinical audit, a function of clinical governance, is the means by which the health care being provided is compared with accepted standards. It allows care providers and patients to know how their service is doing (known as quality assurance) and to identify where there could be improvements. Clinical audits can look at care nationwide or locally within hospitals and their departments, in GP practices or anywhere health care is provided (***Table 15.3***).

Measuring clinical outcomes as part of a quality improvement cycle can help to:

- improve the quality of clinical care, with shorter hospital stays, better outcomes and fewer complications, reduced readmissions and greater patient satisfaction;
- inform the development of national clinical audits, including driving participation, data completeness and accuracy;
- support shared decision making and empowerment of patients, including their treatment options and choice of provider;
- improve the oversight and management of clinicians, their teams and practises, thus reassuring patients that their clinical care is being actively monitored and improved;
- help medical specialty associations to become increasingly transparent and patient focused;

- support team and individual quality improvement, including providing information for appraisal and revalidation;
- learn from, spread and celebrate best practice.

TABLE 15.3 Four stages of high value quality improvement or clinical audit activity

- Preparation and planning
- Measurement of performance
- Implementation of change
- Sustainment and evaluation of the improvement

QUALITY MEASURES

Measurement is a key principle of quality improvement. Although many changes take place in health care, without measurement it is impossible to determine whether those changes actually result in improved quality. Measurement of improvement requires different methods from those used in research, being concerned more with testing of how best to effectively introduce and replicate best practice rather than determining for the first time what best practice should be. Quality measures are tools that help to quantify the characteristics of high-quality health care and may measure the healthcare process, its outcomes, the patient's experience or the organisational structures or systems that support care delivery. Quality may be measured in terms of structure, process and outcomes.

Structural measures outline the characteristics of the health system that affect the system's ability to meet the healthcare needs of individual patients or a population. Structural measures usually refer to the availability of material, infrastructural or human resources, e.g. the number of surgeons per 100 000 population or the number of staffed operating theatre sessions in a hospital. Structural measures are especially useful in evaluating and improving equity of access to health care. They may include measurement of the availability in a healthcare setting of policies or procedures needed to deliver high-quality care, such as standards for the frequency and nature of clinical observation of postoperative patients.

Process measures assess what the healthcare provider did for the patient and how well it was done. The term process is used to refer to the implementation of procedures and practices by staff when planning, prescribing, delivering and evaluating care. Each surgical patient's journey is a composite of multiple processes, such as preoperative assessment, hospital admission and undergoing an operation, among others. Measurement for improvement most commonly involves tracking processes at the same site over time in an attempt to reduce inappropriate variation. Process improvement measures should be associated with better outcomes of care and, ideally, should be important from a patient's perspective. An example of a clinical process measure might be the starting times of operating lists. Consistently starting the operating day on time reduces delays for patients awaiting surgery and has a number of associated possible benefits, such as shorter fasting times preoperatively and a greater ability to plan the theatre day. Sometimes process measures are used as a management tool, comparing sites or performance against defined thresholds. In this example, starting theatres on time might be part of a wider improvement plan that aims to reduce underutilisation of staffed theatre time.

Outcome measures describe the effects of care on the health status of patients and populations – they are specific, observable and measurable changes that represent the achievement of an outcome of a quality improvement initiative. **Clinical outcome measures** refer specifically to outcomes of healthcare interventions, whether they are to do with diagnosis, treatment or care received by service users. Ideally, they should be outcomes that are important to patients rather than to the healthcare provider (PROM: patient-reported outcome measure), and there should be evidence that they reflect the quality of the interventions and their effect. Outcome measures are what are commonly used in **clinical audit** when outcomes achieved are compared with evidence-based standards of clinical care.

An important principle of healthcare improvement is patient-centred co-design, a process by which healthcare providers work in partnership with the people receiving care to identify and prioritise desirable outcomes. Such outcomes may include factors experienced by people accessing care, such as:

- the speed of their access to reliable health advice;
- the effectiveness of their treatment delivered by trusted professionals;
- the continuity of their care and its smooth transitions;
- the involvement of, and support for, their family and carers;
- the availability of clear, comprehensible information and support for self-care;
- their involvement in decisions and the respect for their preferences;
- the emotional support, empathy and respect provided;
- the attention paid to their physical and environmental needs.

The collection and interpretation of reliable data are of fundamental importance to any quality improvement exercise (*Table 15.4*).

THE PROCESS OF SURGICAL CARE

Patients attend surgeons in many different settings depending on whether they present **electively** (scheduled) or **urgently** (unscheduled). An elective patient's journey is usually predictable and typically starts with referral from primary care for outpatient (ambulatory) consultation and investigation. If a surgical procedure is required, the patient undergoes assessment from both a surgical and anaesthetic perspective prior to admission. Ideally the patient is then admitted in a timely manner to the level of care that best meets their needs, whether as a day case, on the day of surgery, or for as short a time as possible before surgery as an inpatient. Preoperative checking is followed by the theatre journey, which includes reception, anaesthesia, the surgery itself and recovery – each, in their own way, a series of complex interventions. Returning to the ward and recovery demands another set of skills, procedures and processes followed by a final 'discharge from hospital'

TABLE 15.4 Three pioneers of quality improvement and their quotes on data.

William Edwards Deming (1900–1993)	American engineer, statistician, author and management consultant. Pioneered the PDSA (plan–do–study–act) cycle	'In God we trust, all others bring data.'
Peter Ferdinand Drucker (1909–2005)	Austrian-born American management consultant and educator	'What gets measured gets improved.'
Donald Berwick (b.1946)	American paediatrician. Former President and Chief Executive Officer of the Institute for Healthcare Improvement	Sequence of reactions that challenge data: "The data are wrong." "The data are right but it's not a problem." "The data are right; it is a problem but not my problem." "I accept the burden of improvement."

process and transition of care back to the community services if required.

The urgent, emergency or unscheduled patient journey is different because it is unpredictable for each individual, although patterns of presentation do emerge when managing large numbers. The patient commonly presents at the emergency department of a hospital either as a self-referral, as a primary care referral or by ambulance. The journey begins with triage by a team, who assess the severity of the illness and then stream the patient to the most appropriate area for their needs, which might include, for example, a resuscitation unit, a rapid assessment and treatment unit, an acute surgical assessment unit, a minor injuries unit or an ambulatory care unit. The objective is that the patient is seen as soon as possible by a **senior decision maker**, so that the patient can be treated or discharged as expeditiously as possible or, if admission and surgery are required, this too can be expedited. Thereafter, the journey follows a similar course to that of an elective admission.

This simple outline of surgical patients' journeys serves to illustrate the many individual steps or processes in that journey, each with scope for errors, delays and inefficiencies. Opportunities for improvement are almost limitless.

THE QUALITY IMPROVEMENT PATHWAY

Quality improvement can be applied to almost any step, process or activity. The science of improvement is an applied science that prioritises innovation, rapid-cycle testing and spread with the aim of identifying what changes, and in what contexts, will result in improvement. Healthcare Improvement Scotland identifies seven stages when undertaking improvement:

1. **discovering** – is about defining the aims and vision; understanding what the problem is and what data are available;
2. **exploring** – is about defining the present state and visualising the future state;
3. **designing** – is about defining how to move from the present state to the future state and identifying the priorities;
4. **refining** – is about testing change, learning from the data and identifying the benefits;
5. **introducing** – is about managing communications and building the will and culture to change;
6. **spreading** – is about showing the improvements, telling the story and disseminating the message;
7. **closing** – is about capturing and sustaining the learning.

Each step is supported by the use of tools and methodologies that are appropriate to the design and planning of each step, depending on the improvement exercise being undertaken (*Table 15.5*).

TABLE 15.5 Examples of tools used in quality improvement.

Root cause analysis Benefits realisation planning Demand and capacity planning Process mapping Value stream mapping Kanban and 5 'S'	Driver diagrams Fishbone cause and effect diagrams Spaghetti diagrams Box, frequency and scatter plots Pareto charts Run charts Statistical process control charts

Model for improvement

Based on the teachings of W. Edwards Deming (*Table 15.4*), the model for improvement is a system popularised by the Institute for Healthcare Improvement that asks three questions: 'What are we trying to accomplish?', 'How will we know that a change is an improvement?' and 'What changes can we make that will result in improvement?' The system employs plan–do–study–act (PDSA) cycles to perform and evaluate small, rapid-cycle tests of change.

Lean

Lean improvement methodologies originated in industrial settings among frontline workers and were pioneered in Japan, giving rise to much of the terminology used. *Kaizen* is the Japanese word for improvement. A single 'cycle' of kaizen activity is defined as requiring similar steps to a PDSA cycle. The same application can be used in health care, with many sequential cycles growing to 'continuous improvement'. The essential

TABLE 15.6 Seven types of waste in health care and possible solutions.

Overproduction Example: ordering unnecessary preoperative tests Solution: implementation of evidence-based preassessment pathways
Inventory Example: storing excessive medication or supplies in ward storage with a risk of them going out of date Solution: alphabetically ordered medication cupboards with small amounts of commonly used drugs in conjunction with an efficient replenishment system
Waiting Example: patients waiting long periods to come to theatre Solution: staggered admission times aligned to operating theatre schedule
Waste of transportation Example: using trolleys to bring ambulatory day patients to the operating theatre Solution: better design of the admissions process to enable patients to walk to theatre
Waste of overprocessing Example: using computed tomography scans to assess children with possible appendicitis Solution: consider whether ultrasound could be used instead
Defect Example: patients arriving for surgery with incomplete or inappropriate preoperative paperwork Solution: more robust checking systems before patients come to theatre
Motion Example: frequent searching in theatres and the anaesthetic room to find necessary drugs and equipment Solution: an efficient theatre layout, common to all operating theatres in the hospital, where everything needed is easily available with minimal movement and always in the same place

philosophy behind lean methodologies is the elimination of waste through continuous improvement. Lean identifies seven forms of waste, each of which is relevant to health care (*Table 15.6*). Identifying waste leads inevitably to the need to define value from the perspective of the patient, a factor that is central to the Choosing Wisely initiative (https://www.choosingwisely.org).

Clinical microsystems

A **clinical microsystem** is an interdependent quality improvement unit made up of a small group of people who work together, usually on a regular basis, to provide care. Such groups are typically multidisciplinary. The patients who receive that care can also be recognised as members of a discrete group, such as patients with cancer or people attending an emergency department. Clinical microsystems share clinical and business aims, have linked processes and share information. Each microsystem produces services or care that can be measured as performance outcomes. Microsystems evolve over time and normally form part of a larger macrosystem or organisation.

They are considered 'living adaptive systems' as each microsystem must carry out work, meet staff needs and maintain its coherence as a clinical unit. Clinical microsystems can be assessed on their evidence base, leadership, patient and staff focus, and information systems.

Six Sigma

Six Sigma refers to another business performance methodology that has been adopted for use in health care. The fundamental objective of the Six Sigma methodology is the implementation of a measurement-based strategy that focuses on process improvement and especially on reducing unnecessary variation. One of its sub-methodologies is DMAIC (Define, Measure, Analyse, Improve, Control), which is an improvement system for existing processes that fall below specification and require incremental improvement.

Systems thinking and leadership

In a system as complex as health care, 'systems' thinking allows the whole system and the relationships of the parts to be considered rather than just isolated functions. Health care is a shared resource with many interdependencies; for surgery these include anaesthesia, critical care, nursing and other specialties we work with to manage comorbid patients.

If quality problems exist primarily because of systems problems, solutions are more likely in systems where relationships and integration are considered important and where emphasis is placed on HF such as communication, team building, conflict management, process management and education. Systems work best when there is a non-punitive culture and when they have leaders who understand the complexity of systems and foster a culture of continuous quality improvement. Those leaders should be visible at the front line and be champions of a supportive practice environment.

Improvement in the quality of care does not occur by chance and a programme team, armed with just organisational and graphical tools, will not succeed in producing sustainable change. True change can only happen when supported and driven by front-line staff. The underlying, central and agreed principles must include the creation of value for the patient, a constancy of purpose and systems thinking. These should be enabled by the intentional actions of trained staff supported by humble leadership and respect for individuals. Such a culture

adjustment also requires integrated and coherent strategies and a sustained commitment of time, patience and resources.

Health care as a sector has been slow to recognise the important contribution that the theory and practice of quality improvement are able to make in delivering better value care. The experience of a relatively small number of healthcare organisations that have successfully done so, such as the Virginia Mason Medical Centre in Seattle, WA, is a challenge to others to invest in acquiring the necessary skills and capabilities.

A recent report by the Academy of the Medical Royal Colleges of UK and Ireland (2016) has argued that quality improvement should be at the heart of medical training and that there is a pressing need to develop quality improvement learning across the continuum of medical education. Understanding how health systems can be improved and how evidence-based practice can be implemented in complex healthcare settings are important skills for surgeons to master.

Summary box 15.5

Understanding quality improvement and its application in health care

- The definition of quality improvement and its relationship to clinical audit
- The different kinds of quality measures
- The patient's surgical journey and its potential for improvement
- Examples of quality improvement pathways, organisational methodologies and tools
- What systems thinking is and its importance alongside leadership
- The requirement for more education and training in quality improvement

PART 1 | Basic principles

CHAPTER 16

Global health and surgery

Learning objectives

To define:
- The term global surgery

To describe:
- The role of a global surgeon

To understand:
- That surgery can be cost-effective
- Concepts of surgery and impoverishment
- How essential surgery can be delivered through surgical healthcare delivery platforms

To appreciate:
- The importance of access to surgical care
- The global surgical workforce
- The importance of global surgical metrics and research

INTRODUCTION AND DEFINITION

Global health is the health of populations in the global context. Global surgery is surgery with an understanding of public health. Surgeons understand the needs of their individual patients, while public health adds the understanding of the surgical operations needed in the population. Global surgery aims to provide equitable and improved surgical care across the world.

Global surgeons are not system-specific surgeons but are 'specialised' in providing the surgical needs of their communities. A practising surgeon can be viewed as a 'retailer' for the individual patient, whereas a global surgeon is typically the 'wholesaler' of the surgical needs of the population. This means that all surgeons working in non-tertiary hospitals who perform life-saving and essential surgeries, guided by the prevalent burden of surgical disease, are global surgeons. There is a misconception that a global surgeon is primarily a high-income country (HIC) surgeon helping low- and middle-income country (LMIC) surgeons periodically or through surgical missions. The HIC surgeons and subspecialist surgeons will be able to mitigate only a very small part of the vast unmet need of surgical disease burden in LMICs. Global surgery focuses on improving surgical health systems in parts of the world with a high surgical burden of disease by the local surgeons in those communities.

SURGERY AS AN ESSENTIAL AND COST-EFFECTIVE INTERVENTION

With the decline in the burden of communicable diseases in the world, one-third of the total disease burden is now due to surgical disease, with the majority being injury and cancers. In 2015, responding to this epidemiological transition, the World Health Organization (WHO) declared surgery to be a part of public health at the World Health Assembly, a meeting of all health ministers. Previously, surgical and anaesthesia care were perceived as too expensive and too complex to be a public health priority in resource-poor settings. The fact that early surgery saves lives and boosts the economy encouraged health planners to put surgery in the essential group of services in any national health strategy. Since then, scaling up surgical and anaesthesia care became a new worldwide movement under the umbrella term of 'global surgery'.

The Disease Control Priorities group of the World Bank has clearly identified surgical procedures that address the substantial needs of populations. In the absence of investments in surgical care, case-fatality rates and lifetime costs to the individual and society are high for common and easily treatable conditions, including appendicitis, hernia, fractures, obstructed labour, congenital anomalies and breast and cervical cancer. Furthermore, the cost-effectiveness of surgery for cataracts, hydrocephalus, limb deformity, general surgery and cleft lip or palate repair is comparable to widely used public health strategies, such as the bacille Calmette–Guérin (BCG) vaccine, and is much greater than other standard public health measures, such as antiretroviral therapy. Surgery becomes more cost-effective when not delivered as isolated interventions, but rather as a group of interventions within a platform of clinical care, such as a district hospital.

ACCESS TO SURGICAL CARE

The Lancet Commission on Global Surgery (2015) estimated that 5 billion out of the 7 billion people on the planet do not have access to surgery (see ***Summary box 16.2***). This is concerning, as access to timely life-saving essential surgery is a fundamental need for all. Although barriers to surgical access appear to be pronounced in LMICs, there are also disadvantaged and vulnerable populations in HICs. Access to

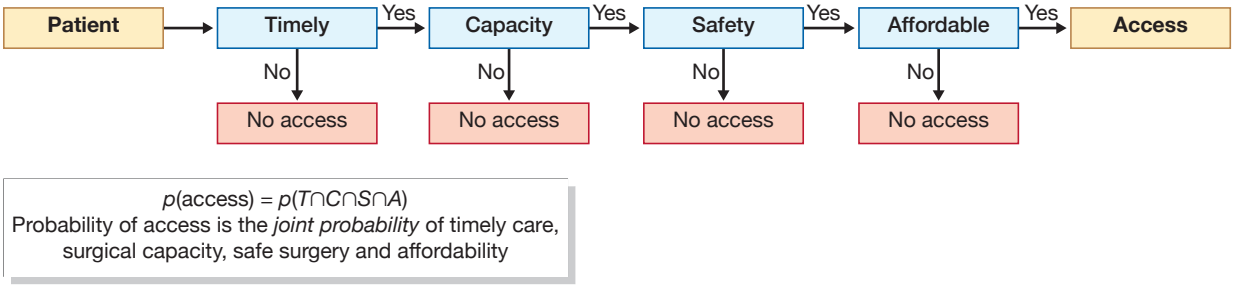

Figure 16.1 Access to surgery: the four dimensions.

surgery can be viewed through four lenses, namely; timeliness, capacity, safety and affordability (***Figure 16.1***).

Geographical access is the ability of a patient to reach a surgical facility within 2 hours, which is the crucial time for life-threatening haemorrhage. Capacity denotes that the facility has the required infrastructure and workforce and is able to perform safe surgery. However, the final barrier is when a patient cannot afford the surgery offered. A staggering nine out of 10 people in LMICs do not have access to surgery. Consequently, patients with acute surgical needs in LMICs do not reach hospital or reach it too late, in advanced stages of cancer, with already infected open fractures, with a perforated bowel or with burn contractures.

The world needs 143 million more surgical operations (unmet need) to be performed each year to save lives and prevent disability. Of the 313 million procedures undertaken worldwide each year, only 6% occur in the poorest countries, where over one-third of the world's population lives (see ***Further reading***). Unmet need is greatest in eastern, western and central sub-Saharan Africa and South Asia. These regions have young mothers dying of physiological conditions such as pregnancy, for want of a caesarean section. The global surgical community hopes to achieve an optimum operative volume of 5000 surgical procedures per 100 000 population across the world by 2030. Currently, there are countries such as Ethiopia which do 150 operations per 100 000 population, while Hungary performs 23 000. However, more than 5000 operations and further expenditure do not bring commensurate health benefits to the population. Low operative volumes are also associated with high case-fatality rates from common, treatable surgical conditions, which include injuries, early cancer and burns.

THE GLOBAL SURGICAL WORKFORCE

A surgeon, anaesthetist and obstetrician (SAO) at the district hospital are considered essential staffing. In many LMICs the SAO density is less than 5 per 100 000 population. As the SAO number increases, there is a dramatic improvement in key indicators, such as the maternal mortality ratio. However, the benefits plateau beyond 20 SAOs per 100 000 population. By 2030, all LMICs are committed to scaling up their surgical workforce to at least 20 SAO providers per 100 000 population. For all countries to reach this benchmark 1.27 million providers will need to be trained by 2030. Where there is a workforce shortage with a high surgical burden of disease, 'task-shifting' is common, whereby appropriate tasks are moved to less specialised health workers. For example, essential life-saving anaesthesia is a short course for medical graduates to address the specialist anaesthetist shortage in rural areas. In countries where there are still too few medical graduates, task-shifting in both anaesthesia and surgery involves appropriately trained non-medically qualified clinicians or midwives.

Ironically, the countries in the world where the fewest children are born have the greatest number of paediatric surgeons. There is much redundancy in human resources and low volumes of surgery in many HICs. In countries with a large burden of surgical disease and large populations, often a single surgeon caters to the surgical needs of many millions of people. However, these global surgical champions have high burnout rates. Healthcare workers, including doctors and nurses, in LMIC settings are often mobile and may choose to migrate overseas, either staying in healthcare or taking up alternative professions (commonly referred to as the 'brain drain'). Twelve per cent of SAOs in HICs have graduated from LMICs and two-thirds of these graduates are from countries with fewer than 20 SAOs per 100 000 population. More surgeons and anaesthetists are needed in LMICs, but the trend cannot be mitigated by simply training more, as the migration rates and the in-country maldistribution of surgeons remain. The answer is starting global surgery units in teaching universities, e-grand rounds, remote specialist support, e-intensive care units, low-cost robotics, online learning platforms, supportive supervision, recognition, peer support and collegiality for upskilling these champions.

A surgical system goes beyond a surgeon and a sterile operating theatre. Clearly, it requires a contribution from many other people to make the surgical ecosystem work, both before and after the patient's visit to the operating theatre. Global surgery includes healthcare workers beyond anaesthetists, obstetricians and all surgical specialities. It encourages a multidisciplinary team approach to the profession and acknowledges the important role of physicians, nurses, public health practitioners, health managers, surgical, laboratory, supply-chain specialists, biomedical engineers, radiology and blood bank technicians. The role of community health workers in reducing delays and facilitating the referral pathway is vital in LMICs. Engaged and caring hospital managers are critical

in coordinating this process. Finally, private practitioners constitute a significant portion of the surgical manpower in LMICs and can contribute greatly to achieving the 2030 surgical burden goals, when appropriately incentivised and regulated for quality.

SURGERY AND IMPOVERISHMENT

Surgeons are tasked to operate and, in so doing, aim to successfully treat the surgical condition. A hernia not operated upon in a timely fashion costs the nation (and the individual) more when it becomes incarcerated. A delayed caesarean section puts mother and child at risk of death. In addition to risks associated with timing, the financial implications of a procedure can lead to poverty and catastrophic expenditure (more than 40% of annual household income). The one-time payment for surgery can push vulnerable populations into financial ruin, and those in poverty to extreme poverty. Forty-four per cent of the world's population is at risk of financial catastrophe with a single major operative procedure. In numbers, 33 million people (which is more than the population of Australia) each year will be pushed into poverty by paying for the surgery and anaesthesia that they need. Catastrophic expenditure is greatest for time-critical surgical conditions, such as peritonitis. Surgeons may have at times been less engaged with the patients' economic and social conditions that influence their health status. In many instances those who cannot afford to pay simply do not reach the operating theatre. Furthermore, lay people and policy makers alike can view surgery as an expensive business. This can lead to a problem, in that we can appreciate that everyone needs access to surgery, but commonly only the upper wealth quintiles are privileged to be in this position. When aggregated, the national estimate of out-of-pocket expenses of injury care alone exceeds the total health budget of many LMICs.

GLOBAL SURGICAL METRICS AND RESEARCH

Surgeons are familiar with vital-sign-based scoring systems for individual patients and with hospital metrics for inpatient hospital stay, surgical site infection or ventilator-associated pneumonia. Global surgery requires the addition of population-level metrics for the surgical burden of disease, which are less readily available. Household-level surveys of injury burden, vision care, cancer screening and worldwide metrics such as maternal mortality ratio and caesarean section rates are indicative of the surgical health systems in countries. Demographic surveillance systems and surveys such as the Million Death Study have been used to assess acute abdominal disorders at the national level. Most public health interventions are measured in terms of disability-adjusted life-years (DALYs) averted, which calculates how much it costs to avert 1 year of suffering due to a disability. One-third of all deaths worldwide are the result of conditions needing surgical care, and this surpasses human immunodeficiency virus, malaria and tuberculosis combined.

The core indicators to monitor the realisation of universal access to safe, affordable surgical and anaesthesia care are shown in ***Table 16.1***.

TABLE 16.1 Core indicators to monitor the realisation of universal access to safe, affordable surgical and anaesthesia care.

Preparedness	a	Access to timely essential surgery (proportion of population within 2 hours of a facility that can perform the bellwether procedures)
	b	Density of surgeons, anaesthetists and obstetricians working per 100 000 population
Surgical service delivery	a	Procedures done in an operating theatre, per 100 000 population per year
	b	All-cause death rate before discharge of patients who have undergone a procedure in an operating theatre, divided by the total number of procedures
Affordability of surgery	Proportion of households protected against impoverishment and catastrophic expenditure from direct out-of-pocket payments for surgical care	

ESSENTIAL SURGERY THROUGH SURGICAL HEALTHCARE DELIVERY PLATFORMS

The 44 essential surgeries listed by WHO are critical to life, and 29 of them can be done at a district hospital. The bellwether procedures include caesarean sections, laparotomies and treatment of open fractures. These serve as a proxy measure to gauge the functionality of the surgical health system and its ability to perform a broad range of other essential surgical procedures. In places where there are few specialist surgeons, surgical needs are triaged as: 'must-do' procedures (cannot wait for 24 hours), 'should-do' procedures (cannot be delayed beyond a week) and 'can-do' procedures (can wait for more than a week), rather than by specialty.

The suggested core packages for strengthening emergency and essential surgical care and anaesthesia as a component of universal health coverage are shown in ***Summary box 16.1***.

National surgical plans consider country-specific contexts of disease burden, severity of disease, effectiveness of surgical intervention, economic effects and social implications. These plans influence decisions to tailor these procedures, packages and platforms for delivery. National standard treatment guidelines, which are commonplace in HICs, are now being adapted and used in the context of LMICs. They ensure that incentives for hospital management and clinical leadership align with the goal of efficient, system-wide reductions in the burden of surgical disease.

In the interconnected world, HICs can contribute in many important ways to global surgery: in elective and planned surgeries, academic grand rounds, relevant LMIC research

Summary box 16.1

Core packages for strengthening emergency and essential surgical care and anaesthesia

- *Emergency procedures packages* include:
  - Basic trauma package (e.g. fracture treatment, trauma laparotomy, debridement)
  - Basic obstetric package (e.g. caesarean section)
  - Basic emergency general surgical package (e.g. laparotomy, incision and drainage)
- *Planned care packages* can include:
  - General surgical package (e.g. hernia repair, bowel resection)
  - Obstetric and gynaecological package (e.g. hysterectomy)
  - Specialist surgical package (e.g. cataract, clubfoot correction)
  - Palliative surgical package (e.g. diversion colostomy, analgesics)

and research into the burden of surgical disease. Traditionally, mission surgeries for rarer conditions such as cleft lip and palate have contributed to high-quality protocols of safety and standards in surgery (Operation Smile, Smile Train). The critiques and concerns have been around HIC surgeons parachuting into LMICs and a lack of follow-up of their operated patients. Short-term visiting teams can draw resources away from local providers delivering continuous care, creating a perception within the community that visiting teams provide higher quality care. Improved LMIC institutional partnerships, local capacity building and collegiality are key to global surgery collaborative work with HICs. On their part, HICs have learned from LMIC institutions, such as the Aravind Eye Institute, about affordable surgery through remarkable cost reductions in high-volume cataract surgeries. While achieving high-volume surgeries, surgical safety is paramount and is dependent on training and upskilling of human resources in health, health infrastructure, the supply chain and equipment maintenance. Improved connectivity, infrastructure, Internet and wearables as well as low-cost simulation and robotics are remarkable global innovations that may make surgery accessible to those who were previously unable to reach it.

In the future, global surgery will drive surgeons in academic university hospitals to partner with their public health and community medicine colleagues for creating hub-and-spoke models for outreach surgery. Surgical practices will evolve to address the high unmet surgical burden of disease with high-volume and low-profit operations, with enhanced recovery in hospitals and postdischarge follow-ups by community health workers. Surgeons will go beyond the technical aspects of surgical practice to advocate for affordable and equitable surgical care for everyone, without compromising on safety.

Summary box 16.2

Key messages from the Lancet Commission on Global Surgery

- 5 billion out of the 7 billion people on the planet cannot access the surgeons who read this book for safe and affordable surgery
- 143 million more surgical procedures are needed each year in the world
- 33 million people each year will be impoverished because of paying for the surgery and anaesthesia that they need
- Investing in surgery is affordable, saves lives and promotes economic growth
- Surgery is an indivisible, indispensable part of health care. Surgical and anaesthesia care should be an integral component of a national health system in countries at all levels of development

PART 2 | General paediatrics

CHAPTER
17 Paediatric surgery

Learning objectives

After studying this chapter, you will be able to:

- Outline subspecialisations within children's surgery
- Safely prescribe perioperative fluids in children
- Compare and contrast inguinal hernias and hydroceles
- Discuss the causes and management of the acute scrotum
- Outline the presentation, resuscitation and operation for pyloric stenosis
- Outline causes and management of abdominal pain in children of different ages
- Describe two solid abdominal tumours of childhood

INTRODUCTION

In high-income countries paediatric surgeons have subspecialised, whereas in low-income countries surgeons must maintain diverse skills and knowledge. Some conditions, previously managed by paediatric surgeons, are now managed by others (e.g. clefts in plastic surgery, syndactyly in hand surgery, spina bifida and ventriculoperitoneal shunts in neurosurgery, ligation of patent ductus arteriosus in cardiac surgery and cervical cystic hygromas, thyroglossal cysts, preauricular sinuses and branchial remnants in ear, nose and throat surgery). This new edition recognises specialisation with chapters devoted to neonatal surgery, specialist paediatric urology and paediatric trauma. Those managing the general surgery of childhood in non-specialist hospitals should study the inguinoscrotal conditions described here and the foreskin as outlined in *Chapter 20*.

AGE

Biological domains (e.g. physiology, pathology, pharmacology) change continuously with age, whereas hospital services recognise artificial boundaries often set at 12, 16 or 18. The terminology related to children and young people (CYP) includes **neonate** (<4 weeks) and **infant** (<1 year). The World Health Organization defines **adolescence** as ages 10–19 and **young people** as 10–24. Some anatomical differences between infants and older children appear in *Table 17.1* and *Figure 17.1*. A few conditions described in *Chapter 18* require management throughout childhood and later after handover in transitioning by adult surgeons.

ENVIRONMENT

Children, especially infants, should be managed in a warm environment. Compared with adults, children lose more heat and fluid with surface area to weight ratios being higher;

TABLE 17.1 Some examples of differences between infants and older children

Facts	Infants and some young children have a wide abdomen, a broad costal margin and a shallow pelvis
	The edge of the liver comes below the costal margin, and the bladder is partly intra-abdominal
	The ribs are more horizontal and are flexible
	The umbilicus is relatively low lying
Implications	Transverse supraumbilical incisions can give greater access than vertical midline incisions
	Abdominal trauma (including surgical incisions) can easily damage the liver or bladder
	The geometry of the ribs means that ventilation requires more diaphragmatic movement than in adults
	A stoma in the lower abdomen of an infant must be carefully sited for its bag not to interfere with the umbilicus

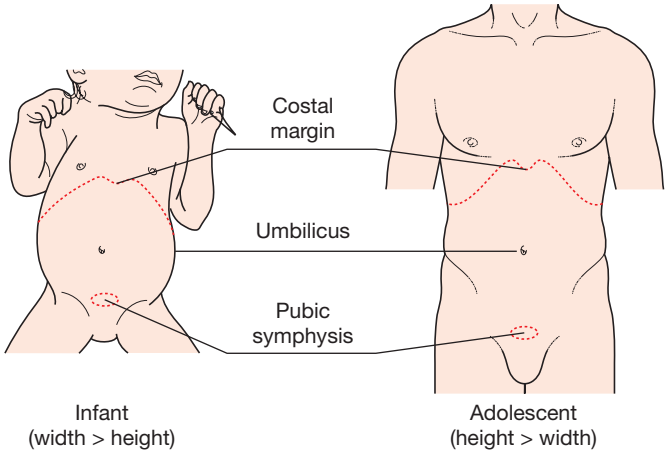

Figure 17.1 Topographical differences in the abdomen.

consider this in the clinic, emergency room, anaesthetic rooms and theatres. An infant's head accounts for 20% of the surface area compared with 10% in adults. Intravenous infusions are warmed, and respiratory gases are both warmed and humidified. Core temperature is monitored in operations, and warming devices are used (e.g. heated mattresses, warm air blowers).

PERIOPERATIVE FLUIDS

There are four reasons for giving intravenous fluids: acute circulatory support, correction of previous losses, replacing ongoing losses and maintenance fluids (***Summary box 17.1***). Before prescribing fluids, weight, vital signs and fluid requirements are considered (***Table 17.2***). Dehydration as a percentage loss of total body water is difficult to assess; moderate dehydration (5%) causes low urine output, dry mouth and sunken eyes and fontanelle; severe dehydration (>10%) causes drowsiness, tachycardia and slow capillary refill (>2 seconds).

Hyponatraemia (<135 mmol/L) is common, but progression risks an encephalopathy from water movement into the brain. Water diffuses slowly by osmosis, equalising osmotic pressures, or swiftly through aquaporins. Sodium homeostasis maintains intravascular volume through antidiuretic hormone (ADH) and thirst. ADH binds to receptors in the distal nephron, inducing aquaporins and water retention. Increasing plasma osmolarity and hypotension both increase ADH levels.

Summary box 17.1

Fluids in children

Fluids are given intravenously for four reasons:

- Circulatory support in resuscitating vascular collapse
  - 0.9% saline, Blood, 4.5% albumin, Colloid → Given as a bolus of 10 or 20 mL/kg over periods of up to 20 minutes while monitoring the response. Can be repeated up to 40 mL/kg then seek help
- Replacement of previous fluid and electrolyte deficits
  - 0.9% saline 0.15% KCl, Hartmann's solution → Given over a longer period of up to 48 hours with clinical and biochemical review
- Replacement of ongoing losses
  - 0.9% saline + 0.15% KCl, Hartmann's solution → Or a fluid tailored to the losses, e.g. 4.5% albumin if protein loss is great. Replace losses millilitre for millilitre
- Maintenance outside the neonatal period
  - Plasma-Lyte 148, Hartmann's solution ± glucose, 0.9% saline + 0.15% KCl ± glucose → Hypotonic 0.18% saline should not be used outside the neonatal period

TABLE 17.2 Basic paediatric data.

Vital signs			
Age (years)	**Heart rate (bpm)**	**Systolic blood pressure (mmHg)**	**Respiratory rate (b/min)**
<1	110–160	70–90	30–40
2–5	90–140	80–100	25–30
5–12	80–120	90–110	20–25
Maintenance fluid requirements			
Weight		**Daily fluid requirement (mL/kg/day)**	**(mL/kg/h)**
Neonate		120–150	5
First 10 kg		100	4
Second 10 kg		50	2
Subsequent kg		20	1

Systolic blood pressure = 80 + (age in years × 2) mmHg
Circulating blood volume = 70–80 mL/kg (90–100 mL/kg in preterms)
b/min, breaths per minute; bpm, beats per minute.

An abundance of free water causes hyponatraemia. Since glucose is metabolised to water, glucose is ignored when calculating tonicity; 0.45% saline in 5% dextrose is considered hypotonic. Hyponatraemia is seen in normovolaemia if ADH rises inappropriately (e.g. surgical stress, trauma, chest infections, head injuries). Clinical problems arise if hypotonic fluids are used to resuscitate or replace losses or if maintenance fluids are given in excess.

Restricting maintenance fluids to 50–70% is appropriate after major surgery, gradually increasing the rate daily if sodium levels are not falling. Urine output naturally decreases after major surgery, but a common pitfall is to increase maintenance fluids, predisposing to hyponatraemia. A postoperative fluid bolus is appropriate in hypovolaemia, hypotension or poor peripheral perfusion, but given simply because urine output is low can be inappropriate. If hyponatraemia is mild and asymptomatic fluids are restricted, if symptomatic with headache, lethargy or seizures and the sodium concentration is <125 mmol/L, intravenous 3% saline is given.

HISTORY AND EXAMINATION

An opportunistic rather than a systematic approach may be needed in the preschool child. Children should be told what to expect from examinations, investigations or procedures in terms they can understand. Fear, anxiety and pain are reduced in a child-friendly environment. Consent is requested from someone with parental responsibility.

OPERATIVE SURGERY

Preoperative fasting should be limited (***Summary box 17.2***). Surgery requires meticulous and gentle tissue handling, strict haemostasis, fine sutures and magnification. Tissues should

Alexis Frank Hartmann, 1898–1964, paediatrician, St Louis, MO, USA, described the solution; should not be confused with Henri Albert Charles Antoine Hartmann, French surgeon, who described the operation that goes by his name.

be well vascularised, tension avoided and contamination minimised. The intestine can be anastomosed with single-layer interrupted or continuous extramucosal sutures. Wounds are closed with absorbable sutures in layers or a mass closure. Establishing a layer of fat between skin and muscle in the malnourished or thin child prevents the skin from adhering to muscle. Toothed forceps may be used when closing the skin, but the skin must not be punctured; epidermal tunnels can form, trapping skin debris and creating a comedo-like blackhead. Clean skin incisions are closed with absorbable subcuticular sutures or skin glue, avoiding staples. Minimally invasive approaches can be used at all ages with appropriate instruments, flow rates and pressures. Postoperatively, children recover swiftly with adequate analgesia.

Summary box 17.2

Fasting instructions

- 1 hour for clear fluids
- 4 hours for breast milk
- 6 hours for solids

INGUINOSCROTAL DISORDERS

Undifferentiated gonads, influenced by the Y chromosome, develop into testes in the posterior abdominal urogenital ridges. An abdominal phase in testicular descent involves migration towards the internal ring guided by the gubernaculum. Descent into the scrotum requires fetal testicular testosterone. The peritoneum preceding the testis through the inguinal canal becomes the processus vaginalis, which usually obliterates after birth; failure of obliteration leads to an indirect inguinal hernia or hydrocele (***Figure 17.2***).

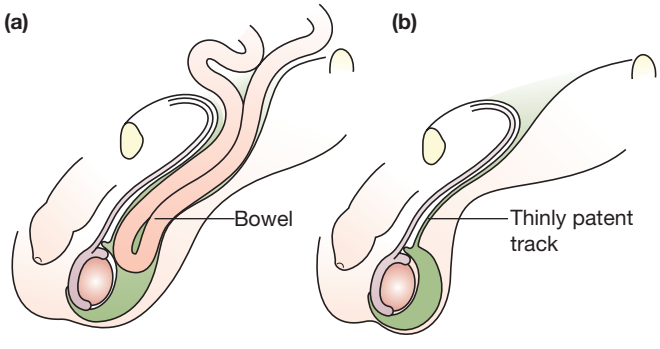

Figure 17.2 (a) Inguinal hernia and **(b)** hydrocele in children are the result of incomplete obliteration of the processus vaginalis.

Inguinal hernias

Inguinal hernias occur in 4% of infants with prematurity, low birth weight and male sex being risk factors (M:F 6:1). Inguinal hernias are twice as common on the right side as on the left, with 10% occurring bilaterally. The hernia may contain omentum, intestine, appendix (Amyand's) or a Meckel's diverticulum (Littre's). An ovary can prolapse and twist in a girl, requiring emergency exploration. Prolapsed ovaries, therefore, need prompt repair. Rarely in phenotypic girls, a testicle is found, suggesting androgen insensitivity (see ***Chapter 20***).

An inguinal hernia presents as an intermittent bulge in the groin extending to the scrotum (***Figure 17.3***) or labia, often exacerbated by crying or straining. Most reduce on lying down or with gentle manipulation. A thickened cord in boys, or round ligament in girls, may be all that is palpable. Reducible inguinal hernias are repaired electively. If the herniated contents become firm, tender and irreducible, there may be oedema and erythema, irritability, vomiting and the passage of some rectal blood. An attempt to reduce an incarceration with sustained gentle pressure may be successful; if unsuccessful, emergency exploration, reduction and repair are required.

Inguinal hernia repair

The herniated contents may reduce after the induction of anaesthesia. If incarcerated, the neck of the sac is found at the external ring. Open repair involves ligating the sac at the external or the internal inguinal ring. In a repair at the internal ring, an incision is made over the inguinal canal, Scarpa's fascia is incised and the fat cleared to expose the external oblique rolling over to form the inguinal ligament. The external

Figure 17.3 A left inguinal swelling. Clinical examination is needed to confidently distinguish a hydrocele from an inguinal hernia.

Claudius Amyand, 1660–1740, French surgeon who performed the first successful appendectomy in 1735. He was first Principal Surgeon to the Westminster Hospital, and founder and first Principal Surgeon to St George's Hospital in London.
Johann Frederick Meckel (the Younger), 1781–1833, Professor of Anatomy and Surgery, Halle, Germany, described his diverticulum in 1809.
Alexis Littre, 1654–1726, surgeon and lecturer in anatomy, Paris, France, described Meckel's diverticulum in a hernial sac in 1700, 81 years before Meckel was born.
Antonio Scarpa, 1752–1832, Italian anatomist and pupil of Morgagni.

oblique is incised to identify the cremaster overlying the sac. The cremaster is opened with fine scissors or blunt dissection. The cord is lifted through the cremaster and a clip passed behind. The sac is mobilised from the testicular vessels and vas deferens. The sac is divided, twisted to reduce any contents and transfixed/ligated at the internal ring. The wound is closed in layers. A laparoscopic approach places an encircling suture at the internal ring.

Hydroceles

A hydrocele is a fluid collection between the parietal and visceral layers of the tunica vaginalis and is usually confined to the scrotum – one can feel the cord above it. Occasionally, it extends into the external ring and one cannot feel the cord. Hydroceles are typically asymptomatic, non-tender and may fluctuate, reducing overnight; they can be bilateral. Infant hydroceles can be tense and uncomfortable, especially if over-examined, causing confusion with an incarcerated inguinal hernia. Although hydroceles transilluminate, this is a flawed test for distinguishing one from an incarcerated inguinal hernia since light easily shines through an infant's intestine.

Surgery is rarely indicated before 2 years because a majority resolve. Occasionally an encysted hydrocele of the cord (or hydrocele of the canal of Nuck in a girl) forms as the processus obliterates; persistence warrants exploration. Occasionally, a febrile boy presents with a viral-like illness and an acute hydrocele. These generally resolve over a few weeks, and only those that remain need exploration. Ligation of a patent processus vaginalis is similar to an inguinal hernia repair.

Teenage boys may have a non-communicating hydrocele with fluid arising from the tunica vaginalis; a plication (Lord's procedure) or excision/eversion of the tunica vaginalis (Jaboulay procedure) are needed.

Undescended testes

A normally descended testis reaches the scrotal floor with a good cord length above it and remains there. Testicular descent is usually complete by the 30th week of gestation. At birth, 4% of full-term and 30% of premature boys have an undescended testis (UDT). Boys should be examined at birth and at 6 weeks; if a UDT is found, they should be seen at 3 months since a testis is unlikely to descend after this time. An orchidopexy is then scheduled for between 6 and 12 months. Occasionally a palpable UDT undergoes torsion and presents as a painful lump in the groin with an empty hemi-scrotum.

Clinical examination distinguishes a normal testis from a palpable or an impalpable UDT. A testis cannot be palpated in the canal; it can only be felt when delivered to the superficial pouch, which is also called Denis Browne's pouch (a pocket between Scarpa's fascia and the external oblique fascia at the external ring). Cremasteric activity may draw a testis into the pouch or the canal. Gentle strokes over the canal, directed towards the scrotum, may deliver a normal scrotal or a palpable UDT. Ectopic testes are found beneath the skin of the medial thigh or lower abdomen; they have a long cord, facilitating easy scrotal placement at operation. If hypospadias is seen with bilateral, impalpable UDTs, then a disorder of sexual differentiation is possible and referral indicated (see ***Chapter 20***).

Retractile testes

A retractile testis is palpable in the groin and can be brought into the scrotum but promptly returns to the groin. Retractile testes are common in infants and most eventually settle in the scrotum; follow-up is needed because some permanently ascend and require an orchidopexy.

Ascending testes

Some scrotal testes in infancy are later found in the high scrotum or groin with ascent attributed to insufficient cord growth; a few were retractile in infancy. An orchidopexy is required. An argument exists for screening all boys for ascending testes in late childhood.

Palpable undescended testes

Palpable UDTs require an orchidopexy at between 6 and 12 months. The canal is opened through an external oblique incision. The testis is mobilised on its vas and vessels, and the gubernaculum is usually divided. Any peritoneal outpocketing is ligated and divided at the internal ring, where dissection adds length to the cord. The testis is placed in a subdartos scrotal pouch. Early orchidopexy, placing the testis in a cooler environment, improves spermatogenesis and may reduce the risk of testicular malignancy.

Impalpable undescended testes

Impalpable UDTs are absent, canalicular or abdominal. Imaging is unreliable. Examination under anaesthesia and laparoscopy is performed at around 1 year. If palpable under anaesthesia, an inguinal orchidopexy is performed. At laparoscopy, a testis is absent if a blind-ending vas is seen. If the vas and vessels enter the inguinal canal, then the groin is explored. A canalicular testis may be amenable to an inguinal orchidopexy, or there may be a remnant to excise. If there is a viable intra-abdominal testis (***Figure 17.4***), a two-stage Fowler–Stephens orchidopexy is performed. In the first stage, testicular vessels are ligated, leaving the testis *in situ*, anticipating survival on the vessels accompanying the vas. Three

months later a second operation is performed; if the testis has survived, it is brought into the scrotum.

ACUTE SCROTAL DISORDERS

Testicular torsion

Intravaginal (bell clapper) testicular torsion is well recognised in adolescents but may occur at any age. Abnormal posterior anchoring of the testis allows torsion within the tunica vaginalis. Torsion compromises blood flow, causing acute scrotal or abdominal/groin pain, nausea and vomiting. Tenderness, an absent cremasteric reflex and a high testis may be found on examination; oedema and erythema appear later. Sometimes there have been transient episodes (intermittent torsion). Doppler ultrasound may help (***Figure 17.5***). Exploration within 6–8 hours of the onset of symptoms improves the chances of testicular salvage.

At operation, testicular viability is assessed after derotation (***Figure 17.6***). Only gangrenous testes should be excised since some severely compromised testes survive, and those that then atrophy are not harmful. If salvageable, three-point fixation of both testes with non-absorbable sutures is performed or a dartos pouch is fashioned.

Extravaginal torsion is seen in newborns, with 70% occurring prenatally and 30% postnatally; emergency neonatal exploration remains controversial since salvage rates are low.

Torsion of the appendix testis and appendix epididymis

The appendix testis (hydatid of Morgagni) is a remnant of the Müllerian (paramesonephric) duct, whereas the appendix epididymis is a Wolffian (mesonephric) remnant. Both are

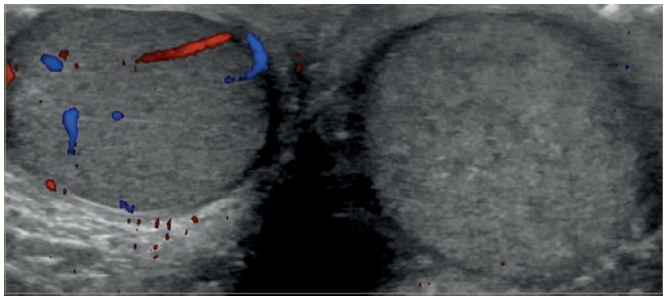

Figure 17.5 The red and blue colour on one testis shows normal blood flow whereas the contralateral testis has no blood supply, consistent with a torsion.

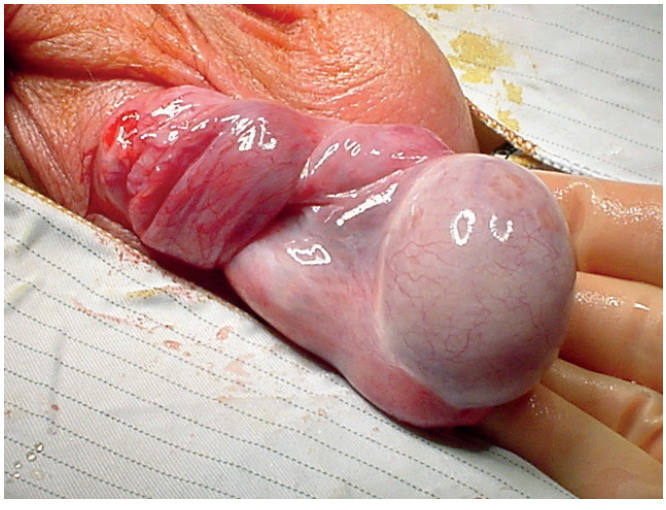

Figure 17.6 Torsion of the right testis with only modest vascular compromise in a boy with a history of intermittent pain.

small and pedunculated and are located on the upper testis or epididymis; they can twist and infarct (***Figure 17.7***). Appendage torsion occurs most commonly between 7 and 14 years. Mild to severe acute scrotal pain is present, usually without vomiting. On examination, a small area just above the testis may be tender; occasionally, a dark mass is visible, known as the blue-dot sign. A Doppler ultrasound can help exclude testicular torsion. Analgesia, and rest, may be sufficient, with exploration reserved for severe pain and equivocal cases.

Epididymo-orchitis

Bacterial or viral inflammation is occasionally found on exploration for suspected torsion. Epididymitis is seen before 6 months and is caused by infected urine travelling up the vas. Epididymo-orchitis (*Chlamydia trachomatis, Neisseria gonorrhoea* and *Escherichia coli*) is seen after puberty in sexually active boys presenting with acute testicular pain, dysuria, frequency, urethral discharge and fever. In addition, there may be scrotal

Giovanni Battista Morgagni, 1682–1771, Italian anatomist, considered the father of modern anatomical pathology.
Johannes Peter Müller, 1801–1858, German physiologist, comparative anatomist, ichthyologist and herpetologist.
Caspar Friedrich Wolff, 1733–1794, German physiologist and one of the founders of embryology.

Figure 17.7 Two torted and infarcted hydatids, one arising from the epididymis and one from the testis.

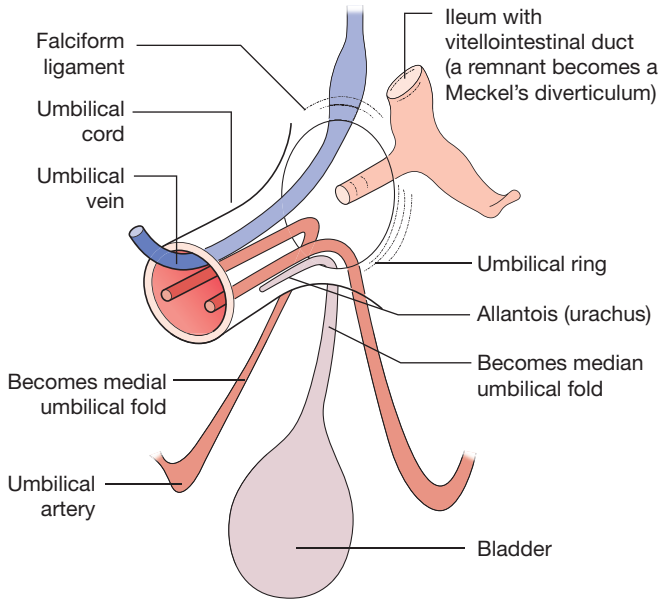

Figure 17.8 Structures at the umbilicus.

erythema and oedema with a normal cremasteric reflex. Pain may subside on elevation of the testis (Prehn's sign). Management includes rest, analgesia, antibiotics and re-evaluation if there is no improvement.

Idiopathic scrotal oedema

Typically, a 5- to 7-year-old boy presents with a swollen hemi-scrotum with erythema extending towards the anus and the groin. The testicle is scrotal and not tender, though the dartos and skin are swollen. Antihistamines may help.

MIDLINE HERNIAS

The embryonic umbilical ring encircles a defect in the ventral abdominal wall transmitting structures connecting the fetus to the placenta (***Figure 17.8***). Umbilical hernias are common following incomplete closure of the umbilical ring, though incarceration is rare. Most umbilical hernias resolve by 4 years. Supraumbilical hernias are defects in the linea alba just above the umbilical ring; these do not close but are still repaired around 4 years. Epigastric hernias are defects higher still that allow a small amount of preperitoneal fat to prolapse; they are repaired if symptomatic.

INFANTILE HYPERTROPHIC PYLORIC STENOSIS

Pyloric stenosis presents with non-bilious projectile vomiting starting between 2 and 6 weeks of age. Its presentation differs from infective causes of vomiting (e.g. meningitis, urinary tract infections [UTIs]) because of postprandial hunger. Once vomiting starts, its frequency and forcefulness increase daily, distinguishing it from gastro-oesophageal reflux (GOR), which waxes and wanes and starts shortly after birth. In the UK, pyloric stenosis affects 1:300 infants with a M:F ratio of 4:1. There is often a maternal family history.

If the presentation is early, clinical findings are unremarkable; if late, weight loss and dehydration requiring resuscitation predominate. The diagnosis is made on a test feed or on abdominal ultrasound showing a thickened and lengthened pylorus. In a test feed, gastric peristalsis is seen passing from left to right across the abdomen, and in a relaxed (feeding) baby, the pyloric 'tumour' is palpable as an 'olive' in the right upper quadrant. Feeds are discontinued, and the stomach is emptied with an 8–10Fr nasogastric tube. Loss of gastric acid causes a hypochloraemic, hypokalaemic alkalosis and correction may take 24–48 hours; 0.9% saline with 0.15% KCl in 5% glucose given at 6–7.5 mL/kg/h provides maintenance and corrects deficits in most babies. As the chloride deficit is replaced, the kidneys correct the pH.

Ramstedt's pyloromyotomy is performed laparoscopically or through a supraumbilical or right upper quadrant incision. A pyloric serosal incision is made, and the 'tumour' spread (***Figure 17.9***), leaving an intact submucosa from the duodenal fornix to gastric antrum. The incision must extend onto the stomach; short incisions cause an early recurrence. Postoperatively, intravenous fluids are continued until feeds are re-established within 24 hours. Early postoperative vomiting usually swiftly resolves, with GOR being more likely than an incomplete myotomy if it persists.

GOR is common and tends to resolve spontaneously with maturity. Persistent symptoms respond to thickened feeds and antireflux medication. Failure to thrive or respiratory problems demand investigation and, in some cases, laparoscopic fundoplication.

Douglas Prehn, 1901–1974, American urologist, Wisconsin, USA.
Wilhelm Conrad Ramstedt, 1867–1963, German surgeon credited with describing the pyloromyotomy.

Figure 17.9 Pyloromyotomy for infantile hypertrophic pyloric stenosis.

Figure 17.10 Ileocolic intussusception causing small bowel obstruction.

INTUSSUSCEPTION

Most intussusceptions occur between 2 months and 2 years. More than 80% are ileocolic (*Figure 17.10*), beginning proximal to the ileocaecal valve with an apex in the ascending or transverse colon. Strangulation can progress to gangrene and perforation. The lead point is commonly viral-induced hyperplasia in a Peyer's patch, but a few have a pathological lead such as a Meckel's diverticulum, duplication cyst or a small bowel lymphoma. Pathological leads are found more commonly in those over 2 years and in a recurrence.

A previously healthy infant presents with colicky pain, vomiting and drawing up their legs. Between episodes, they initially appear well. Later, they may pass a 'redcurrant jelly' stool. Signs include dehydration, abdominal distension and a palpable right upper quadrant mass.

A plain radiograph shows small bowel obstruction, a mass and a paucity of gas in the right iliac fossa. A concentric target sign is seen on an abdominal ultrasound. An air reduction enema is attempted after resuscitation with intravenous fluids, broad-spectrum antibiotics and nasogastric drainage (*Figure 17.11*). Success is recognised if air flows into the small bowel and symptoms and signs resolve. An air enema is contraindicated if there is peritonitis, perforation or shock. More than 70% are reducible non-operatively. Strangulation and pathological lead points are unlikely to reduce. Colonic perforation during pneumatic reduction is rare. Recurrence occurs in 5% after non-operative reduction. Operative reduction is performed open or laparoscopically. An irreducible intussusception or one complicated by infarction or a pathological lead point requires resection.

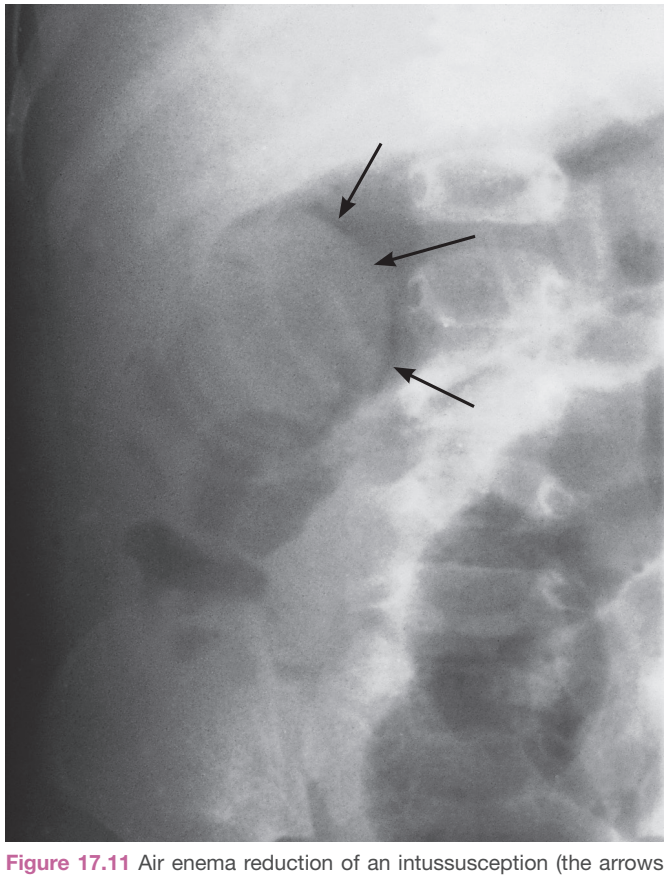

Figure 17.11 Air enema reduction of an intussusception (the arrows mark the soft tissue shadow of the intussusceptum).

ACUTE APPENDICITIS

In early appendicitis, there is a fever of 37.3–38.4°C, anorexia, a few vomits and central abdominal pain settling in the right iliac fossa. Persistent guarding in the right iliac fossa distinguishes it from self-resolving non-specific abdominal pain (NSAP). Investigations and scoring systems may help but neither replace regular clinical review. Treatment starts with intravenous fluids, analgesia and broad-spectrum antibiotics. Early appendicitis is managed laparoscopically, though some mild cases may resolve with antibiotics alone.

Johann Conrad Peyer, 1653–1712, Swiss anatomist.

Complicated appendicitis describes any of the following: perforation, abscess formation, a mass or generalised peritonitis. One pitfall is to diagnose gastroenteritis when there are loose stools, and another is to attribute pain on micturition and pyuria to a UTI; both can occur in pelvic appendicitis with a collection. Referred pain from right lower lobe pneumonia should be considered. Antibiotics given for any reason may mollify signs and delay or complicate a presentation. The diagnosis can be difficult in those under 5 years, with many presenting after a perforation. Before 5 years, the omentum is less well developed and inflammation less well contained. An appendix mass in an unobstructed child may respond to non-operative management with antibiotics. An interval appendicectomy can be considered 6 weeks later but is not mandated.

Non-specific abdominal pain

The clinical features of NSAP are similar to acute appendicitis, but the pain is poorly localised, not aggravated by movement and not accompanied by guarding. The site and severity of maximum tenderness vary on repeated examinations. Symptoms are typically self-limiting. The aetiology is obscure, but viral infections are hypothesised if there is lymphadenopathy. In some children, recurrent abdominal pain can be organic; in others, it is eventually attributed to an underlying psychosocial problem.

Rare causes of abdominal pain

Other causes of acute abdominal pain include Henoch–Schönlein purpura, sickle cell disease, primary peritonitis, acute pancreatitis, biliary colic, testicular torsion, gynaecological pathology (e.g. ovarian cysts and tumours, pelvic inflammatory disease, haematometrocolpos) and urinary stone disease. UTIs in children may be due to a urinary tract abnormality and may lead to renal scarring from ascending infection. Infection and obstruction are particularly hazardous; see *Chapter 20*.

ANORECTAL PROBLEMS

Constipation

The passage of hard or infrequent stools may be secondary to an anal fissure, Hirschsprung's disease, an anorectal malformation, a neuropathic bowel, a mega-rectosigmoid or idiopathic constipation. A detailed history and examination of the abdomen, anus and spine identify most causes. A rectal biopsy may be needed to exclude late presenting Hirschsprung's disease. In the absence of surgical pathology, the child is best managed by a paediatrician.

Rectal prolapse

Rectal mucosal prolapse occurs in toddlers and is exacerbated by straining or squatting on defecation. It is typically intermittent and self-limiting. Underlying constipation should be treated. Rarely, it may be secondary to cystic fibrosis or spinal dysraphism. A rectal polyp can mimic a prolapse. Recurrent symptomatic prolapse may respond to injection sclerotherapy. Rare cases need laparoscopic rectopexy.

Meckel's diverticulum

A 4-year-old presenting with a haemoglobin level of 40 g/L will most likely have bled from an ulcer adjacent to a Meckel's diverticulum containing ectopic gastric mucosa (***Figure 17.12***). A technetium scan may demonstrate ectopic gastric mucosa (***Figure 17.13***). A Meckel's diverticulum may also be complicated by an obstructing band between the diverticulum and the umbilicus, diverticulitis, intussusception, intestinal volvulus or perforation.

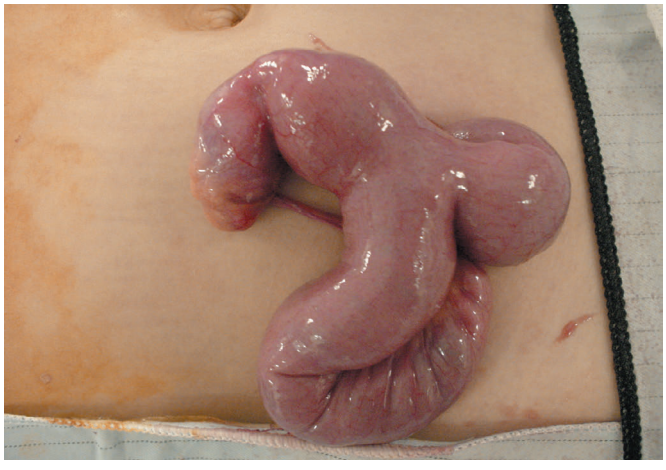

Figure 17.12 Meckel's diverticulum containing ectopic gastric mucosa.

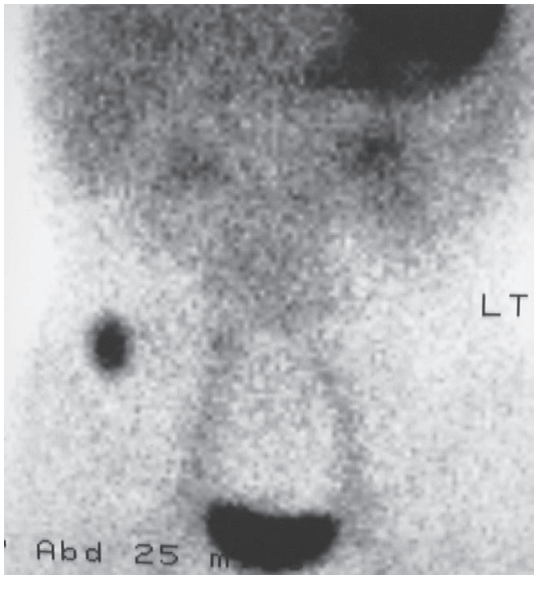

Figure 17.13 A positive Meckel's scan.

Eduard Heinrich Henoch, 1820–1910, Professor of Diseases of Children, Berlin, Germany, described this form of purpura in 1868.
Johann Lucas Schönlein, 1793–1864, Professor of Medicine, Berlin, Germany, published his description of this form of purpura in 1837.
Harald Hirschsprung, 1830–1916, physician, The Queen Louise Hospital for Children, Copenhagen, Denmark, described congenital megacolon in 1887.

Swallowed or inhaled foreign bodies

Coins and other foreign bodies are often swallowed and, if radio-opaque, are seen on a plain radiograph. Oesophageal objects are removed endoscopically under general anaesthesia. Oesophageal button batteries must be removed within hours as they can perforate into the trachea or aorta. Once beyond the cardia, most objects pass in a few days. Batteries in the stomach are removed urgently or followed closely with repeat radiographs. The need to remove sharp objects depends on their size, location and the age of the child. Ingested magnets can cause entero-enteric fistulae when they fix to one another in adjacent loops of bowel.

Inhaled foreign bodies cause sudden-onset coughing and stridor. If there is worsening dyspnoea or hypoxia in an infant they should be given back blows in a head-down position. Abdominal thrusts (Heimlich manoeuvre) are reserved for older children. A foreign body in a bronchus is suggested by a unilateral wheeze, decreased transmitted breath sounds and a hyperinflated lung on an expiratory chest radiograph. Rigid bronchoscopy with a ventilating bronchoscope facilitates removal.

GASTROSTOMY

A gastrostomy may be requested for nutritional support. Options include an open Stamm gastrostomy, a Ponsky–Gauderer percutaneous endoscopic gastrostomy (PEG) or a laparoscopic approach using a Seldinger technique. The Stamm gastrostomy employs two gastric purse-string sutures imbricated to fashion a tunnel. In the PEG technique, a gastroscope illuminates the stomach and abdominal wall, allowing identification of a site through which a needle and wire are passed into the stomach and extracted orally. A gastrostomy tube is then drawn into place. In the Seldinger technique, the stomach is punctured percutaneously with a needle through which a guidewire is advanced, and the needle is then withdrawn. A series of dilators are passed over the guidewire and finally the gastrostomy tube; the guidewire is then withdrawn.

PAEDIATRIC SURGICAL ONCOLOGY

Neuroblastoma and nephroblastoma are two solid abdominal tumours.

Neuroblastomas arise in the adrenal medulla or sympathetic ganglia and present with an abdominal or paravertebral mass. They metastasise to lymph nodes, bone and liver, raising urinary catecholamine levels. Small, localised tumours are excised. Advanced tumours are excised after chemotherapy. Survival exceeds 90% for small, localised tumours but is less than 50% for advanced tumours.

Wilms' tumour (nephroblastoma) is a malignant renal tumour derived from embryonal cells and typically presenting with an abdominal mass between 1 and 4 years. A mutation in the Wilms' tumour suppressor gene (*WT1*) causes some cases. The tumour can extend into the renal vein and vena cava and metastasises to lymph nodes and lungs. Treatment is with chemotherapy and surgery. Survival depends on tumour spread, completeness of excision and histological appearance but exceeds 70% even with advanced tumours.

Henry Judah Heimlich, 1920–2016, thoracic surgeon, Xavier University, Cincinnati, OH, USA.
Martin Stamm, 1847–1918, American gastric surgeon, educated in Germany.
Jeffrey Ponsky, contemporary, endoscopist, Rainbow Babies & Children's Hospital, University Hospitals of Cleveland, Cleveland, OH, USA.
Michael WL Gauderer, contemporary, paediatric surgeon, Greenville, SC, USA.
Sven Ivar Seldinger, 1921–1998, Swedish radiologist, introduced the procedure in 1953.
Carl Max Wilhelm Wilms, 1867–1918, German pathologist and surgeon, died of diphtheria after operating on the larynx of a French prisoner of war.

PART 2 | General paediatrics

CHAPTER
18 Neonatal surgery

Learning objectives

To be able to:

- List five aetiological classes underlying structural congenital anomalies
- Give five examples of how neonatal physiology and anatomy influence surgical care
- Describe at least five congenital anomalies managed by neonatal surgeons
- Outline the presentation and management of necrotising enterocolitis
- Describe two newborn tumours
- Explain why adult surgeons need an overview of neonatal surgery

INTRODUCTION

Neonatal surgeons are paediatric surgeons who manage life-threatening non-cardiac congenital anomalies and the acquired condition necrotising enterocolitis (NEC), seen in premature babies. Structural anomalies are associated with gene defects, aneuploidies (abnormal number of chromosomes), infections (e.g. toxoplasmosis, cytomegalovirus, rubella) and teratogens (e.g. drugs, smoking, alcohol). Late mechanical aetiologies are illustrated by ileal volvulus in cystic fibrosis, some lung hypoplasia in congenital diaphragmatic hernias and small intestine loss in closing gastroschisis. Insults acting during gastrulation – when cells are told what to do and where to go – may cause multiple anomalies, e.g. VACTERL syndrome (**v**ertebral, **a**norectal, **c**ardiac, **t**racheo**e**sophageal, **r**enal and **l**imb anomalies) and CHARGE syndrome (**c**oloboma, **h**eart defects, choanal **a**tresia, growth **r**etardation, **g**enital anomalies and **e**ar anomalies). See ***Chapter 44*** for neural tube defects and ***Chapter 59*** for heart defects. See ***Chapter 48*** for the overlap with general surgery of childhood. ***Table 18.1*** illustrates the need for careful examination, imaging and genetic investigations to screen for associations when an anomaly is found. When well-recognised anomalies are identified antenatally, neonatal surgeons, working with fetal medicine specialists and neonatologists, counsel parents about prognosis and postnatal surgical management.

NEWBORN PHYSIOLOGY AND THE PRINCIPLES OF NEONATAL SURGERY

Neonatal physiology can pose challenges when there is a surgical condition (***Table 18.2***). Perioperatively, a newborn needing ventilation is best managed in a surgical unit co-located with a medical neonatal intensive care unit (NICU). Some babies are transferred many miles between units. If a neonatal surgical transfer team is not available, accompanying clinicians should be reminded that neonates with bowel obstruction need a nasogastric tube to decompress the stomach; this should be left on free drainage and regularly aspirated.

Neonates, especially the premature, lose heat and fluid rapidly, have poor nutritional reserves, are susceptible to infection and have an immature blood-brain barrier. Surgery should be efficiently performed in a warm environment with gentle tissue handling and broad-spectrum antibiotic cover. The liver can be fragile, and blood should be available for laparotomies. Sick babies with NEC or an acute volvulus may be best operated upon at the cot side in a NICU. In an unstable infant with an acute abdomen, damage control principles should be applied with a second-look laparotomy and definitive repair following stabilisation. Electrocautery is delivered on the lowest working setting. Avoid the Trendelenburg position in the preterm when placing a diathermy pad as elevation risks intraventricular haemorrhages.

A laparotomy may be performed through a right-sided transverse muscle-cutting incision just above the umbilicus, taking care to avoid the large, fragile liver, or through a midline longitudinal incision, avoiding the bladder, which rises into the abdomen. A muscle-sparing symmetrical supraumbilical

Friedrich Trendelenburg, 1844–1924, Professor of Surgery successively at Rostock (1875–1882), Bonn (1882–1895), Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

TABLE 18.1 Congenital malformations managed by neonatal surgeons.

Primary abnormality	Incidence/ 100 000 live births	Associations illustrating the need for screening
Oesophageal atresia/ tracheoesophageal fistula	24	VACTERL, CHARGE, aneuploidy/other gene defects, duodenal atresia, anorectal malformations, tracheomalacia, gastroesophageal reflux
Duodenal atresia	13	Trisomy 21, other intestinal atresias, oesophageal atresia/tracheoesophageal fistula, intestinal malrotation
Intestinal atresias	10	Cystic fibrosis, other atresias
Anorectal malformations	26	Oesophageal atresia/tracheoesophageal fistula, VACTERL, Trisomy 21
Hirschsprung's disease	14	Trisomy 21, other chromosomal defects, familial **Structural anomalies**: Cardiac, craniofacial, cleft palate, polydactyly, intestinal atresias/anorectal malformations **Syndromic**: Multiple endocrine neoplasia, Waardenburg–Shah syndrome, congenital hypoventilation syndrome (Ondine's curse)
Biliary atresia	3	Biliary atresia splenic malformation (BASM) syndrome: polysplenia, vascular and cardiac anomalies, defects of situs Cytomegalovirus
Gastroschisis	20	Intestinal atresias, undescended testes
Exomphalos (major and minor)	12	Aneuploidy, chromosomal anomalies, cardiac defects, Beckwith–Wiedemann syndrome
Congenital diaphragmatic hernia	20	Aneuploidy, chromosomal anomalies, CHARGE, malrotation. Syndromic
Congenital pulmonary airway malformations (CPAM)	10	Vertebral/chest wall deformities, intestinal duplications, cardiac anomalies, congenital diaphragmatic hernia

CHARGE, **c**oloboma, **h**eart defects, choanal **a**tresia, growth **r**etardation, **g**enital anomalies and **e**ar anomalies; VACTERL, **v**ertebral, **a**norectal, **c**ardiac, **t**racheoesophageal, **r**enal and **l**imb anomalies.

incision or an omega incision are options with the recti pulled laterally. A left-sided diaphragmatic hernia can be approached through a subcostal incision. The umbilical vein remains patent for many days and is divided between ligatures if the midline is crossed. Gastrointestinal surgery may involve bowel resection with a single layer interrupted or continuously sutured anastomosis or formation of a temporary spouted enterostomy. In stable, well babies, laparoscopy is suitable for some procedures (e.g. duodenal atresia repair, malrotation without acute volvulus, excision of large ovarian cysts). Central venous access is needed for parenteral nutrition (PN) if enteral feeds are likely to be delayed.

NEONATAL GASTROINTESTINAL SURGERY

Oesophageal atresia/ tracheoesophageal fistula (OA/TOF)

Five anatomical variations appear in *Figure 18.1*. When the oesophagus ends blindly, amniotic fluid cannot be swallowed and polyhydramnios results. If there is no fistula (type A), the stomach may be small or difficult to detect antenatally and is often wrongly referred to as 'absent'. Postnatal presentations are with drooling, aspiration or cyanosis on feeding.

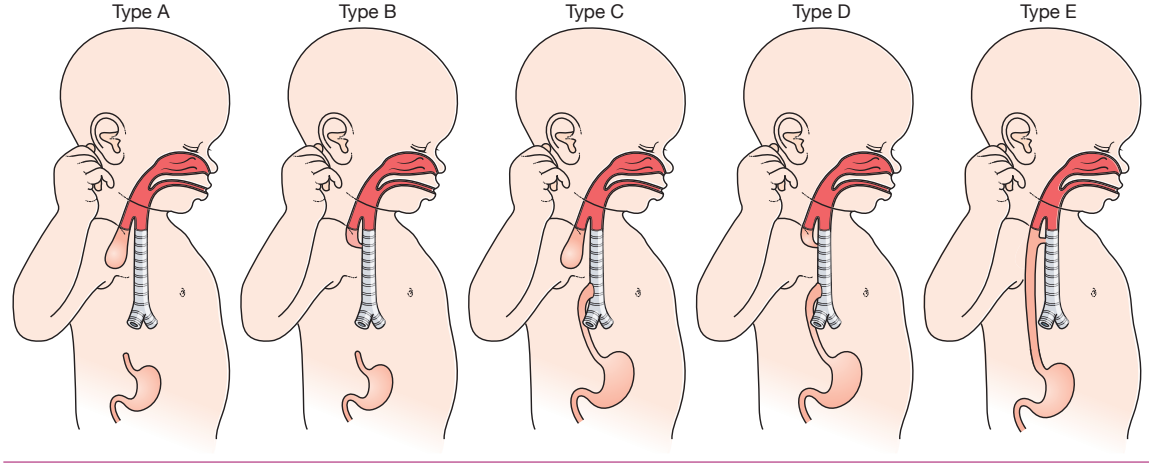

Figure 18.1 Anatomical variations in tracheoesophageal fistula with or without oesophageal atresia. In Type C, the upper pouch ends in the neck or upper chest but occasionally it reaches the fistula where muscle fibres are shared.

Harald Hirschsprung, 1830–1916, first Danish paediatrician, considered Hirschsprung's disease to be developmental.

Table 18.2 Physiological considerations in newborn infants.

Airway

Intubation can be challenging as the occiput flexes the neck, the tongue is large and the epiglottis is long, angulated and positioned high and close to the soft palate.

- A straight blade laryngoscope, an uncuffed tube and a neutral position for the neck

Abdomen

The liver is large and fragile and the bladder rises out of the pelvis. The abdomen must be entered carefully. The umbilical vein is patent for many days after birth and is ligated before being divided.

Respiratory (respiratory distress syndrome [RDS], chronic lung disease)

Preterm delivery, gestational diabetes and birth asphyxia all lower pulmonary surfactant levels, resulting in decreased lung volume and compliance and promoting airway collapse on expiration and atelectasis. Fewer type 1 muscle fibres in the diaphragm and intercostals increases early fatigue. Chronic inflammatory lung disease with scarring is seen in preterm babies from prolonged ventilation, overinflation, high pressures and oxygen toxicity.

- Surfactant, oxygen, continuous positive airway pressure (CPAP) or mechanical ventilation

Cardiovascular

A fall in pulmonary vascular resistance (PVR) at birth helps establish the postnatal circulation.

- In the early postnatal period, hypoxia, stress, high PCO_2 or acidosis may raise PVR; if the ductus arteriosus and foramen ovale are open, blood shunts R→L causing hypoxaemia
- An underdeveloped baroreflex means unchecked blood loss leads rapidly to hypotension

Fluids and electrolytes

Excess total body water and extracellular fluid are excreted after birth in a physiological diuresis. Insensible losses increase with low birth weight and low gestational age. The immature kidney loses sodium, bicarbonate, glucose, amino acids and phosphates. Low glycogen stores at birth promote hypoglycaemia, particularly in the preterm.

- Use local neonatal intensive care unit (NICU) protocols. Maintenance fluids need 10% glucose and appropriate electrolytes
- Watch for hyperglycaemia with hypernatraemia, which increases the risk of intraventricular haemorrhage in the preterm
- Replace nasogastric losses or stoma losses (>15 mL/kg/day) millilitre for millilitre with 0.9% NaCl, 0.15% KCl

Nutrition

Reserves are deficient in the premature and postnatal starvation affects neurological development.

- Start central parenteral nutrition as a matter of urgency

Thermoregulation

A high surface area to bodyweight ratio increases heat loss; particularly during exposure for anaesthesia (exacerbated by vasodilation) and surgery, there is an inability to shiver. Low temperatures promote coagulopathy, which is compounded by the acidosis from poor peripheral perfusion and myocardial depression.

- Warm incubators, limit exposure for procedures, warm theatre, warm fluids

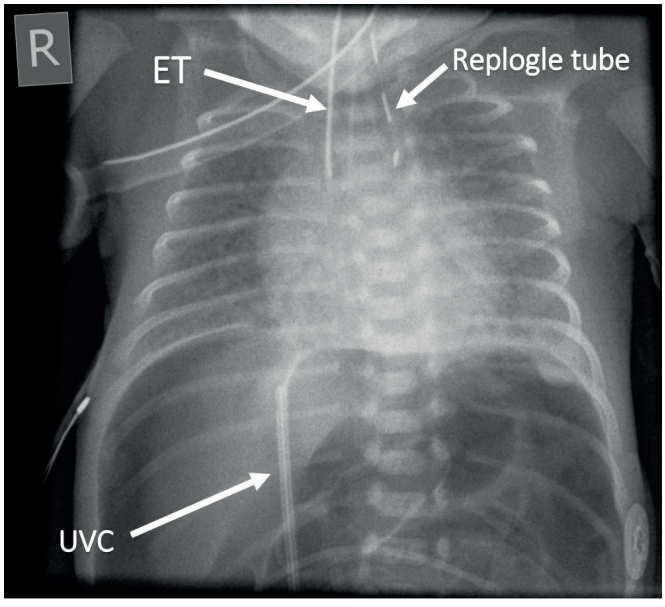

Figure 18.2 Tracheoesophageal fistula/oesophageal atresia with gastric perforation in a 28-week gestation, 1000-g baby. Note the endotracheal tube (ET), Replogle tube in the upper pouch, the umbilical venous catheter (UVC), free abdominal air around the liver and either side of the falciform ligament above the UVC and patchy lung fields of respiratory distress syndrome.

A nasogastric tube coiled in the upper oesophageal pouch on a chest radiograph suggests the diagnosis. A nasal or oral sump Replogle tube is placed to drain saliva and prevent aspiration. Positive airway pressure is avoided as air passing through the fistula causes gastric distension, compromised ventilation, and risks perforation (***Figure 18.2***). If pressure support is needed, perhaps because of RDS, prompt fistula ligation is needed.

Types A and B typically have a long gap and may require oesophageal replacement; options include colonic or jejunal interposition or gastric transposition some months after a cervical oesophagostomy and a gastrostomy. In many cases the ends can be brought together by progressive traction and delayed anastomosis.

In types C and D, the fistula is divided through a right thoracotomy or thoracoscopically. If the neonate is stable and the gap favourable, an anastomosis is fashioned over a trans-anastomotic tube, facilitating early feeding. If a primary anastomosis is not possible, then options include a delayed anastomosis after a few weeks of growth, or the use of traction sutures and an earlier anastomosis, or a much later interposition. Traction sutures can be internal or external. Nutrition is supported through a gastrostomy.

Complications after a repair include anastomotic leaks, oesophageal strictures and refistulation. Minor leaks often settle without intervention, strictures need dilating with a bougie or a balloon, and refistulation needs repair.

Type E is an isolated 'H'-type tracheoesophageal fistula without atresia. The fistula is usually found in the neck on a contrast swallow. Type E presents with recurrent chest infections or coughing after feeds and is usually repaired in the neck.

Robert L Replogle, 1931–2016, Chicago, the last trainee of Robert E Gross.

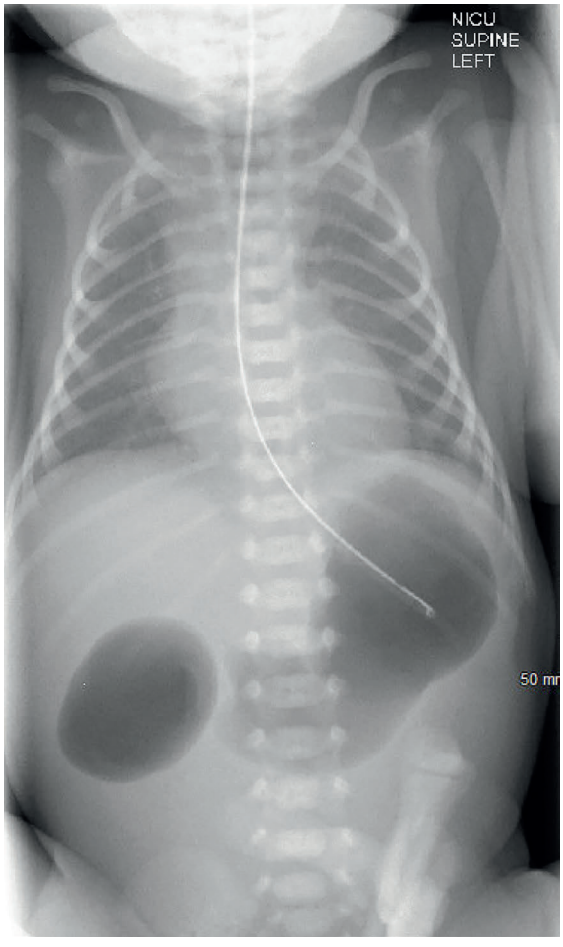

Figure 18.3 Double bubble in duodenal atresia (gastric and first part of the duodenum). Note the umbilical cord and clamp in the lower part of the image.

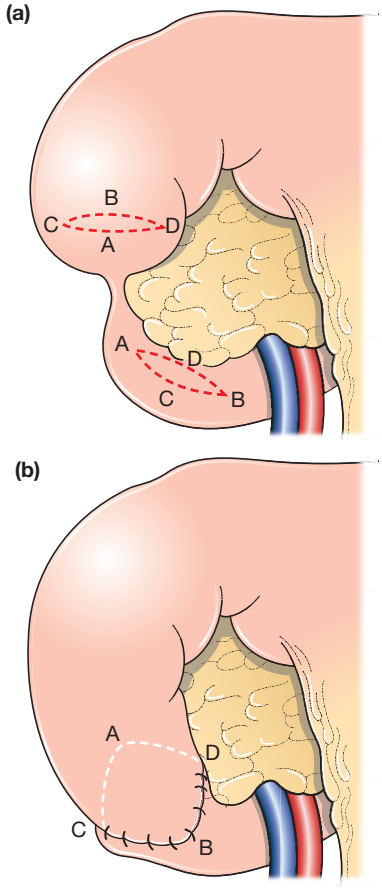

Figure 18.4 (a, b) Duodenal atresia and the incisions used to repair it: a diamond anastomosis is shown.

Duodenal atresia

The obstruction in duodenal atresia usually lies just distal to the ampulla of Vater. The proximal duodenum and pylorus dilate with swallowed amniotic fluid, rendering the pylorus temporarily incompetent. Occasionally, there is a web that may stretch like a windsock. If suspected antenatally, duodenal atresia is confirmed postnatally on an abdominal radiograph, showing a 'double bubble' (***Figure 18.3***); if missed, it presents with bilious vomiting. The hepatopancreatic duct may have openings on either side of the atresia, and a little gas can pass distally. Repair is by open Kimura duodenoduodenostomy (***Figure 18.4***) with or without a trans-anastomotic tube.

Small bowel atresias

Small bowel atresias may be isolated (***Figure 18.5***) or multiple. If seen without other anomalies, they are thought to have been caused by localised vascular events occurring after organogenesis. Rarely multiple intestinal atresias are seen with an immune deficiency related to mutations of the tetratricopeptide gene (TTC7A). A segmental ileal volvulus can cause an atresia; thick meconium in cystic fibrosis is a risk factor. The upstream bowel dilates and becomes dysmotile, while the downstream bowel remains narrow; a primary anastomosis can accommodate up to a 5:1 discrepancy. Resection of the dilated portion is appropriate if this does not sacrifice too much intestine. Otherwise, a temporary stoma and mucous fistula facilitate a staged repair.

Malrotation and volvulus

Complex rotations *in utero* give the small bowel mesentery its broad, stable base, running from the duodenal–jejunal (DJ) flexure in the left upper quadrant to the caecum in the right lower quadrant. Incomplete rotations leave the mesentery with a narrow, unstable base at risk of twisting. Sometimes, fibrous Ladd's bands run between a central upper abdominal caecum and the right lateral abdominal wall, obstructing the duodenum (***Figure 18.6***). A chronic volvulus that spares the vessels may present with protein-losing enteropathy or chylous ascites, while acute luminal obstruction presents with green bilious vomiting and is the harbinger of vascular compromise

Abraham Vater, 1684–1751, Professor of Anatomy and Botany, and later of Pathology and Therapeutics, Wittenberg, Germany.
Ken Kimura, contemporary, paediatric surgeon, Kobe University, Kobe, Japan, and Iowa City, IA, USA.

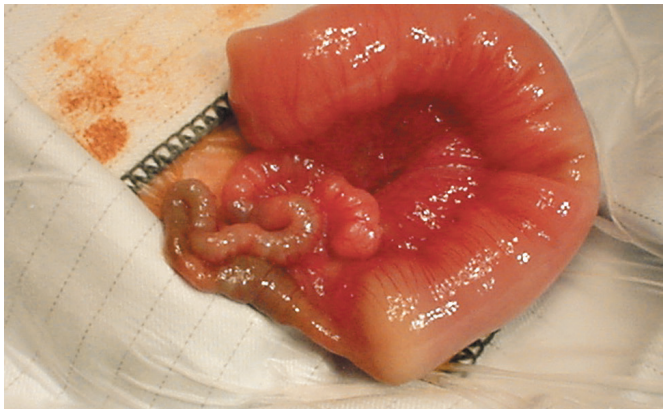

Figure 18.5 Small bowel atresia.

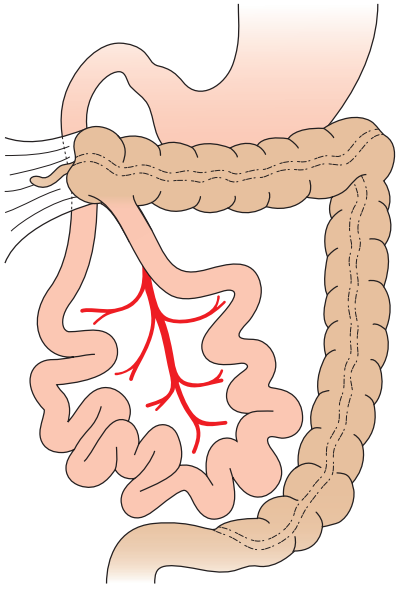

Figure 18.6 The narrow origin of the small bowel mesentery predisposes to midgut volvulus.

Figure 18.7 An acute small bowel volvulus with vascular compromise: the baby's head is to the right. Note that the terminal ileum, caecum and appendix in the upper central abdomen are well perfused.

(***Figure 18.7***), which can be fatal. An acute small bowel volvulus suspected in an acidotic baby vomiting bile with a gasless abdominal radiograph and a scaphoid abdomen demands an immediate laparotomy. Well babies presenting with bilious vomiting have a contrast study to locate the DJ flexure. If the DJ flexure lies to the left of the vertebral column, at the level of the pylorus, the mesentery is likely to be stable. At operation, the bowel is placed in the non-rotated position and the mesentery is broadened – Ladd's procedure (***Figure 18.8***).

Figure 18.8 Ladd's procedure: the duodenum is placed on the right, the colon on the left and the mesentery is broadened. The duodenum appears to lie near the colon since the wound is small. The appendix may be removed.

Meconium ileus

Inspissated meconium may cause a distal ileal obstruction. A segmental ileal volvulus can follow and create an atresia. If the ileum perforates, it may seal or persist and cause a large meconium pseudocyst. An abdominal radiograph shows obstruction with a ground-glass appearance. Peritoneal calcification indicates an antenatal perforation. Simple cases are managed with a water-soluble hyperosmolar contrast enema (diatrizoate) using fluoroscopy in a well-hydrated neonate (***Figure 18.9***). Complicated cases require a laparotomy and enterotomy for a luminal washout; a temporary stoma may be required. Postoperatively, N-acetylcysteine can be given by nasogastric tube and as enemas to loosen residual meconium. Genetic investigations look for defects in the cystic fibrosis transmembrane conductance regulator (CFTR) protein.

Necrotising enterocolitis

NEC is a patchy haemorrhagic enteritis seen in about 10% of preterm babies on NICUs; all are more than a few days old and have been fed. NEC is less common in breastfed than in

Figure 18.9 Water-soluble contrast in meconium ileus showing a microcolon.

Figure 18.10 A ventilated neonate with an acute abdomen awaiting laparotomy.

formula-fed babies. NEC commonly involves the colon and terminal ileum, less commonly the jejunum and rarely the duodenum. Mild NEC presents with feed intolerance, bilious aspirates, distension and rectal bleeding – gut rest, antibiotics and PN may be sufficient treatment. If tenderness and signs of sepsis are present surgical intervention may be needed, especially if there is a deterioration needing mechanical ventilation and inotropes. Some can be observed closely for a short time. A laparotomy is needed if there is no improvement, a persistent mass, worsening obstruction, perforation, or further deterioration. The sickest babies have a rapidly progressing multiorgan failure with a discoloured abdomen (***Figure 18.10***) and a mortality of around 30%. Radiological signs include pneumatosis intestinalis (***Figure 18.11***), gas in the portal vein and if perforated, a pneumoperitoneum. A peritoneal drain can occasionally be sufficient, but definitive surgery is usually needed. At laparotomy (***Figure 18.12***), bowel resection and anastomosis or a defunctioning stoma are options. In the sickest babies, dead intestine is removed, open bowel ends closed (clip and drop), and the abdomen left open (laparostomy) with a vacuum dressing applied on low suction. Definitive surgery follows stabilisation. Survivors with >40 cm of small intestine usually adapt over a few months, but others may need prolonged admissions or home PN.

Figure 18.11 Abdominal radiograph showing pneumatosis.

Biliary atresia/choledochal malformation

Congenital or acquired (e.g. cytomegalovirus) extrahepatic biliary atresia is a progressive obliterative cholangiopathy with absent or narrow bile ducts. Type I involves the common bile duct, type II the common hepatic duct, and 80% have the most common type III, involving the proximal bile ducts. Biliary atresia presents with conjugated hyperbilirubinaemia, pale stools and dark urine in the first few weeks of life. If presenting late, there may be malabsorption, growth failure and coagulopathy. Some associations appear in ***Table 18.1***. The diagnosis is confirmed with a radionucleotide hepatobiliary iminodiacetic acid (HIDA) scan. Early diagnosis and avoiding sepsis may prevent irreversible liver fibrosis and death. The Kasai hepatico-portoenterostomy using a jejunal Roux-en-Y loop anastomosed to the portal plate gives drainage for some years,

Morio Kasai, 1922–2008, pioneering Japanese surgeon, trained by C Everett Koop.

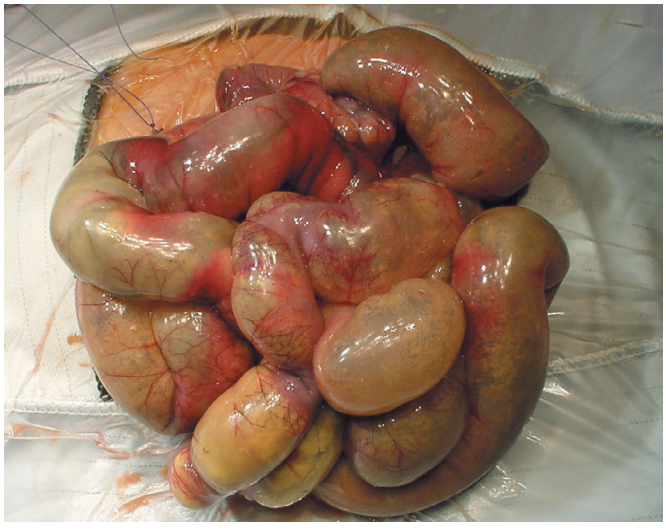

Figure 18.12 Operative appearance of neonatal necrotising enterocolitis.

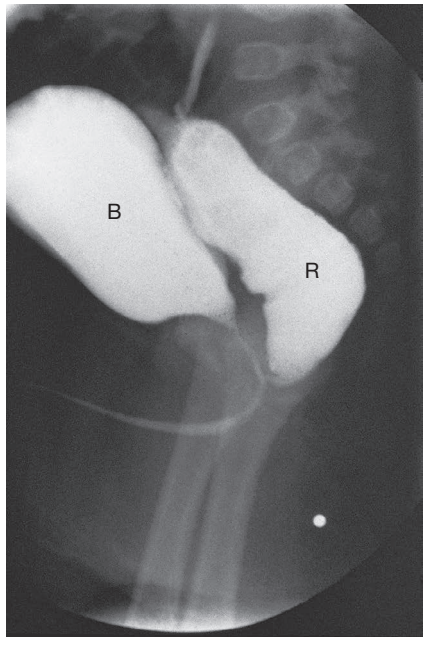

Figure 18.14 A rectourethral fistula, visible on a contrast study performed via a sigmoid colostomy. The bladder is filled with contrast via the fistula and the radio-opaque dot has been placed on the infant's perineum over the normal site of the anus. B, bladder; R, rectum.

but many need liver transplantation. Congenital choledochal malformations manifest as cystic dilatations of the biliary tree and are also managed with resection and portoenterostomy.

Anorectal malformations

In an anorectal malformation, there is usually no opening in boys, and the rectum ends either blindly (notably in aneuploidies) or with a fistula to the bulbar urethra (***Figure 18.13a***), prostate or bladder neck. Occasionally, there is a rectoperineal fistula in a boy. In contrast, there is usually a rectovestibular (***Figure 18.13b***) or rectoperineal fistula in girls; meconium is passed and therefore, many are missed on cursory newborn examinations. In girls, the rectum may join a common channel with the vagina and urethra; this is referred to as a cloaca (***Figure 18.13c***).

In boys, a divided proximal sigmoid colostomy allows feeding. A contrast study is performed through the defunctioned end (***Figure 18.14***). Repair of prostatic and bladder neck fistulae may be approached with a combined laparoscopic and perineal approach, whereas prostatic and bulbar urethral fistulae can both be approached in a posterior sagittal anorectoplasty (PSARP). The stoma is closed at a third stage. Most perineal and some vestibular fistulae can be transposed into the muscle complex without a stoma.

Hirschsprung's disease

Genetic defects (e.g. *RET, EDNRB, EDN3*) can affect the migration of neural crest-derived intestinal neurones (neurocristopathy), leading to aganglionosis and thickened nerve trunks in the distal bowel. There may be a family history. Aganglionic bowel fails to relax, causing a functional obstruction. Aganglionosis extends from the anus to the sigmoid colon in 75%, the proximal colon in 15%, and the terminal ileum in 10% of cases. A transition zone lies between dilated, proximal, normal bowel and narrow, distal aganglionic bowel. Neonatal Hirschsprung's disease presents with delayed passage of meconium, abdominal distension and bilious vomiting requiring resuscitation, gastric decompression, antibiotics and a bowel washout. The diagnosis is made on a cot-side suction rectal biopsy. A contrast enema may show the narrow aganglionic segment, a cone and dilated proximal bowel (***Figure 18.15***). Daily rectal washouts may allow a period of growth at home before surgery. If decompression fails, a stoma is fashioned using frozen section histopathology to identify ganglionic bowel. Definitive surgery removes the aganglionic segment

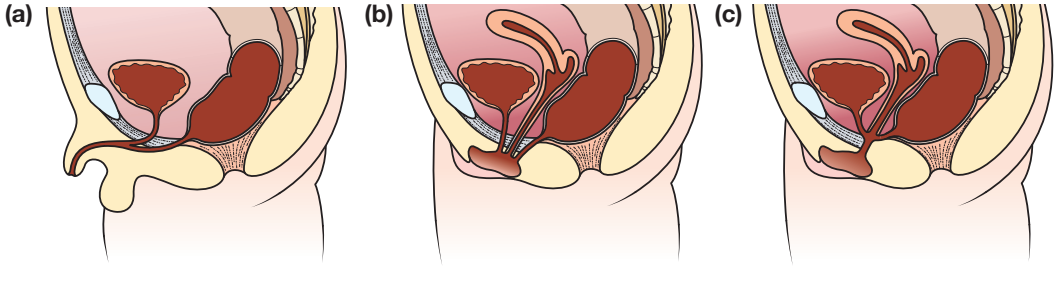

Figure 18.13 (a) Rectobulbar urethral fistula in a boy. **(b)** Rectovestibular fistula in a girl. **(c)** Cloaca in a girl.

Figure 18.15 Barium enema in an infant, showing a 'transition zone' in the proximal sigmoid colon between the dilated proximal normally innervated bowel and the contracted aganglionic rectum.

and brings ganglionic bowel to the anus; Swenson, Duhamel, Yancey–Soave and transanal 'pull-throughs' are options. Most children achieve reasonable bowel control, but some have residual constipation, incontinence or episodes of enterocolitis.

Gastroschisis

In gastroschisis, an abdominal wall defect lies to the right-hand side of the umbilical cord and transmits the small and large intestine, stomach, bladder and sometimes the ovaries or undescended abdominal testes (***Figure 18.16***). Risk factors include teenage pregnancy, recreational drugs, smoking and genitourinary infection in pregnancy. It is easily diagnosed antenatally, allowing delivery near a surgical unit. Vaginal delivery is appropriate. After birth, twisting or kinking of the mesenteric blood supply must be avoided. The abdomen and viscera are wrapped using a transparent plastic food wrap (e.g. cling film, Saran wrap), a large-bore nasogastric tube is placed, and fluid resuscitation is initiated. The bowel may have a thick wall and be matted together. Sometimes, the defect closes antenatally, causing an atresia and an external length of damaged intestine (***Figure 18.17***). A narrow defect may need to be widened and a sutured silo (silo: structure for storage) created using Silastic sheeting or an empty intravenous fluid bag. Primary closure under general anaesthesia usually requires NICU admission for postoperative ventilation. An alternative is to place a preformed silo at the bedside (***Figure 18.18***), followed by gradual reduction, which sometimes avoids general anaesthesia altogether. PN is needed for around 4 weeks or longer while intestinal motility improves.

Figure 18.16 Gastroschisis.

Figure 18.17 Closing gastroschisis: the defect has narrowed and occluded the vessels to a few loops of intestine. Note the atresia found at laparotomy.

Exomphalos

Exomphalos describes a central abdominal wall defect in which prolapsed viscera are covered in a thin, three-layered membrane (peritoneum, Wharton's jelly and amnion) in continuity with the umbilical cord. Exomphalos minor (<5 cm, liver not involved) is commonly associated with other anomalies (***Table 18.1***) and the defect is easily closed. In exomphalos major (***Figure 18.19***) the sac can be dressed with a topical antibacterial agent (e.g. manuka honey, silver sulfadiazine), allowing epithelialisation

Figure 18.19 Exomphalos major.

and later closure of the ventral hernia. If an early closure of an exomphalos major is attempted, close observation for an abdominal compartment syndrome is mandated.

Summary box 18.1

Neonatal abdominal wall defects

Gastroschisis

- Environmental risk factors (young maternal age, drug use)
- Bowel complications common (atresia, matting, volvulus)
- Associated anomalies rare

Exomphalos

- Frequent association with aneuploidies and other genetic syndromes (e.g. Beckwith–Wiedemann)
- Other structural anomalies common (e.g. cardiac malformations)
- Large defects may contain liver (exomphalos major) and require delayed or staged closure

THORACIC SURGERY

Congenital diaphragmatic hernia

Several genes share roles in diaphragmatic, pulmonary, cardiac and foregut development; consequently, congenital diaphragmatic hernias are associated with lung hypoplasia, pulmonary hypertension, cardiac defects and gastroesophageal reflux, with half having additional anomalies. The pulmonary hypoplasia is partly due to lung compression from herniated abdominal contents (mechanical aetiology) and partly due to genetic causes (e.g. *FOG2, GATA4*). Commonly, there is a left posterolateral or Bochdalek defect, less commonly a ventral or Morgagni defect.

The diagnosis is usually made antenatally. A prognosis based on an observed-to-expected lung–head ratio (ultrasound), total fetal lung volume (magnetic resonance imaging) and whether or not the fetal liver is in the chest informs counselling.

After birth, intubation, muscle relaxation and gentle ventilation aim to maintain pH, and oxygen saturation so avoiding right-to-left shunting. Permissive hypercapnia and high-frequency oscillation may help. Pulmonary hypertension may lead to vascular shunting, hypoxia, hypercapnia and cardiac dysfunction. Cardiac dysfunction, assessed by echocardiography, may respond to nitric oxide, prostaglandin E1, milrinone and inotropes, but severe dysfunction requires extracorporeal life support (ECLS). Repair is offered if the pulmonary circulation stabilises. Unlike in traumatic diaphragmatic hernias, urgently reducing the bowel does not improve gas exchange in a congenital diaphragmatic hernia. The defect can be approached from the abdomen or the chest, either open or minimally invasively. The defect may be small, needing only a few sutures, or larger, needing a conical Silastic or GOR-TEX patch. A hernial sac may be present, which may be removed or plicated.

Pulmonary airway malformations

There are three groups: congenital cystic adenomatoid malformations (CCAMs), bronchopulmonary sequestrations (BPSs) and congenital lobar emphysema (CLE). The sequestrations may be intralobar or extralobar and are accompanied by an aberrant arterial supply from a major vessel, usually the aorta. Hybrid lesions have both a CCAM and a BPS. Some malformations cause respiratory or cardiovascular compromise at birth and require excision, but most are asymptomatic and imaging may be delayed for several months. Cross-sectional computed tomography imaging defines the anatomy and vasculature.

Vincent Alexander Bochdalek, 1801–1883, Professor of Anatomy, Prague, Czech Republic.
Giovanni Battista Morgagni, 1682–1771, Italian anatomist, the father of modern anatomical pathology.
John Bruce Beckwith, 1933, American paediatric pathologist.
Hans-Rudolf Wiedemann, 1915-2006, German paediatrician. Both Beckwith and Wiedemann reported cases of the syndrome independently in 1963 and 1964.

NEWBORN TUMOURS

Sacrococcygeal teratoma

These germ cell tumours arise from the coccyx and are usually diagnosed antenatally. They may have internal and external components or both (***Figure 18.20***). Most are benign mature teratomas, but some contain immature embryonic elements. Complete excision is usually achieved in the prone position and must include removing the coccyx and reconstruction of the pelvic floor. If the intra-abdominal component is large or vascular, the median sacral artery can be ligated through the abdomen. Bladder and bowel function are assessed following the pelvic floor repair. α-Fetoprotein levels are measured to detect recurrence.

Figure 18.20 Sacrococcygeal teratoma.

Congenital mesoblastic nephroma

This renal tumour may present as a large palpable mass in a newborn with some having hypertension and hypercalcaemia (paraneoplastic syndromes). Cross-sectional imaging distinguishes a tumour from a multicystic dysplastic kidney. A nephroureterectomy is usually curative, but some may recur locally or metastasise.

WHY ADULT SURGEONS NEED AN OVERVIEW OF NEONATAL SURGERY

Rarely, malrotation, congenital diaphragmatic hernias and lung malformations described in this chapter may present for the first time in adulthood. More commonly, adults who had neonatal surgery may present with incidental or related pathology. Children who had anorectal malformations or Hirschsprung's disease need colorectal follow-up, with girls also needing a gynaecologist and obstetrician who understands the pathology; those with oesophageal atresia/tracheoesophageal fistula need an upper gastrointestinal surgeon.

CHAPTER
19 Trauma in children

Learning objectives

To be able to:

- Systematically assess an injured child
- Give examples of how mechanisms of, and responses to, injury differ from those in adults
- Distinguish the elements of the primary and secondary surveys
- Explain when and how to transfuse blood products in children
- Describe some common patterns of injury in children
- Request appropriate investigations for an injured child
- Outline the non-operative management of solid organ injuries
- Outline the principles of the trauma laparotomy and the clamshell thoracotomy
- Explain the principle of damage control surgery

INTRODUCTION

Trauma is the leading cause of death in children over 1 year old, and blunt trauma is the most common mechanism. Prompt, guideline-driven management by a trauma team reduces complications and saves lives. For cranial injuries in children, see ***Chapter 28***; for orthopaedic injuries in children, see ***Part 4, Trauma***.

THE PRIMARY SURVEY

Injured children are assessed using the Advanced Trauma Life Support (ATLS) structured **cABCDE** approach: **c**ontrol of catastrophic bleeding with pressure, **A**irway with C-spine control, **B**reathing with oxygen, **C**irculation with further control of haemorrhage, **D**isability, **E**xposure and Environment. In contrast to managing trauma in adults (see ***Part 4, Trauma***), the following should be considered:

- **A** – overextension of the neck can cause airway obstruction; a neutral position is used for infants and a 'sniffing the morning air' position for older children.
- **B** – hypoxia is usually the cause of cardiac arrest in children; if easily reversed, the cardiac rhythm returns.
- **C** – hypotension occurs comparatively late after 20% of the circulating volume is lost.
- **D** – an age-dependent modified Glasgow Coma Scale (GCS) is used.
- **E** – small children lose heat rapidly, with hypothermia exacerbating any coagulopathy. If their weight in kilograms is unknown, it can be estimated from 2 × (age in years + 4).

In cardiac arrest, the four Hs and four Ts are considered: **H**ypoxia, **H**ypovolaemia, **H**ypothermia/Hyperthermia, **H**yperkalaemia/hypokalaemia, **T**ension pneumothorax, cardiac **T**amponade, **T**oxins, **T**hrombus.

Spinal cord injury without radiological abnormality (SCIWORA)

Cervical hyperextension can occur during a rear impact in a car accident or from a frontal impact to the head. If such a mechanism dissipates a lot of energy, the spinal cord can be damaged even though a cervical radiograph may look normal. Compared with adults, children have a proportionally heavier head and weaker cervical muscles, which together with more elastic spinal ligaments and horizontal facet joints permit displacement without fracture and spontaneous anatomical resolution. A myelopathy can follow a contusion or follow ischaemia from temporary vertebral artery occlusion. If an older child gives a history of transient paraesthesia, numbness or paralysis, cervical immobilisation should be continued, and magnetic resonance imaging obtained. Immobilisation of the cervical spine can be with blocks and tapes or, if tolerated, a collar.

Resuscitation

All children initially receive high-flow oxygen, preferably via a non-rebreathe mask; this can be stopped if there is cardiorespiratory stability after a period of observation. Intubation and ventilation are required if oxygenation is inadequate or if there is a low GCS, combative behaviour, an inability to cooperate, severe burns, prolonged seizures or imminent operative intervention. Ideally, seriously injured children require two large well-secured cannulae. Alongside the antecubital fossa, other suitable veins include the long saphenous at the ankle, the femoral, the external jugular and, in neonates, scalp veins. If intravenous access cannot be established, an intraosseous needle can be placed in the tibia (***Figure 19.1***) or the humeral head, which has the benefit of being easily accessed by an anaesthetist.

Fluid volume resuscitation aims to restore and maintain age-adjusted cardiovascular parameters. Initially, 10 mL/kg of a warmed isotonic fluid is given. Total blood volume (TBV) is around 85 mL/kg in a neonate, rising to 100 mL/kg at 1 month and then falling to 75–80 mL/kg in a child. Major haemorrhage is defined as loss of 50% of TBV in <3 hours, 100% in 24 hours or >20% in <1 hour, but is challenging to assess, especially in blunt trauma. Hospitals should have a major haemorrhage protocol. If the capillary refill is >2 seconds and the child has lost mainly blood, then blood is given, using O rhesus-negative blood until type-specific or cross-matched blood is available. Severe trauma-induced coagulopathy is best managed by correcting specific coagulation factors and using point-of-care testing thromboelastography (TEG) and thromboelastometry (ROTEM), but if these are not available the following are given: packed cells 20 mL/kg, fresh-frozen plasma 20 mL/kg, platelets 10 mL/kg and cryoprecipitate 5 mL/kg, and repeated maintaining these ratios and aiming for a haemoglobin level >80 g/L, platelets >75 × 10^9/L, fibrinogen >1.5 g/L and activated partial thromboplastin time (APTT)/prothrombin time (PT) <1.5 × normal midpoint. If the major haemorrhage occurred within 3 hours, a slow tranexamic acid bolus of 15 mg/kg followed by an infusion (15 mg/kg over 8 hours) should be given.

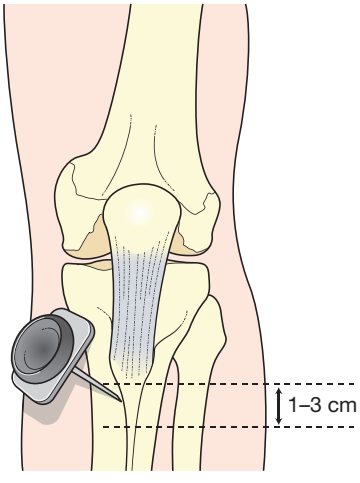

Figure 19.1 The intraosseous needle is inserted into the proximal tibia's medullary cavity about 1–3 cm below the tibial tuberosity.

Trauma-induced coagulopathy

Tissue damage releases factors that encourage coagulation but acidosis and hypothermia prolong it; therefore, blood products should be warmed. For each 1°C fall in temperature, factor activity falls by 10%. Below 34°C clotting times are prolonged, and platelets pool in the spleen and have poor adherence and aggregation. Poor perfusion increases thrombomodulin, which binds to thrombin and activates protein C, so inhibiting cofactors V and VIII. Activated protein C can deplete plasminogen activator inhibitor-1, which results in the formation of plasmin and fibrinolysis. Citrate in blood products can bind to calcium and, if this falls below 0.6 mmol/L, platelets are less effective.

Haemostasis is immature in neonates with procoagulant and anticoagulant proteins, remaining low until 6 months old. Fibrinogen is qualitatively dysfunctional, existing in a fetal form for 6–12 months after birth and contributing to an increased risk of bleeding. Burns can also cause a consumptive coagulopathy with microangiopathic haemolysis.

Children are more susceptible to hypothermia than adults: wet clothes should be removed early and warming blankets used. Children are more likely to become hypoglycaemic after a major injury as they mobilise glycogen poorly – blood sugar should be monitored in the significantly injured child, especially if they are nil by mouth.

A nasogastric tube and a urinary catheter should be considered for children who have had a major abdominal or head injury or are unconscious or ventilated. An orogastric tube is used if there is suspicion of a basal frontal skull fracture and a suprapubic catheter if a urethral injury is suspected.

Injury Severity Score

An Injury Severity Score (ISS) (see *Chapter 26*) >15 predicts mortality in adults, but children require an ISS >25 for the same prediction; this is because most children have an isolated head or extremity injury. Only around 10% of children have multiple injuries.

- **Head**: in a neonate, the fontanelle or 'soft spot' may not have closed, leading to a bony space that could be confused with a fracture. A bulging fontanelle may suggest raised intracranial pressure, whereas a sunken fontanelle is seen in hypovolaemia.
- **Chest**: a child's rib cage is very compliant and ribs may bend and recover rather than break, leading to lung contusions or mediastinal injuries without fractures. If diagnosed clinically, a tension pneumothorax need not be confirmed with a chest radiograph before needle thoracocentesis and placing a chest drain. Although uncommon, cardiac tamponade should be considered and requires an emergency subxiphoid needle pericardiocentesis; a limited echocardiogram may confirm the diagnosis.
- An emergency department clamshell thoracotomy should be performed for penetrating chest injury where the patient had a witnessed arrest within the last 15 minutes. An incision is made across the chest in the fifth intercostal space. It may be possible to cut the sternum with scissors rather than needing a Gigli saw. The pericardium is opened, blood removed and bleeding controlled. A hole in the heart can be oversewn, taking care to avoid the coronary vessels. If the bleeding appears to be from lung, the lung can either be rotated 180° (lung twist) or the hilum slooped. The aim is not to perform a definitive repair but to buy time, allowing resuscitation, including internal massage until cardiac output returns. The clamshell thoracotomy also allows compression of the aorta just above the diaphragm to aid vascular filling.

Leonardo Gigli, 1863–1908, Florentine surgeon and obstetrician.

- **Abdomen**: the liver and spleen in children are less well protected by the rib cage than they are in adults and are at greater risk of injury from blunt trauma. Signs may be subtle, and tenderness should be investigated with cross-sectional imaging. If there is significant abdominal bleeding, aortic compression may be helpful, and this may be easier to achieve through a thoracotomy than a laparotomy; it can be challenging to reach the aorta above the liver.
- **Extremities**: in comparison with adults, children's bones are more compliant – they may bend or fracture one cortex. Children's bones also remodel as they grow; therefore, the position of an angled distal limb fracture may be accepted in a child when it would be manipulated in an adult. The growth plates in children are not yet fused and a fracture involving the growth plate can limit future limb growth – these fractures should be referred to a paediatric orthopaedic surgeon.

SECONDARY SURVEY

The secondary survey is performed after resuscitation and stabilisation. The history is reviewed and a complete clinical examination is performed to assess for other injuries.

Imaging

The choice of imaging depends on the mechanism of injury and the findings on examination. Cross-sectional imaging can be invaluable, but a head-to-toe computed tomography (CT) scan should only be performed with good reason to limit exposure to ionising radiation.

Plain radiograph

A chest radiograph is mandated in major trauma. The cervical spine is rarely injured, but if the injury mechanism leads to suspicion of cervical damage, then a cervical spine series is requested. Lateral and anteroposterior images must include the base of the skull and the C7–T1 junction. The odontoid or 'peg' projection can be difficult to obtain as the mouth needs to be open for the anteroposterior projection to see C1 (atlas) and C2 (axis). A pelvic radiograph is requested if a pelvic fracture is suspected. Suspected limb fractures initially undergo anteroposterior and lateral radiographs with CT reserved for those that are complex.

CT scans

A head CT scan should be performed within 1 hour if the GCS is <14 at the initial assessment or within 2 hours if the GCS is <15 after the injury. Other indications include a tense fontanelle, suspicion of an open or depressed skull fracture or a basal skull fracture, abnormal pupillary response, abnormal posturing, a focal neurological defect or concern about a non-accidental injury. A head CT scan should also be performed if there are three or more vomiting episodes, a witnessed loss of consciousness for >5 minutes or amnesia >5 minutes.

A CT scan of the chest, abdomen and pelvis is performed if there is abdominal wall bruising (*Figure 19.2*), tenderness, distension, peritonitis, blood per rectum or blood in the nasogastric tube. Some relative indications include an aspartate aminotransferase >200 U/L, amylase >100 U/L or microhaematuria >5 erythrocytes/high-power field. Abdominal and pelvic CT should be single-volume dual-contrast to minimise radiation exposure using the Camp Bastion or Afghan protocol.

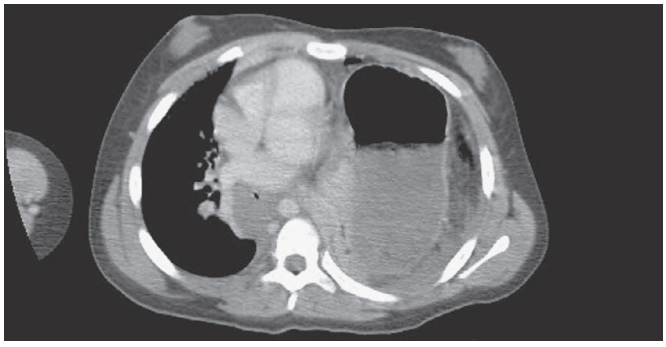

Figure 19.2 Traumatic diaphragmatic rupture found in a child with abdominal wall bruising.

A CT scan of the chest should be performed after a penetrating chest injury or a significant deceleration. However, most blunt chest injuries are detected on a chest radiograph; if the mediastinal silhouette is normal, a chest CT is not usually required.

A focused abdominal sonography trauma (FAST) scan is not helpful in children as the findings can be difficult to interpret.

Patterns of injury

There are some well-recognised patterns of injury in children.

Lap belt

If a child experiences a forced flexion over a lap belt in a car accident, the small bowel or its mesentery or the bladder's abdominal portion may get compressed against the spine. These tissues may fail up to 72 hours after the injury. Lumbar fractures may also be seen. In small children, the pancreas can be compressed by a lap belt.

Handlebar injury

A child who falls onto the end of a bicycle handlebar may crush the pancreas, duodenum, small intestine or its mesentery against the spine. A duodenal haematoma may cause an obstruction, the pancreas may be injured or divided and contused intestine may perforate after a delay of a few days, so a period of observation is required. When this injury pattern is seen in a child under 3 years old, a non-accidental injury must be considered.

Straddle injury

A child typically falls onto the side of a bath or a toy, causing a perineal injury that may involve the urethra or vagina.

Non-accidental injury

Non-accidental injuries should be suspected when the reported mechanism of injury or its timing are unusual. Fractures,

abdominal injuries and intracranial haemorrhages in those under 2 years old are often non-accidental. Bruises are remarkably difficult to date, but their shape and pattern may distinguish accidental from abusive bruising if they leave an imprint. Patterned bruises generally do not occur during regular play. Bruises over soft tissues in an immobile infant are suspicious, whereas those over bony prominences such as the knees, elbows and the forehead in a mobile child are not. Bruises on the cheeks, neck, genitals, buttocks and back are unlikely to be accidental. Some benign entities may be confused with abusive bruises, such as Mongolian spots and haemangiomas. Children with idiopathic thrombocytopenic purpura or leukaemia may present with unexplained bruises in different stages of healing.

DEFINITIVE MANAGEMENT

Chest

A small pneumothorax detected on a chest radiograph may be observed rather than drained. Lung contusions require analgesia and chest physiotherapy to prevent secondary infection. Penetrating lung injuries may be assessed at either thoracoscopy or thoracotomy and the underlying lung injury sealed with fibrin glue or by applying a stapler; segmentectomy or lobectomy are rarely required.

Abdomen

Intraperitoneal air mandates a laparoscopy or laparotomy. Penetrating wounds that have not entered the abdominal cavity should be cleaned and closed. The spleen and liver account for 70% of all visceral injuries caused by blunt trauma. In the haemodynamically stable child, most solid organ injuries can be managed without an operation, but if unstable despite appropriate transfusion, or only transiently responding, interventional radiology and embolisation or a laparotomy should be considered. Recurrent instability may reflect an inadequate initial resuscitation, and the need for a second transfusion does not mandate an operation.

Following an abdominal solid organ injury, bed rest is advised until pain free, with mobilisation after a minimum of 1 night for grade I and II injuries and after a minimum of 2 nights for grade >III injuries. High-impact activities and contact sports should be limited for grade IV and V injuries for 6 weeks. However, delayed haemorrhage can arise spontaneously several days after an injury and is thought to occur in a hyperosmolar setting when a haematoma breaks down. Discharged patients need to know to return to the hospital if unwell.

TABLE 19.1 Spleen injury scale.

Grade	Injury type	Description of injury
I	Haematoma	Subcapsular, <10% surface area
II	Laceration	Capsular tear, <1 cm parenchymal depth
	Haematoma	Subcapsular, 10–50% surface area, intraparenchymal, <5 cm in diameter
III	Laceration	Capsular tear, 1–3 cm parenchymal depth not involving a trabecular vessel
	Haematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal haematoma, intraparenchymal haematoma ≥5 cm or expanding
IV	Laceration	>3 cm parenchymal depth or involving a trabecular vessel
	Laceration	Laceration involving segmental or hilar vessels producing major devascularisation (>25%)
V	Laceration	Completely shattered spleen
	Vascular	Devascularised by a hilar injury

TABLE 19.2 Liver injury scale.

Grade	Injury type	Description of injury
I	Haematoma	Subcapsular, <10% surface area
	Laceration	Capsular tear, <1 cm parenchymal depth
II	Haematoma	Subcapsular, 10–50% surface area, intraparenchymal, <10 cm in diameter
III	Haematoma	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal haematoma; intraparenchymal haematoma ≥10 cm or expanding
	Laceration	>3 cm parenchymal depth or involving a trabecular vessel
IV	Laceration	Parenchymal disruption involving 25–75% of hepatic lobe or 1–3 Couinaud segments in a single lobe
V	Laceration	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe
	Vascular	Juxtahepatic venous injuries
VI	Vascular	Hepatic avulsion

Specific considerations

Spleen

There is a risk of splenic pseudoaneurysm after splenic trauma, which is unrelated to the severity of the injury (***Table 19.1***). Therefore, a follow-up ultrasound is recommended.

Liver

The grades of liver trauma are given in ***Table 19.2***. Bile leaks are rare and often resolve after drainage rather than repair but should be discussed with a paediatric liver surgeon.

Claude Couinaud, 1922–2008, French surgeon and anatomist, described the segmental anatomy of the liver.

Pancreas

Pancreatic trauma may lead to a pancreatic pseudocyst, which requires endoscopic drainage into the stomach. For distal lacerations in the pancreatic tail, some surgeons prefer an early distal pancreatectomy rather than non-operative management. Proximal pancreatic duct injuries in older children can be stented.

Renal

After severe renal injuries, hypertension can develop, which may need treatment. A dimercaptosuccinic acid (DMSA) scan is used to assess function in those with hypertension or following grade IV or V injuries (*Table 19.3*).

TABLE 19.3 Renal injury scale.

Grade	Injury type	Description of injury
I	Contusion	Microscopic or gross haematuria. Normal imaging
	Haematoma	Subcapsular, not expanding and without parenchymal laceration
II	Haematoma	Non-expanding peri-renal haematoma confined to the retroperitoneum
	Laceration	<1.0 cm parenchymal depth without extravasation of urine
III	Laceration	>1.0 cm parenchymal depth without collecting system rupture or extravasation of urine
IV	Laceration	Parenchymal laceration extends through the cortex, medulla and collecting system
	Vascular	Main renal artery or vein injury with contained haemorrhage
V	Laceration	Shattered kidney
	Vascular	Avulsion of the renal hilum devascularising the kidney

Duodenum

A duodenal haematoma has a risk of late perforation, which may be retroperitoneal. Therefore, a second abdominal CT scan or a contrast study should be considered if there is deterioration or recovery is particularly slow.

Bowel

There are three mechanisms: the bowel wall may fail instantly if pressure rises rapidly in a trapped loop, it may fail up to 72 hours after a direct crush injury or it may become ischaemic following a mesenteric injury damaging its blood supply.

Urethral injury

In straddle injuries and pelvic fractures there may be blood at the urethral meatus. Urethral catheterisation can aggravate a urethral injury, and so a suprapubic catheter should be placed.

DAMAGE CONTROL SURGERY

Damage control surgery aims to break the 'vicious cycle' of hypothermia, tissue hypoxia, coagulopathy and acidosis before later definitive repair. Anatomy is restored when the physiology is optimised. The principles are in sequence: (i) short operations aiming to control haemorrhage and limit contamination; (ii) ongoing correction of deranged physiology – acidosis, hypothermia, perfusion and organ function on intensive care; (iii) definitive surgical repair.

In a trauma laparotomy, a midline incision is made from the xiphisternum to the pubic symphysis. Large clots are removed and the abdomen is packed in all four quadrants with large swabs to tamponade bleeding. If packing does not control bleeding, it is either inadequate packing, and more should be applied, or there is a significant arterial bleed, and so pressure should be applied to the aorta above the liver. Once bleeding is stemmed and the intravascular volume restored, the packs are removed systematically one quadrant at a time to find the source of the bleeding. Control is by vessel repair, ligation or removal of the organ or reapplication of the packs. Contamination is controlled by either repairing a simple bowel injury with a continuous suture or resection of multiple areas of perforated bowel with a clip-and-drop technique (either stapling or tying off the ends but not attempting primary anastomosis). Bile injuries are managed with a drain, and bladder injuries are oversewn and a urethral catheter placed. The abdomen is left open, allowing transfer to critical care for ongoing physiological correction before returning to theatre in the following days for further procedures.

Summary box 19.1

Paediatric trauma

- Use the Advanced Trauma Life Support (ATLS) guidelines
- Overextension of the neck can compromise the airway
- Cervical spine injury can be present without radiographic signs
- Intraosseous access is helpful in small children
- Lung contusion can occur without rib fractures
- In a stable child, abdominal injuries are best assessed by CT
- Blunt abdominal organ injury can usually be managed non-operatively
- Damage control surgery aims to correct physiology before definitive repair

PART 2 | General paediatrics

CHAPTER 20

Paediatric urology

Learning objectives

At the end of this chapter, you will be able to:

- Explain the indications for circumcision in childhood and list the complications
- Describe three levels of urinary tract obstruction and outline their management
- Describe the anomalies of hypospadias and epispadias
- List risk factors for urolithiasis and describe three methods of stone management
- Categorise with examples three differences of sex development (DSD)
- Describe the ileocystoplasty with appendicovesicostomy for managing neuropathic bladders

INTRODUCTION

Paediatric urologists are paediatric surgeons who subspecialise in the conditions outlined in this chapter; they also manage the acute and elective inguinoscrotal pathology described in *Chapter 17*. Surgeons in many specialities are consulted about the foreskin; this is covered in detail here. Specialist paediatric urological conditions include hypospadias, epispadias, bladder exstrophy, vesicoureteral reflux, renal duplications, urolithiasis and urinary tract obstruction. Obstruction occurs at three levels: dysfunction at the ureteropelvic junction, dysfunction at the ureterovesical junction and in the posterior urethra with congenital valves. Obstructions may present with fetal hydronephrosis. Postnatally, obstruction with infection causes renal damage. The relevant embryology and epidemiology are summarised. Choosing the right time to operate, often based on diagnostic imaging, and gentle tissue handling are central to achieving good outcomes with few complications. Diagnostic imaging includes ultrasonography, voiding cystourethrography and the use of the radioisotope technetium-99m (^{99m}Tc) linked to dimercaptosuccinic acid (DMSA) or mercaptoacetyltriglycine (MAG-3). The management of the neuropathic bladder may involve an ileocystoplasty with a continent catheterisable channel. Many specialist paediatric urological conditions require close follow-up and later transfer to specialist adult surgical care.

EMBRYOLOGY

Four areas of developmental biology are relevant: (i) the two stages of testicular descent; (ii) the Weigert–Meyer rule – in a duplex system the ectopic upper pole ureter has an orifice lying inferomedial to the lower pole ureter; (iii) the role of the urethral plate in the tubularisation of the urethra and the aetiology of hypospadias and its relevance to operative repairs; and (iv) morphological differentiation in relation to disorders, or differences, of sex development. These areas are addressed in the recommended further reading.

THE PENIS

Foreskin disorders and circumcision

Surgical referrals for foreskin problems are common in early childhood, and reassurance is often all that is needed after taking a careful history and examination. The foreskin, or prepuce, is a highly innervated, double-layered fold of skin. The inner layer is a mucous membrane and the outer layer is skin, with a mucocutaneous zone where the layers meet. The prepuce has similarities to the eyelids, labia minora, anus and lips. The prepuce provides mucosa and skin to cover the erect penis. The foreskin is adherent to the glans at birth and gradually separates in most boys by the age of 5 years and in the remaining before puberty, allowing the foreskin to become fully retractile. Forceful retraction is not recommended as it can cause tears and scarring. The adhesions are natural and not pathological. The foreskin may balloon on micturition as the plane between glans and prepuce develops. Ballooning is not an indication for circumcision. If spraying of urine on micturition is causing concern, the parent and child can be taught to partially draw back the foreskin so the meatus is unobstructed and spraying is reduced. Occasionally a nodule of entrapped smegma, termed a 'smegma pearl', accumulates in the developing plane between the glans and prepuce, causing parental anxiety. These are harmless collections that discharge on their own when the developing plane finally opens onto the exposed glans.

Carl Weigert, 1845–1904, German pathologist and anatomist known for work on cellular staining.
Robert Meyer, 1864–1947, German pathologist in Berlin, removed from his position for being Jewish, emigrated in 1939 to Minneapolis, MN, USA.

Circumcision, being the removal of the foreskin, is the oldest and most common surgical procedure and is usually performed for cultural reasons. About 40% of males worldwide are circumcised. Circumcision is performed in Judaism, on day 8 of life (brit milah), and in Islam (khitan), at varying ages. In early infancy, circumcision can be performed under local anaesthesia using simple devices like the PlastiBell or Gomco clamp. In older boys under general anaesthesia, the foreskin is removed with a blade or scissors, followed by attention to haemostasis and skin apposition with sutures or glue. Complications include bleeding, dehiscence, infection, cicatrix, adhesion formation, meatal stenosis, the removal of too little or too much tissue, cosmetic concerns and rarely urethral injury or amputation. Medical indications for circumcision include:

- **True phimosis**: the foreskin is non-retractile because of a tight fibrotic preputial ring.
- **Balanitis xerotica obliterans (BXO)**: a chronic, possibly autoimmune, preputial inflammation that may also affect the distal urethra and is rarely seen before 5 years of age. Boys present with progressive phimosis and white, hard preputial skin (***Figure 20.1***), dysuria and ballooning on micturition. Usually, circumcision is required, although some boys respond to topical corticosteroids. Follow-up is required to exclude meatal stenosis.
- **Recurrent balanoposthitis**: an inflammation of the glans penis and its retractile foreskin due to infection, irritation or trauma. Boys may present with pain, itching, rash, dysuria and a non-urethral penile discharge. Most boys have only one or two episodes and need no intervention, but a few have sufficient trouble with recurrence that circumcision is indicated.
- **Recurrent urinary tract infections (UTIs)**: though rare in most boys, UTIs are a particular risk with some anomalies, such as posterior urethral valves, where infection can lead to pyelonephritis, renal scarring and renal insufficiency. In these boys, circumcision may reduce those risks.
- **Paraphimosis**: sometimes, the prepuce retracts back over the glans and cannot be brought forward again; the glans swells and becomes painful. If manipulation fails, an emergency dorsal slit or circumcision is indicated.

Figure 20.1 Balanitis xerotica obliterans.

Hypospadias

The genital tubercle becomes a penis under the influence of androgens with a tubular urethra arising from the urethral plate. The urethral plate develops a diamond-shaped groove whose edges fold over and fuse in the midline, forming a tube. In girls, the urethral plate's homologue forms the vestibular groove with edges that do not fuse but form the labia minora. Hypospadias is a congenital malformation seen in 1 in 300 boys. The urethral opening lies on the ventral aspect of the penis anywhere from the proximal glans to the perineum in association with a ventral curvature (called a chordee) and a ventrally deficient foreskin leading to a dorsal 'hooded' prepuce. Clinicians should document phallus length, meatal location, glans volume, depth and width of the urethral plate, degree of chordee, foreskin appearance and the testes' presence and location. Circumcision is contraindicated because the foreskin may be needed for the reconstruction. The anomaly should be diagnosed in the newborn examination.

Hypospadias repair aims to achieve the usual meatal location and a straight penis to facilitate micturition and ejaculation. Distal hypospadias, where the opening is on the glans, may be repaired in a single stage, whereas more proximal openings and those with severe curvatures require staged procedures. Many operations have been described. One technique is the tubularised incised plate procedure, which widens and then tubularises the urethral plate (***Figure 20.2***). Staged repairs may use the foreskin as a first-stage graft, followed by tubularisation in a second stage. Complications include urethrocutaneous fistulae, meatal stenosis, glans dehiscence and hypospadias persistence.

Epispadias/bladder exstrophy

Epispadias is a rare dorsal penile defect with an opening whose upper limit lies anywhere from the penopubic junction to the glans (***Figure 20.3***). Epispadias may be part of the bladder exstrophy–epispadias complex in which the bladder and bladder neck are also open on the lower abdominal wall. Ileocaecal exstrophy (cloacal exstrophy) represents the most severe variant, in which there is a small exomphalos with an everted caecum and ileum separating halves of the bladder and, in males, a split penis. If we imagine hypospadias as the anatomy that might result from making an opening with scissors placed with one blade into the urethra and one blade ventrally, then epispadias is akin to making this opening on the dorsal aspect and through the pubis into the bladder for the bladder exstrophy. Children with epispadias have problems with urinary incontinence but are often otherwise healthy. Boys with epispadias and a functioning bladder neck may have a

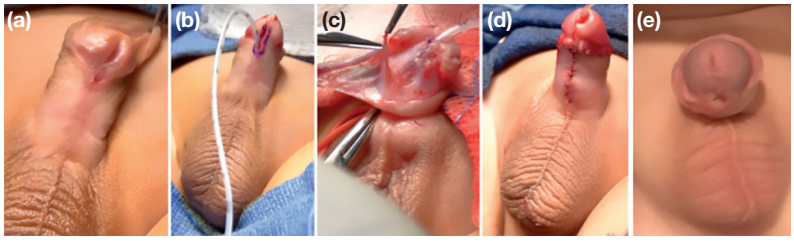

Figure 20.2 **(a)** Subcoronal hypospadias with dorsal hooded prepuce. **(b)** 5-Fr feeding tube in hypospadiac meatus. **(c)** Urethroplasty. **(d)** Creation of a terminal neo-meatus with skin closure. **(e)** Healed penis after hypospadias repair.

penile reconstruction around 2 years of age. Follow-up is required to monitor bladder emptying, continence and the upper urinary tracts, which may deteriorate if reconstruction causes a degree of obstruction.

UROLITHIASIS

The prevalence of urolithiasis in children varies from around 1–5% in Asia, 5–10% in Europe to 15% in North America. Investigations include serum electrolytes, urinalysis, urine culture and stone analysis. Common metabolic risk factors include high oxalate and calcium levels and low levels of citrate in the urine. Therapy aims to alter these levels to reduce recurrence. Approximately 25% of stones are caused by a UTI from urease-producing bacteria, *Proteus mirabilis* or *Klebsiella pneumoniae*. Anatomic anomalies leading to urinary stasis and urolithiasis include ureteropelvic junction obstruction, polycystic kidney and neurogenic bladder. Children may present with flank or abdominal pain, gross haematuria, dysuria, nausea or vomiting. Stones are easily detected with ultrasound. Non-contrast computed tomography scans are very sensitive but involve ionising radiation.

Small stones may pass with generous oral hydration and analgesia. Some stones with associated infection require intravenous hydration and antibiotics. α-Blockers and calcium channel blockers may reduce dysmotile ureteric contractions initiated by a stone while preserving helpful expulsive peristaltic activity. Reimaging may confirm the passage of a stone. Intervention may be required to manage pain, obstruction and treatment-resistant stones. Extracorporeal shock wave lithotripsy (ESWL) can safely and effectively fragment stones smaller than 2 cm using focused, high-energy shock waves delivered under general anaesthesia. Ureteroscopy allows fragmentation and removal of stones smaller than 2 cm from the ureter or kidney but is avoided in those younger than 5 years. Percutaneous nephrolithotomy (PCNL) can be used to extract stones from the kidney through a dilated tract. PCNL is used for stones larger than 2 cm, ESWL-refractory stones smaller than 2 cm and multiple stones.

Summary box 20.1

Urolithiasis

- Children with urolithiasis should be evaluated for metabolic risk factors
- Urological management depends on the size of calculi, age, number of stones and the presence of obstruction, infection or pain

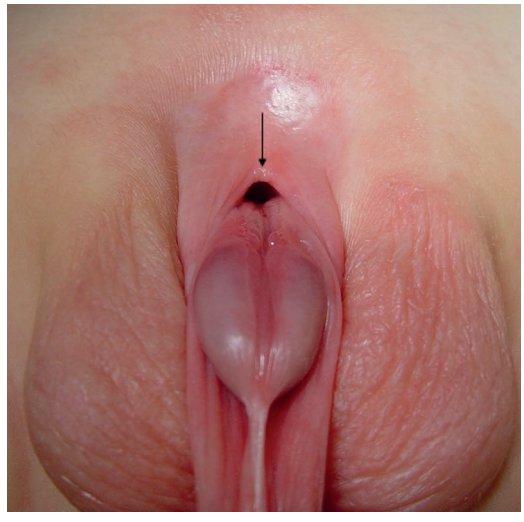

Figure 20.3 Penopubic meatus (arrow) in epispadias in a boy.

URINARY TRACT OBSTRUCTION

Antenatal fetal hydronephrosis

Hydronephrosis – a dilated renal pelvis – is found in 1% of antenatal scans and most commonly it resolves, especially if the dilatation is mild to moderate. Severe dilatation is associated with urinary tract obstruction or vesicoureteral reflux. Antenatal interventions are rarely indicated except in posterior urethral valves (PUVs), but postnatal imaging is needed to confirm resolution or make a diagnosis. Amniotic fluid is principally fetal urine; thus, if there is antenatal bilateral hydronephrosis with decreased amniotic fluid, PUV is a likely cause. If the PUV obstruction is thought to be damaging the kidneys, then there may be a role for an antenatal vesicoamniotic shunt to take the pressure off the upper tracts.

Radioisotope renal imaging

The metastable radioisotope ^{99m}Tc emits gamma rays during an isomeric transition to ^{99}Tc. It has a 6-hour emission half-life and a 1-day biological half-life, so imaging with low exposure is possible. For static imaging, ^{99m}Tc is linked to DMSA and given intravenously; an image is captured after 2–3 hours to assess renal morphology (e.g. agenesis and duplex systems), structure (e.g. renal scarring in reflux nephropathy) and function. For dynamic imaging, ^{99m}Tc is linked to diethylenetriaminepentaacetate (DTPA) or MAG-3 and given intravenously; a series

of images capture renal excretion. If the renal blood supply is compromised, the kidney is not imaged; if it is well perfused but partially obstructed, delayed transit is seen. Activity curves and comparison with the contralateral kidney are informative. MAG-3 is preferred to DTPA in neonates and children with impaired function and when an obstruction is suspected since it is more efficiently extracted from the blood by the proximal tubules and clearance correlates with blood flow. After extraction by the proximal tubules, MAG-3 is secreted into the tubular lumen, whereas DTPA is filtered by the glomerulus and provides a measure of the glomerular filtration rate.

Ureteropelvic junction obstruction

Ureteropelvic junction (UPJ) obstruction, also often called pelviureteric junction (PUJ) obstruction, describes an incomplete and intermittent reduction in urine flow from the kidney to the proximal ureter and occurs in 1 in 1000 live births with a male and left-sided predominance. It is the most common cause of serious antenatal hydronephrosis. Commonly a disruption of circular muscle or collagen fibres in the proximal ureter results in an intrinsic narrowing near the renal pelvis. Extrinsic compression is less common and results from an aberrant renal vessel compressing the ureteropelvic junction. Most cases are diagnosed in the postnatal evaluation of an antenatally detected hydronephrosis, although some newborns present with an abdominal or flank mass and a history of urinary tract infection or haematuria. Older children may present with severe intermittent flank or abdominal pain associated with nausea and vomiting, known as Dietl's crisis. MAG-3 imaging confirms the diagnosis, and knowing the differential renal function helps to decide between surgical and non-surgical management (***Figures 20.4 and 20.5***).

In symptomatic children, a pyeloplasty is indicated. In many countries, this is now commonly performed laparoscopically, with some using robotic assistance. A pyeloplasty involves transection at the obstruction and the fashioning of a funnel-like anastomosis; a temporary stent and a drain may be placed. Follow-up with serial ultrasounds and MAG-3 imaging is required.

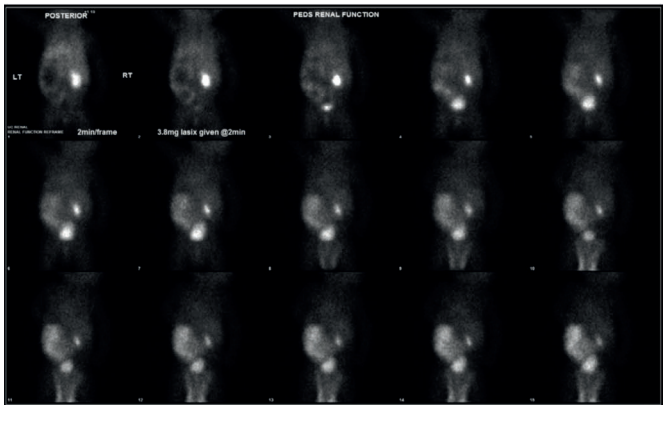

Figure 20.4 Mercaptoacetyltriglycine (MAG-3) renal scan showing poor drainage of a hydronephrotic left kidney due to partial ureteropelvic junction obstruction. Note that nuclear scans are shown as if looking from behind the patient.

Ureterovesical junction obstruction/ megaureters

Ureterovesical junction (UVJ) obstruction is the second most common cause of antenatal hydronephrosis and arises from an adynamic and stenotic region obstructing the distal ureter near the bladder (***Figure 20.6***). Older children may have a distal ureteric polyp or calculus and present with a UTI, haematuria, abdominal pain or a hydronephrotic mass. Ultrasonography shows ureteric dilation (megaureter), hydronephrosis or both (hydroureteronephrosis). Importantly, obstruction is not the only cause of a dilated ureter. A primary megaureter refers to one that arises from an abnormality at the junction, whereas a secondary megaureter arises from a problem in the bladder or urethra (myelomeningocele/neurogenic bladder, PUV). Although reflux may cause a megaureter, it is also possible to have a refluxing obstructed megaureter, and so a voiding cystourethrogram is needed to look for reflux. A MAG-3 renal scan indicates the severity of obstruction. If intervention is required, ureteric reimplantation is performed.

Vesicoureteral reflux

Vesicoureteral reflux (VUR) is the retrograde flow of urine from the bladder to the upper urinary tracts. Primary VUR occurs because of a congenitally short intravesical ureter, resulting in inadequate closure of the UVJ during bladder contractions, and is seen in 1% of newborns. Secondary VUR follows from elevated intravesical pressure and is typically caused by PUV or

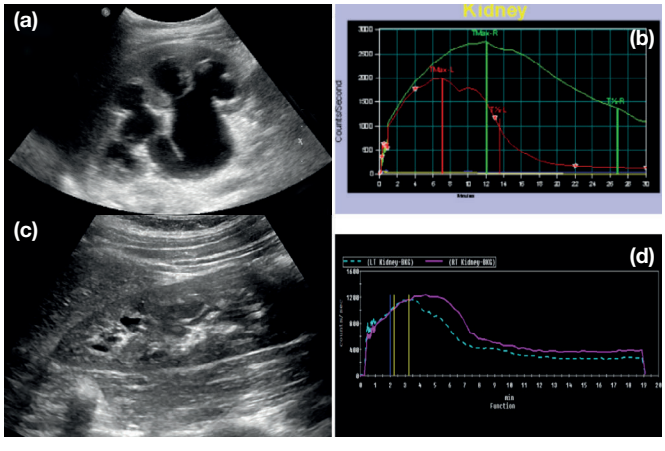

Figure 20.5 (a) Preoperative ultrasound of a right kidney with ureteropelvic junction obstruction showing hydronephrosis. **(b)** Preoperative mercaptoacetyltriglycine (MAG-3) activity curve showing delayed excretion of the obstructed right kidney with a half-life of 26 minutes. **(c)** Ultrasound image of the right kidney after a pyeloplasty showing resolution of the hydronephrosis. **(d)** Postoperative MAG-3 activity curve graph showing improved excretion with a half-life of 7.6 minutes.

Józef Dietl, 1804–1878, Austrian–Polish physician and Mayor of Kraków, reformed medicine by showing through experiments that bloodletting was not only useless but dangerous.

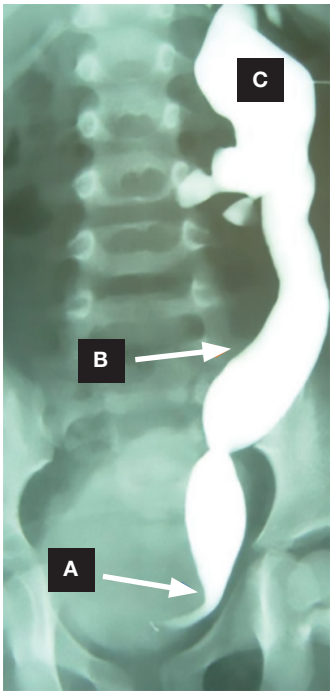

Figure 20.6 A retrograde pyelogram showing a left-sided ureterovesical junction obstruction (A), causing a megaureter (B) and hydronephrosis (C).

a neurogenic bladder. VUR may be seen with hydronephrosis on an antenatal ultrasound or with a symptomatic UTI postnatally. A voiding cystourethrogram establishes the diagnosis and severity of VUR (***Figure 20.7***). Mild VUR typically resolves spontaneously as the patient grows and the intravesical ureter matures and lengthens. These children are managed with surveillance if toilet-trained or prophylactic antibiotics if they are not. Moderate-to-severe VUR less commonly resolves and recurrent UTIs may lead to pyelonephritis and renal parenchymal loss from scarring. Persistent or severe VUR can be managed with a subureteric Teflon injection (STING), which alters the anatomy at the UVJ and limits reflux, or with ureteric reimplantation. Long-term follow-up is required.

Posterior urethral valves

PUVs are membranous folds that obstruct the lumen of the posterior urethra, affecting about 1 in 4000 live-born boys. Girls are not affected. About one-third are identified antenatally with bilateral hydronephrosis, a dilated bladder and a dilated posterior urethra, which, on imaging, looks like a keyhole. In severe cases, there is oligohydramnios and lung hypoplasia. Postnatal presentations include urinary tract infections, bladder distension and voiding dysfunction. The diagnosis is confirmed on a voiding cystourethrogram, which shows a dilated posterior urethra with a thick-walled bladder (***Figure 20.8***). Ultrasonography looks for hydronephrosis and a thickened bladder. Renal function can be assessed with

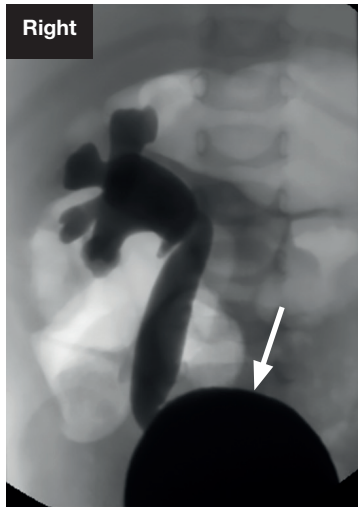

Figure 20.7 Voiding cystourethrogram demonstrating right-sided vesicoureteral reflux. The bladder is full of contrast (arrow).

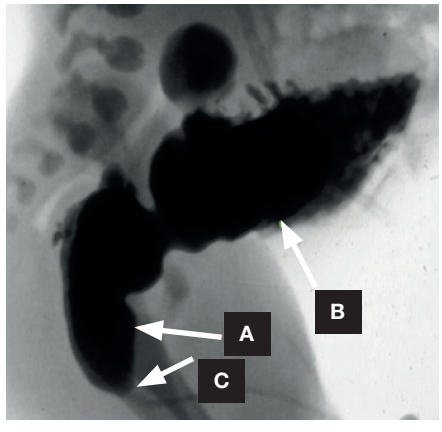

Figure 20.8 Lateral view showing a dilated posterior urethra (A) and trabeculated bladder (B) due to posterior urethral valves (C), seen on a voiding cystourethrogram.

routine blood tests and glomerular filtration rate or a DMSA scan. The valves are ablated or resected; close follow-up is needed since bladder dysfunction is common and 30% develop renal failure.

Summary box 20.2

Urinary tract obstruction

- Prenatal fetal hydronephrosis often resolves under observation alone
- Severe ureteropelvic junction obstruction warrants a pyeloplasty
- Ureterovesical junction obstruction is one cause of megaureter
- Vesicoureteral reflux: severity is determined by voiding cystourethrography
- Posterior urethral valves lead to renal failure in 30% of affected boys

DUPLEX SYSTEMS

One in a hundred people have an upper renal moiety draining into a duplicated ureter. Both ipsilateral ureters may fuse such that only one ureter enters the bladder, or the duplicated ureter may have an ectopic opening into the bladder, urethra, vagina, vulval vestibule, seminal vesicle or rectum and is a rare cause of wetting. A vesical ectopic ureter may be associated with a dilated and obstructed intravesical length of ureter. Such a structure is known as a ureterocele and may be detected antenatally. The ectopic upper pole ureter typically has an orifice lying inferomedial to the lower pole ureter; an arrangement known as the Weigert–Meyer rule. The upper renal moiety has a ureter that may be obstructed at the bladder, whereas the lower renal moiety has a ureter with a predisposition to reflux.

DISORDERS OR DIFFERENCES IN SEX DIFFERENTIATION

Some, but not all, children with abnormalities of their sex chromosomes, gonads or reproductive anatomy are considered to have a disorder or difference in sex differentiation (DSD). Isolated undescended testes, hypospadias and labial adhesions are excluded. Unfortunately, there is no consensus on the indications, timing, best procedures or how to evaluate DSD surgery. The classification of disorders into groups is complex and controversial. For simplicity, only the following groups are described here: 46-XX DSD, 46-XY DSD and sex-chromosome mosaicism DSD variants. DSD management benefits when the paediatric urologist works in a multidisciplinary team, including a geneticist, endocrinologist, an adolescent gynaecologist and a psychologist.

The **46-XX DSD** group is exemplified by congenital adrenal hyperplasia (CAH), in which gender is usually straightforward (female), except with late diagnoses and severe masculinisation. At birth, the urethra may open on a prominent genital tubercle, appearing like a small phallus and looking similar to a 46-XY boy with severe hypospadias and non-palpable testes. In 46-XX CAH, the vagina opens into the posterior wall of the urethra a variable distance from the bladder neck but not higher than where the verumontanum, a Müllerian structure, is typically located in the male urethra. Genital fold fusion varies from a vulval-like to a scrotal-like appearance.

The **46-XY DSD** group is exemplified by androgen insensitivity syndrome (AIS), 17β hydroxysteroid dehydrogenase (17β HSD) deficiency and 5α reductase deficiency. AIS is complete (CAIS), with a feminine phenotype, or partial (PAIS), in which the external genitals are undermasculinised at birth and undervirilised at puberty. Infants with CAIS (reared as girls) may present with bilateral inguinal hernias or with inguinal testes thought to be prolapsed ovaries. Similarly, those with 17β HSD deficiency and 5α reductase deficiency, having low androgens, may have an external feminine phenotype with palpable inguinal testes undergoing virilisation at puberty. In challenging cases, controversy surrounds gender assignment, sex of rearing and surgery.

One critical issue is the fate of the testicles: should gonads be left alone until the individual can determine their gender for themselves? Or, if female sex rearing is decided on, should they be removed early to avoid virilisation at puberty? If conservative management is chosen, temporarily blocking virilisation with a gonadotropin-releasing hormone analogue is an option until gender identity is determined.

Sex-chromosome mosaicism is exemplified by 45X/46XY DSD. These individuals may have a hemiscrotum containing a testis-like gonad, paired with a labia majora with an inguinal or impalpable streak gonad; a streak gonad has stromal tissue without tubules or follicles. There is usually severe hypospadias.

NEUROPATHIC BLADDER

A myelomeningocele, lipomyelomeningocele, fatty filum or an occult tethered cord can cause a neuropathic bladder that may need lifelong care to protect the kidneys from high urinary pressures and reflux, and support continence and independence where appropriate. If reconstructive surgery is needed, it must follow detailed assessments of (i) the adequacy of the bladder neck/sphincter complex, (ii) bladder capacity, (iii) the need for a cutaneous catheterisable channel, and (iv) any associated faecal continence procedures. Bladder neck procedures include endoscopic injections, slings, reconstructions and bladder neck closure. Bladder capacity and compliance can be increased with a bladder augmentation (e.g. ileocystoplasty), which takes the pressure off the upper tracts. An appendicovesicostomy (Mitrofanoff), using the appendix as a conduit between the skin and the bladder, allows intermittent catheterisation as an alternative to urethral catheterisation (*Figure 20.9*).

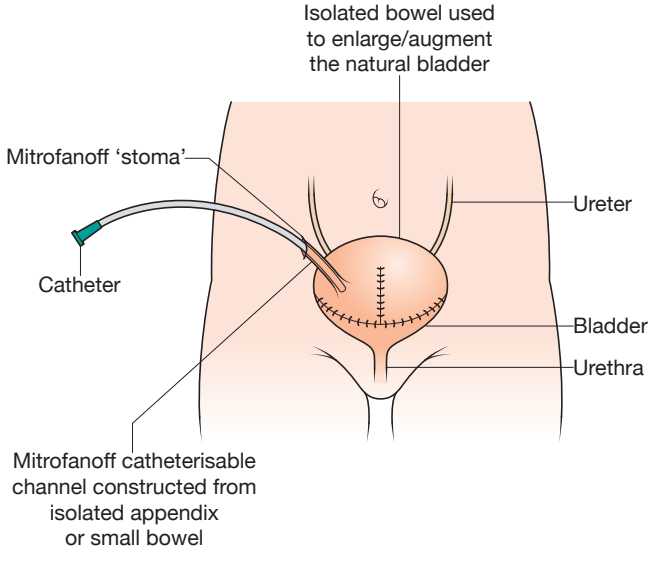

Figure 20.9 Mitrofanoff appendicovesicostomy draining an ileocystoplasty, which augments and converts a high-pressure bladder into a low-pressure system to protect the kidneys in a patient with a neuropathic bladder.

Johannes Peter Müller, 1801–1858, German physiologist and comparative anatomist after whom the paramesonephric duct structures are named.
Paul Mitrofanoff, b. 1934, paediatric surgeon, Rouen, France, devised the appendicovesicostomy in the mid-1970s.

TESTICULAR TUMOURS

Testicular tumours are rare. Most prepubertal tumours arise before 3 years and are benign, allowing testis-sparing surgery. Malignant tumours in older boys require an orchidectomy (performed through the groin) and selective chemotherapy. Germ cell tumours include the teratomas and epidermoid cysts (typically benign) and the malignant yolk sac tumours, seminomas, choriocarcinomas and embryonal carcinomas. Gonadal stromal tumours are typically benign and include Leydig cell tumours, Sertoli cell tumours, juvenile granulosa cell tumours and gonadoblastomas.

PART 3 | Perioperative care

CHAPTER 21

Preoperative care including the high-risk surgical patient

Learning objectives

To understand preoperative preparation for surgery:
- Surgical, medical and anaesthetic aspects of assessment
- How to optimise patients and identify those at higher risk
- Importance of critical care in management
- Emergency cases

To be able to organise preoperative care and the operating list

INTRODUCTION

The stress of major surgery can lead to increased oxygen demand by up to 40%. Inflammatory changes due to cytokine release, endocrine responses, hypercoagulability and redistribution of fluid between compartments may last several postoperative days. The purpose of careful preoperative planning is to minimise the unwanted effects of these physiological changes.

Systematic history taking, examination and investigation at the preoperative clinic should include not only an assessment of functional reserve but also the formulation of advice on optimisation, to best cope with the anticipated operative stress. Primary care physician records and hospital notes are useful sources of baseline information. Ideally a multidisciplinary team approach, including the primary care physician, specialist nurses, physiotherapist, dietician and perioperative physician, is utilised. This allows optimisation of chronic conditions, facilitates weight reduction and smoking cessation, and allows coordination of prehabilitation and postoperative rehabilitation needs. The anaesthetist and surgeon must plan the safest anaesthetic technique and operation for the patient.

A simple questionnaire can identify risk factors for patients undergoing surgery that will require specific tests or optimisation. Patients with severe comorbidities or undergoing high-risk surgery should be referred to specialists to quantify and reduce perioperative risks. The risks of surgery and anaesthesia and the effects of comorbid conditions should be discussed so that the patient can make an informed decision. Patients should be given advice on preoperative fasting times, adjustments to regular medication and specific premedication at the preoperative visit.

To enable the list to run smoothly on the day, key personnel involved in the list (surgeon, anaesthetist and senior theatre staff) should be involved in planning the list order. The National Patient Safety Agency's adaptation of the World Health Organization's checklist recommends a 'team brief' before the start of each list, which is also a valuable opportunity to share information with the theatre team and improve the safety of anaesthesia and surgery.

Summary box 21.1

Preoperative plan for the best patient outcomes
- Gather and record all relevant information
- Optimise patient condition
- Choose surgery that offers minimal risk and maximum benefit
- Informed consent of the patient (see ***Chapter 14***)
- Anticipate and plan for adverse events
- Adequate hydration, nutrition and exercise are advised

PATIENT ASSESSMENT

History taking

A thorough past medical history, surgical history and systemic enquiry should be documented, including important negatives (***Table 21.1***). The history of past surgery and anaesthetic events can reveal the problems one may face during future procedures e.g. intra-abdominal adhesions for planned laparoscopic surgery, a difficult airway or suxamethonium apnoea. The use of recreational drugs and alcohol consumption should be noted as they are known to be associated with adverse outcomes. A full drug history and list of allergies should be documented. Social history, ability to communicate and mobility are important in planning admission, discharge route and rehabilitation after surgery.

Examination

Patients should be treated with respect and dignity, receive a clear explanation of the examination undertaken and be kept as comfortable as possible. A chaperone should be present, especially for intimate examinations. This should be part of a local guideline or policy.

TABLE 21.1 Key conditions in past medical history.

Cardiovascular
- Valvular heart disease
- Ischaemic heart disease: angina, myocardial infarction, coronary stents
- Hypertension
- Heart failure
- Dysrhythmia
- Peripheral vascular disease
- Cardiac devices, i.e. permanent pacemaker

Respiratory
- Chronic obstructive pulmonary disease
- Asthma
- Respiratory infections
- Obstructive sleep apnoea symptoms

Gastrointestinal
- Peptic ulcer disease and gastro-oesophageal reflux
- Liver disease

Genitourinary tract
- Urinary tract infection
- Renal dysfunction
- For females last menstrual period/pregnancy/breastfeeding status

Neurological
- Epilepsy
- Cerebrovascular accidents and transient ischaemic attacks
- Parkinson's disease
- Multiple sclerosis

Psychiatric disorders
- Cognitive function
- Anxiety or depression

Endocrine/metabolic
- Diabetes
- Thyroid dysfunction
- Phaeochromocytoma
- Porphyria

Locomotor system
- Osteoarthritis
- Inflammatory arthropathy, i.e. rheumatoid arthritis
- Disorders of muscle, i.e. muscular dystrophy, myasthenia, myopathy

Haematological
- Bleeding disorders
- Personal or family history of deep vein thrombosis and pulmonary embolism
- Objection to blood product transfusion
- Haemoglobinopathy, i.e. sickle cell disease

Infection
- Human immunodeficiency virus/hepatitis/tuberculosis
- Other, i.e. MRSA/COVID-19/drug-resistant organisms

Previous surgery and anaesthesia
- Problems encountered, i.e. Difficult Airway Society Alert, suxamethonium apnoea
- Family history of problems with anaesthesia, i.e. malignant hyperpyrexia

COVID-19, coronavirus disease 2019; MRSA, methicillin-resistant *Staphylococcus aureus*.

Summary box 21.2

Examination
- General: positive findings, even if not related to the proposed procedure, should be explored further
- Surgery related: type and site of surgery, with reference to imaging and investigations
- Systemic: comorbidities and extent of limitation of each organ's function
- Specific: for example, suitability for positioning during surgery or to plan airway management

Examination is especially important in symptomatic individuals and at a minimum should include cardiorespiratory examination and airway assessment. Specifically, look for signs of heart failure, valvular heart disease, peripheral vascular disease and respiratory disease (***Table 21.2***).

TABLE 21.2 Medical examination.

General	Anaemia, jaundice, cyanosis, frailty, nutritional status, sources of infection (teeth, feet, leg ulcers), height, weight and BMI
Cardiovascular	Pulse rate and rhythm, blood pressure, heart sounds, bruits, jugular venous pressure, peripheral oedema, exercise tolerance
Respiratory	Respiratory rate and effort, chest expansion and percussion note, breath sounds, oxygen saturation at rest and exertion, consider PEFR
Gastrointestinal	Abdominal masses, ascites, bowel sounds, hernia, genitalia
Neurological	Consciousness level, cognitive function, sensation, muscle power, tone and reflexes
Airway assessment	Mouth opening, neck extension, Mallampati score, thyromental distance, jaw protrusion, scarring to mouth or neck, dentition

BMI, body mass index; PEFR, peak expiratory flow rate.

Airway assessment

The difficulty encountered when performing airway manoeuvres, i.e. hand ventilation, intubation and front of neck access, can be predicted to some extent by simple examination. Failure to assess and plan airway management can have fatal consequences.

The patient is assessed for:

- modified Mallampati class (***Table 21.3***);
- mouth opening >3 cm (***Figure 21.1***);
- thyromental distance >6.5 cm;
- thyrosternal distance >12.5 cm;
- ability to protrude the jaw (***Figure 21.2***);
- ability to extend the head at the atlanto-occipital junction (***Figure 21.3***).

James Parkinson, 1755–1824, general practitioner of Shoreditch, London, UK, published *An essay on the shaking palsy* in 1817.
SR Mallampati published the original article suggesting that the size of the base of the tongue is an important factor in determining the degree of difficulty of direct laryngoscopy in the *Canadian Anaesthetists' Society Journal* in 1985. The original Mallampati classification was modified from a total of three to four classes by **GLT Samsoon** and **JRB Young** after reviewing a series of obstetric and general surgical patients who had had difficult intubations.

TABLE 21.3 Airway assessment (Mallampati test as modified by Samsoon and Young).

Grade 1	Fauces, pillars, soft palate and uvula seen
Grade 2	Fauces, soft palate with some part of uvula seen
Grade 3	Soft palate seen
Grade 4	Hard palate only seen

Figure 21.1 Normal mouth opening (>3 cm), demonstrating Mallampati grade 1.

When more than one of the above tests are abnormal, the chances of experiencing difficulty in obtaining and securing the airway become greater. Poor dentition, facial hair, upper airway tumours/scarring/infections, obesity and neck size are also important factors that will affect the airway management plan. Previous anaesthetic charts or alerts carried by patients for a difficult airway are invaluable sources when assessing a patient.

Investigations

Guidelines produced by the UK's National Institute for Health and Care Excellence (NICE) set out the investigations needed for various categories of elective surgery and American Society of Anesthesiologists (ASA) score of the patient. The following are some of the tests done preoperatively, although not all are done routinely or are recommended by NICE.

- **Full blood count (FBC)**. An FBC is needed for major operations, in the elderly and in those with anaemia or pathology with ongoing blood loss and chronic disease.

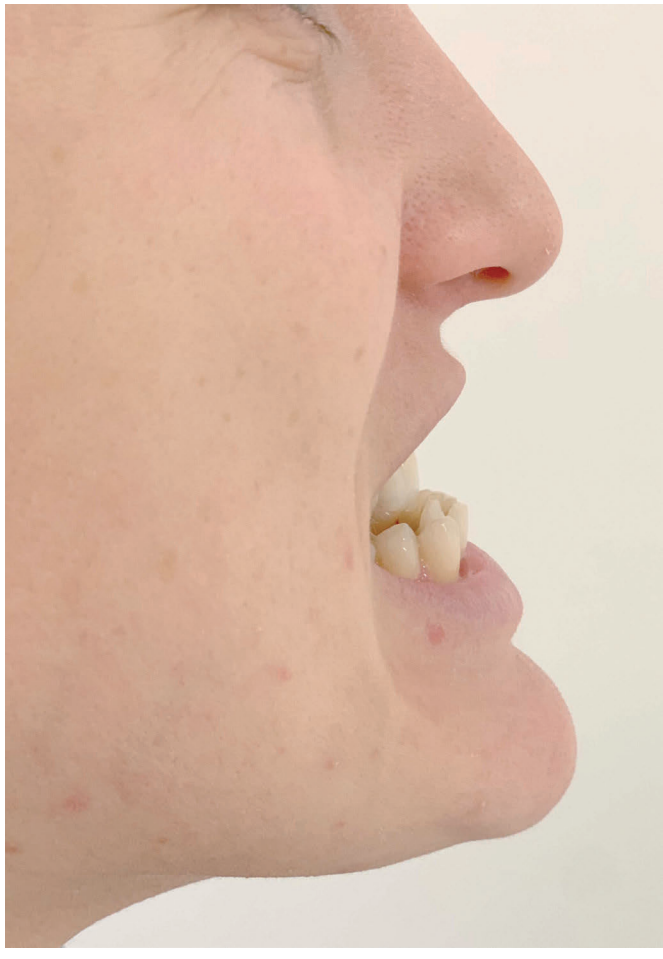

Figure 21.2 Ability to protrude jaw.

Figure 21.3 Normal head extension.

- **Haemoglobin A1c (HbA1c) level**. This should be measured in patients with diabetes who have not had it measured in the last 3 months.
- **Sickle cell test**. Not routinely offered, but in cases of suspicion of a sickle crisis or a family history of sickle cell disease a sickle cell test is needed.
- **Urea and electrolytes (U&Es)**. U&Es are needed before all major operations, in patients over 65 years of age, in patients with cardiovascular, renal or endocrine disease or if significant blood loss is anticipated. They are also needed in those on medications that affect electrolyte levels, e.g. steroids, diuretics, digoxin, non-steroidal anti-inflammatory drugs, intravenous fluid or nutrition therapy, and in those with endocrine problems.
- **Liver function tests**. These are indicated in patients with jaundice, known or suspected hepatitis, cirrhosis, malignancy, alcohol excess or poor nutritional status.
- **Clotting/coagulation screen**. This is needed if a patient has a history suggestive of a bleeding diathesis, liver disease, eclampsia or cholestasis, is on antithrombotic or anticoagulant agents or has a family history of a bleeding disorder. It should be noted that the effects of antiplatelet agents, low-molecular-weight heparins (LMWHs) and newer agents affecting factor Xa cannot be measured by routine laboratory tests.
- **Electrocardiogram (ECG)**. This is required for patients over 65 years of age or symptomatic patients with a history of rheumatic fever, diabetes or cardiovascular, renal or cerebrovascular disease, with or without severe respiratory problems. It will also depend on whether the surgery is minor/intermediate or major, as described in NICE guidance.
- **Chest radiograph**. Not routinely offered unless there is concern on clinical examination.
- **Echocardiogram (echo)**. Consider in those with heart murmurs who are symptomatic or in those with signs of heart failure.
- **Urine tests**. Only consider microscopy and culture of midstream urine if infection would influence the decision to operate.
- **β-Human chorionic gonadotrophin (pregnancy test)**. Women of childbearing age should be asked sensitively about their pregnancy status as this will affect the surgical plan and consent. Pregnant patients must be consented for the risk to a fetus that surgery and anaesthetic pose, and obstetric advice sought. In addition, on the day of surgery the woman should be consented for a urine/serum pregnancy test.
- **Others**:
  - **Venous bicarbonate**. For patients who have screened as being at high risk for obstructive sleep apnoea (OSA). Followed by formal sleep studies if significant OSA is a concern.
  - **Arterial blood gases**. A low-cost tool that can give quick and vital information in acute or chronic severe respiratory conditions, acid–base disturbances and conditions where there is a changing milieu, e.g. immediately before kidney transplant.
  - **Blood group and cross-match** if expected blood loss >500 mL.
  - **Methicillin-resistant *Staphylococcus aureus* (MRSA)** swabs.
  - **Coronavirus 2019 (COVID-19)** polymerase chain reaction (PCR) swabs.
  - **Spirometry**.
  - **Cardiopulmonary exercise testing** to assess fitness for high-risk surgery.
  - **Specialist radiological views** are sometimes required. If imaging is going to be needed during surgery, this needs to be planned in advance.

COMMON PREOPERATIVE PROBLEMS AND MANAGEMENT

Specific medical problems encountered during preoperative assessment should be corrected to the best possible level. Many patients with severe disease will need to be referred to specialists; the referral letter should contain all the details, including history, examination and investigation results.

Cardiovascular disease

Perioperative cardiovascular complications are frequent. Patients who can climb a flight of stairs without getting short of breath, having chest pain or needing to stop are likely to tolerate a wide range of surgeries with an acceptable risk of perioperative cardiovascular morbidity and mortality. However, at preoperative assessment it is important to identify those patients who have a high perioperative risk of a major adverse cardiovascular event (MACE) and to try to reduce this risk. Patients at high risk are those with ischaemic heart disease (IHD), congestive cardiac failure, arrhythmias, severe peripheral vascular disease, cerebrovascular disease or significant renal impairment, especially if they are undergoing major intra-abdominal or intrathoracic surgery.

Ischaemic heart disease

Patients with angina that is not well controlled should be investigated further by a cardiologist. The indications for coronary revascularisation in patients awaiting surgery are the same as at any other time. Pharmacological protection is indicated. Patients established on β-blockers and statins should have their medication continued perioperatively. Initiating statins preoperatively should be considered if not already prescribed. Most long-term cardiac medications should be continued over the perioperative period. Angiotensin-converting enzyme (ACE) inhibitors and receptor blockers are often omitted 24 hours prior to surgery to prevent intraoperative hypotension, and restarted the next day for most surgery.

In patients with IHD the cardiac and coronary reserve can be evaluated using a stress test (stress ECG, stress echo, myocardial scintigraphy). The tests have a high negative predictive value but a relatively low positive predictive value. If the test is negative, the patient is unlikely to have IHD; conversely, if it is positive the chances of the patient actually having IHD are not necessarily very high, but there is a need

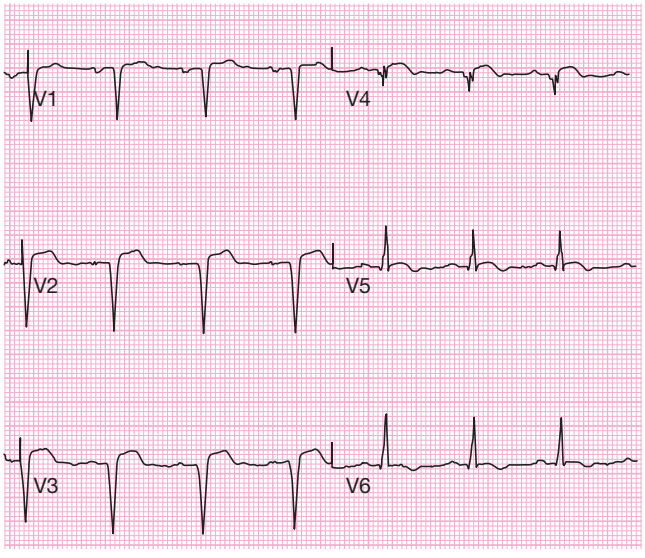

Figure 21.4 Preoperative electrocardiogram of a patient who complained of chest pain the previous day, showing recent transmural anterior myocardial infarction with Q waves and ST elevation.

for further investigation such as coronary angiography or cardiac computed tomography. Recently, measurement of the coronary fractional flow reserve during coronary angiography using a pressure wire has made it possible to identify coronary lesions that have the largest impact on myocardial perfusion.

After a proven myocardial infarction (MI) (***Figure 21.4***), elective surgery should be postponed for 3–6 months to reduce the risk of perioperative reinfarction. Ischaemic changes can be seen on ECG even if the patient is not symptomatic (silent ischaemia/silent MI). These merit discussion with a cardiologist.

Hypertension

Prior to elective surgery blood pressure should be controlled to <160/100 mmHg. If a new antihypertensive agent is introduced, a stabilisation period of at least 2 weeks should be allowed.

Heart failure

Left ventricular failure is the end result of several conditions, including IHD, hypertension, cardiomyopathies and valve dysfunction. Decompensated heart failure puts the patient at risk of multiorgan failure. Those with ejection fractions of less than 35%, and in whom the failure is undiagnosed or its severity underestimated, are at highest risk. The patient's functional capacity needs to be assessed and surgery may have to be delayed for investigations such as an echo and/or for optimisation of medical therapy. B-type natriuretic peptide is a useful marker and can be prognostic.

Drugs used in chronic heart failure can have significant implications for perioperative care, including intraoperative hypotension. β-blockers and probably ACE inhibitors (unless renal perfusion is to be significantly affected) should be continued. A left ventricular ejection fraction of less than 35% should be discussed with a cardiologist and optimised. Cardiac resynchronisation therapy devices may be considered, depending on the QRS duration.

Drug-eluting coronary stents (DES)

Primary percutaneous intervention is the treatment of choice for acute coronary syndromes, and many patients receive stents and are on dual antiplatelet therapy for 12 months. If surgery is absolutely necessary within the period of dual antiplatelet therapy, the management strategy should be decided jointly by the surgeon, cardiologist, anaesthetist and patient, as it is essential to consider the balance of risk of continuing antiplatelet agents (with the risk of increased bleeding) and stopping them (with the risk of stent thrombosis).

Dysrhythmias

In patients with atrial fibrillation (AF), β-blockers, digoxin or calcium channel blockers should be continued in order to control rate. New AF or atrial flutter should be investigated and treated. These patients should be considered for cardioversion as restoring sinus rhythm can improve cardiac output by 15% (***Figure 21.5***). Patients with an abnormal rhythm on ECG, for example tachycardia/bradycardia or heart block, should also be discussed with a cardiologist (***Figure 21.6***). Symptomatic heart blocks and asymptomatic second- (Mobitz II) and third-degree heart blocks, if discovered at the preoperative assessment clinic, will need cardiology consultation and potentially temporary or permanent pacemaker insertion.

Warfarin in patients with AF should be stopped 5 days preoperatively to achieve an international normalised ratio (INR) of 1.5 or less, which is safe for most surgery. The newer anticoagulants such as dabigatran (direct thrombin inhibitor) or rivaroxaban, apixaban and edoxaban (direct factor Xa inhibitors) do not have antagonists and must be stopped preoperatively, generally for 2–3 days in patients with normal renal function and longer when renal function is impaired. Alternative anticoagulation is not required in the perioperative

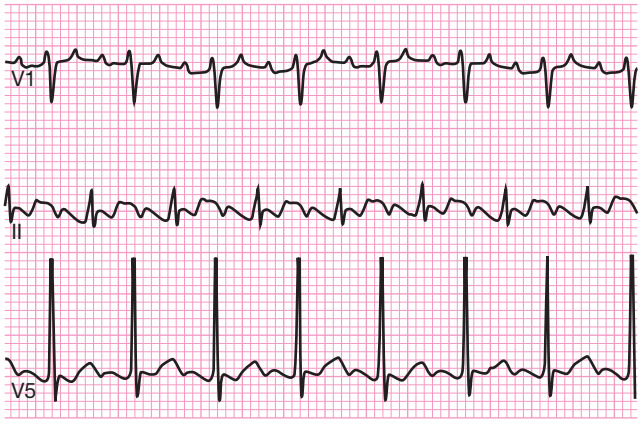

Figure 21.5 Atrial flutter

Woldemar Mobitz, 1889–1951, Russian–German physician, researched atrioventricular dissociation and heart blocks.

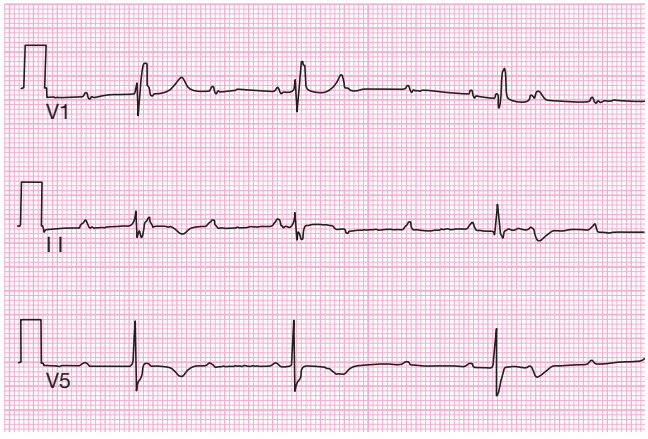

Figure 21.6 Routine preoperative electrocardiogram in an 83-year-old patient with no symptoms other than lethargy for the last 3 months. This shows complete heart block with dissociated P waves and QRS complexes, requiring preoperative pacing.

period unless the risk of stroke is high (assessed using the CHA_2DS_2-VASc [congestive heart failure, hypertension, age ≥75 years, diabetes mellitus, stroke or transient ischemic attack, vascular disease, age 65–74 years, sex category] score). Decisions on bridging therapy should balance the risks of stroke and bleeding.

Implanted pacemakers and cardiac defibrillators

Checks and appropriate reprogramming should be done preoperatively by specialists and advice followed. Monopolar diathermy activity during surgery may be sensed by the pacemaker as ventricular fibrillation or a paced beat. Therefore, cardioversion and over-pace modes must be turned off (and switched back on after surgery) or converted to 'ventricle paced, not sensed with no response to sensing' (VOO) mode. Bipolar diathermy should be made available at surgery.

Valvular heart disease

While anaesthetic management is altered to achieve haemodynamic stability in moderate valvular diseases, patients with severe aortic and mitral stenosis may benefit from valvuloplasty before elective non-cardiac surgery. Appropriate referral to an anaesthetist and cardiologist should be made.

An echo is required in symptomatic patients with a new murmur. Patients with known significant valve pathology may benefit from a recent echo, especially if their clinical status has changed (standard intervals for surveillance echo can be guided by local cardiology policy). Patients with prosthetic valves are normally monitored with surveillance echo at intervals. In patients with mechanical heart valves, warfarin needs to be stopped preoperatively and bridging anticoagulation given to prevent valve thrombosis. Bridging options include unfractionated heparin infusions or LMWHs and should be done under guidance agreed with haematology. Bridging therapy should continue postoperatively until the patient is re-established on warfarin with a therapeutic INR but must be balanced with the postoperative bleeding risk. Thrombin inhibitors and factor Xa inhibitors are not licensed and should not be used in patients with mechanical valves.

Cerebral vascular disease

Patients who have suffered a cerebrovascular accident have been shown to have a higher rate of MACE postoperatively. This is highest in the first 3 months after a stroke. The urgency of surgery needs to be discussed with the surgeon, anaesthetist and a stroke physician. Ideally elective surgery is postponed until MACE risks stabilise after 9 months. The bleeding versus thrombosis risk of continuing dual antiplatelet therapy needs to be considered.

Respiratory disease

Postoperative respiratory complications, such as pneumonia, are a major cause of morbidity and mortality, especially after major abdominal and thoracic surgery. A patient's current respiratory status should be compared with their 'normal state'. Patients with severe disease are at risk of pneumonia and respiratory failure in the postoperative period. Severe disease would include patients with a forced expiratory volume in the first second (FEV_1) of less than 30% of predicted value, dependence on oral steroid treatment, home ventilation or oxygen therapy or a $PaCO_2$ level of greater than 6 kPa.

Patients should continue to use their regular inhalers until the start of anaesthesia. Brittle asthmatics may also need extra steroid cover. Encourage the patients to be compliant with the medications and stop smoking. Information should be provided to indicate perioperative risks associated with smoking. Stopping smoking reduces carbon monoxide levels and offers the patient a better ability to clear sputum. Evidence suggests that preoperative inspiratory muscle training significantly improves respiratory (muscle) function in the early postoperative period, reducing the risk of pulmonary complications.

Regional anaesthetic techniques and less invasive surgical options should be considered in severe cases. Elective surgery should be postponed until acute exacerbations are treated.

The patient should be referred to a respiratory physician if:

- there is a severe disease or significant deterioration;
- major surgery is planned in a patient with significant respiratory comorbidities;
- right heart failure is present – dyspnoea, fatigue, tricuspid regurgitation, hepatomegaly and oedematous feet;
- the patient is young and has severe respiratory problems (may indicate a rare condition).

Gastrointestinal disease

Regurgitation risk

Patients undergoing general anaesthesia or sedation have a risk of regurgitation of stomach contents and aspiration pneumonia. To reduce this risk patients should fast preoperatively. This should be clearly explained to the patient: 6 hours for solids or non-clear fluids (e.g. milk), 2 hours for clear fluids and 4 hours for infants consuming breast milk.

Prolonged fasting is detrimental to the patient so should not be encouraged. Patients with hiatus hernia, obesity, pregnancy or diabetes are at higher risk of pulmonary aspiration, even if they have been fasted appropriately before elective surgery. Clear antacids, H_2-receptor blockers, e.g. ranitidine, or proton pump inhibitors, e.g. omeprazole, may be given at an appropriate time in the preoperative period to reduce stomach acidity.

Liver disease

In patients with liver disease, the cause of the disease needs to be known, as well as any evidence of clotting problems, renal involvement and encephalopathy. Elective surgery should be postponed until any acute episode has settled, e.g. cholangitis. The presence of ascites, oesophageal varices, hypoalbuminaemia or sodium and water retention should be noted, as all can influence the choice and outcome of anaesthesia and surgery. Patients with cirrhosis undergoing major surgery have a very high mortality; the Model for End-stage Liver Disease (MELD) can be used to predict mortality of cirrhotic patients undergoing non-transplant surgery. If alcohol addiction is the aetiology then reduction of alcohol intake should be encouraged but abstinence must be medically supervised to prevent delirium tremens.

Genitourinary disease

Renal failure

Underlying conditions leading to chronic renal failure such as diabetes mellitus, hypertension and IHD should be stabilised before elective surgery. Appropriate measures should be taken to treat acidosis, hypocalcaemia and hyperkalaemia of greater than 6 mmol/L. Arrangements should be made to continue peritoneal dialysis or haemodialysis until a few hours before surgery. After the final dialysis before surgery, a blood sample should be sent for FBC and U&Es.

Patients with chronic renal failure often have chronic anaemia that is well tolerated; therefore, preoperative blood transfusion is often not necessary. Optimisation of the haemoglobin is best guided by the renal team.

Urinary tract infection

Uncomplicated urinary tract infections are common in women, while outflow uropathy with chronically infected urine is common in men. These infections should be treated before embarking on elective surgery where infection carries dire consequences, e.g. joint replacement. For emergency procedures, antibiotics should be started and care taken to ensure that the patient maintains a good urine output before, during and after surgery.

Endocrine and metabolic disorders

Malnutrition

Body mass index (BMI) is weight in kilograms divided by height in metres squared. A BMI of less than 18.5 indicates nutritional impairment and a BMI below 15 is associated with significant hospital mortality. Nutritional support for a minimum of 2 weeks before surgery is required to have any impact on subsequent morbidity. If a patient is unlikely to be able to eat for a significant period postoperatively this can be anticipated and alternative nutritional support must be planned.

Obesity

Morbid obesity can be defined as BMI of more than 35 (other definitions exist) and is associated with an increased risk of postoperative complications. Patients should be made aware of the risks involved and advised on healthy eating and taking regular exercise. If possible, surgery should be delayed until the patient is more active and has lost weight. If this fails, prophylactic measures need to be taken, such as preventative measures for acid aspiration and deep vein thrombosis (DVT).

OSA that is unrecognised has been shown to be associated with a higher incidence of MACE in comorbid patient groups. Identification of those at higher risk by using a clinical scoring system, such as the perioperative sleep apnoea prediction (P-SAP) score, can rationalise referral for formal sleep apnoea studies. Urgency of surgery may preclude full investigation and treatment preoperatively. Patients with severe OSA require 6 weeks of nocturnal continuous positive airway pressure (CPAP) use preoperatively to reduce their risks. Associated risks need to be explained prior to the surgery and an appropriate anaesthetic technique planned with postoperative monitoring.

Diabetes mellitus

Diabetes and associated cardiovascular and renal complications should be controlled to as near a normal level as possible before embarking on elective surgery. Any history of hyper- and hypoglycaemic episodes and hospital admissions should be noted. For elective surgery, an HbA1c of <69 mmol/mol is recommended. Lipid-lowering medication should be started in patients who are in a high-risk group for cardiovascular complications of diabetes.

Patients with diabetes should be first on the operating list and their antidiabetic medication adjusted as per local or national guidance, as they will miss a meal preoperatively. Although tight control of blood sugar is not needed, the patient's blood sugar levels should be checked hourly. Variable rate intravenous insulin infusion (VRIII) should be started for patients with diabetes on insulin undergoing major surgery or if blood sugar is difficult to control for other reasons.

Adrenocortical suppression

Patients receiving oral adrenocortical steroids should be asked about the dose and duration of the medication to determine the need for supplementation with extra doses of steroids perioperatively so as to avoid an Addisonian crisis. A patient taking >5 mg prednisolone equivalent within a month of surgery will require supplementation at induction and postoperatively.

Neuroendocrine tumours, including phaeochromocytoma, carcinoid, gastrinoma, VIPomas and insulinoma, have specific treatments that must be started preoperatively in liaison with specialist endocrinology physicians.

Thomas Addison, 1795–1860, physician, Guy's Hospital, London, UK, described the effects of disease of the suprarenal capsules in 1849.

Haematological disorders

Anaemia and blood transfusion

Patients found to be newly anaemic (haemoglobin <130 g/L), with an expected operative blood loss of >500 mL, should be investigated for the cause of their anaemia. Any vitamin or iron deficiency should be corrected before proceeding for elective surgery. Chronic anaemia is well tolerated in the perioperative period where <500 mL blood loss is expected, but where possible should be corrected. Preoperative transfusion may be considered rarely for elective patients when guided by a haematologist. Local policy should agree which procedures require a preoperative 'group and save' or cross-matched blood sample.

Some patients may refuse blood transfusion, for example a Jehovah's Witness. In such a case, during the consent process discussion should include which blood product and/or device system (e.g. cell salvage, reinfusion from drains) is acceptable. The discussion should extend to other areas, for example whether refusal of transfusion would apply in life-threatening situations. As in all consent processes, the discussion and outcome should be clearly documented.

Thrombophilia

Factor V Leiden and deficiencies in antithrombin III and proteins C and S increase the patient's thrombosis risk. The patient will need special discussion with a haematologist to tailor their venous thromboembolism prophylaxis. For all other patients a DVT risk assessment should be made preoperatively and precautions planned as per local or national guidance. Risk factors are included in ***Table 21.4***.

The progesterone-only contraceptive pill should be continued; however, the risks of continuing the combined pill (slight increased risk of significant thrombosis) should be weighed against the risks of an unplanned pregnancy. Consider stopping oestrogen-containing oral contraceptives or hormone replacement therapy 4 weeks before surgery (NICE guidance; see ***Further reading***).

Bleeding disorders

Bleeding disorders such as haemophilia, von Willebrand disease or thrombocytopenia are best discussed with haematology preoperatively.

Neurological and psychiatric disorders

Anticonvulsants and anti-Parkinson's medication must be continued perioperatively to help early mobilisation of the patient, and patients should be planned early on a theatre list to reduce starvation times. Parenteral medication plans can be set in place preoperatively if there is potential for a prolonged 'nil by mouth' period postoperatively.

Lithium should be stopped 24 hours prior to major surgery but can be continued for minor surgery with careful fluid management and U&Es monitoring. The anaesthetist should be informed if patients are on psychiatric medications, such as tricyclic antidepressants or monoamine oxidase inhibitors (MAOIs), as these may interact with anaesthetic drugs. Case-by-case decisions with a psychiatrist must be undertaken as stopping irreversible MAOIs safely may take many weeks of planning under psychiatric supervision.

TABLE 21.4 Risk factors for thrombosis.

- Age >60 years
- Obesity (BMI >30 kg/m^2)
- Trauma or surgery (especially of the abdomen, pelvis and lower limbs)
- Total anaesthesia time >90 minutes
- Reduced mobility for more than 3 days
- Pregnancy/puerperium
- Varicose veins with phlebitis
- Drugs, e.g. oestrogen contraceptive, HRT, smoking
- Known active cancer or on treatment, significant medical comorbidities, critical care admission
- Family/personal history of thrombosis, e.g. deficiencies in antithrombin III, protein S or C

BMI, body mass index; HRT, hormone replacement therapy.

Musculoskeletal disorders

Muscular disorders have serious implications and require a tailored anaesthetic approach. They include muscular dystrophies, myotonic dystrophy and myasthenia gravis and a personal or family history of malignant hyperpyrexia.

Rheumatoid arthritis can lead to an unstable cervical spine with the possibility of spinal cord injury during intubation. Therefore, flexion and extension lateral cervical spine radiographs should be obtained in symptomatic patients (***Figures 21.7 and 21.8***). Assessment of the severity of renal, cardiac, valvular and pericardial involvement as well as restrictive lung disease should be carried out. Rheumatologists will advise on steroids and disease-modifying drugs so as to balance immunosuppression (chance of infections) against the need to stabilise the disease perioperatively (stopping disease-modifying drugs can lead to flare-up of the disease).

In patients with ankylosing spondylitis, in addition to the problems discussed above, techniques of spinal or epidural anaesthesia are often challenging. Patients with systemic lupus erythematosus may exhibit a hypercoagulable state along with airway difficulties.

PHYSICAL FITNESS

Functional physical fitness can be judged by the ability to tolerate metabolic equivalent tasks (METs) (***Table 21.5***). One MET is equivalent to the oxygen consumption of an adult at rest (~3.5 mL/kg/min). Different tasks are assigned a number of METs. If the patient is able to perform >4 METs (e.g. climbing at least one flight of stairs) they are accepted to proceed for low-risk surgery in the USA and Europe. However this depends on a subjective assessment of the ability of a patient and may be overestimated by them. The Duke Activity Status Index (DASI) is a less subjective patient questionnaire. An estimate of the patient's peak oxygen consumption (VO_2 peak)

Erik Adolf von Willebrand, 1870–1949, physician, Diakonissanstaltens Hospital, Helsinki, (Helsingfors), Finland, described hereditary pseudohaemophilia in 1926.

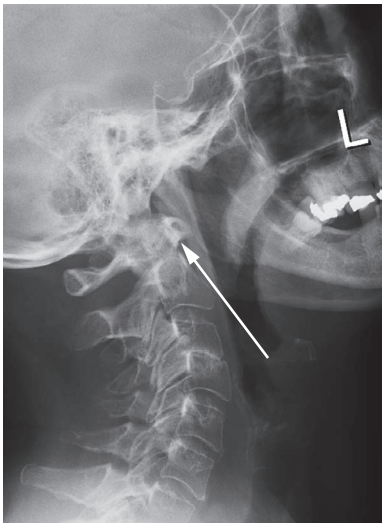

Figure 21.7 Extension view of the cervical spine in a patient with rheumatoid arthritis. Arrow indicates the atlantodens interval.

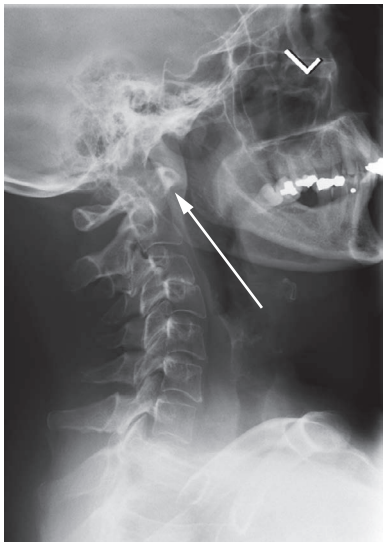

Figure 21.8 Flexion view in the same patient as in ***Figure 21.7***. Note the large increase in the atlantodens interval (arrow), implying significant instability at this level.

can be calculated from their point score. Although it correlates with cardiopulmonary exercise testing (CPET), some patients who score poorly on DASI go on to score well on CPET. An objective measure of fitness is required for high-risk surgery.

Cardiopulmonary exercise testing

CPET is the gold standard measurement of a patient's fitness. The oxygen consumption (VO_2) and carbon dioxide production (VCO_2) of the patient are measured while they undergo a 10-minute period of incrementally demanding exercise (usually on a cycle ergometer) up to their maximally tolerated level (***Figure 21.9***).

CPET is based on the principle that, when a subject's delivery of O_2 to active tissues becomes inadequate, anaerobic

TABLE 21.5 Metabolic equivalent tasks (METs).

- 1 MET = 3.5 mL O_2/kg/min (oxygen consumption by a 40-year-old, 70-kg man at rest)
- 1 MET = eating and dressing
- 4 METs = climbing two flights of stairs
- 6 METs = short run
- >10 METs = able to participate in strenuous sport

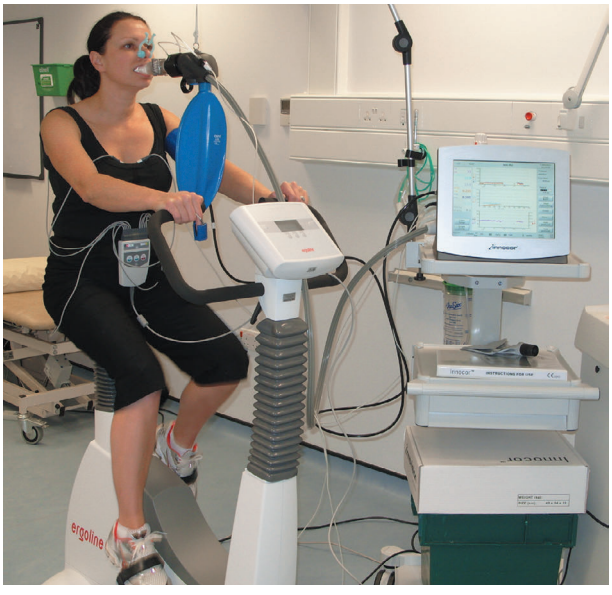

Figure 21.9 Cardiopulmonary exercise testing (CPET).

metabolism begins; lactate is buffered by bicarbonate and the resulting CO_2 increases out of proportion to the escalation in physical difficulty and O_2 consumption. The 'anaerobic threshold' (AT) is the VO_2 in mL/kg/min at which this occurs. Peak oxygen consumption is also measured. This is the end-product of a subject's combined respiratory, cardiac, vascular and musculoskeletal fitness, and subjects with either an AT below 11 mL/kg/min or a VO_2 peak below 15 mL/kg/min are at higher risk of morbidity and mortality after major surgery.

Patients who are found to be unfit can be enrolled in prehabilitation. This involves supervised exercise over 4–6 weeks with the aim of improving the patient's AT and reducing their risk profile.

Where CPET is not available, the low-cost incremental shuttle walk test (ISWT) is an attractive option. It depends on the patient's ability to walk at increasing speed over a flat surface. Patients who fail to achieve 350 metres on the ISWT have been shown to be at higher risk for oesophageal surgery. It correlates well with VO_2 peak but does not identify all low-risk patients as it is subject to patient motivation and is affected by sex, age and height.

CONSENT

Consent is a key part of preoperative care. The process of consent has evolved over the years and, in the UK, is determined by relevant Acts of Parliament, legal judgement and

the development of specific guidance. Consent is considered in detail in ***Chapter 14***.

ASSESSMENT OF RISK

Despite more comorbid patients presenting for surgery, the perioperative mortality has decreased significantly over the last half century, especially in resource-rich countries. In a published systematic review in *The Lancet* by Bainbridge *et al.* (2012), perioperative mortality has declined from 10 603 per million (95% confidence interval [CI] 10 423–10 784) in the 1970s to 1176 per million (95%CI 1148–1205) in the 1990s to 2000s ($P < 0.0001$). However, there remains a subgroup of patients who are at higher risk of morbidity and mortality after surgery. Patients who have a predicted mortality ≥5% should be considered as 'high risk'. It is estimated that, although the high-risk group accounts for less than 15% of all surgical procedures, they contribute to more than 80% of all perioperative deaths in UK.

What causes these patients to be at a high risk of death and complications after surgery? After surgery tissue destruction, blood loss, fluid shifts and changes in temperature, pain and anxiety result in increased demands for oxygen delivery to the tissues. This demand increases from an average of 110 mL/min/m^2 at rest to 170 mL/min/m^2 in the postoperative period. Most patients meet this increase in demand by increasing their cardiac output and tissue oxygen extraction. Patients who are unable to meet these demands, as a result of a limited cardiorespiratory reserve, are at a risk of oxygen debt. Occult hypovolaemia resulting from fluid shift or blood loss can further impair oxygen delivery. Splanchnic vasoconstriction to compensate for this may result in gut ischaemia. Those with coronary or cerebrovascular disease are also at a higher risk of myocardial ischaemia or stroke.

Factors contributing to risk

Risk is a complex interaction of multiple factors that can be classified into patient and surgical factors. Patient factors are listed in ***Table 21.6***. The elderly, although not independently at higher risk, not only have more cardiac, pulmonary and renal disease but also require surgery four times as often as the rest of the population. Around 10% of the population over 65 are frail, with increasing incidence associated with age. Multiple body systems lose their in-built reserves in the elderly.

The type of surgery contributes independently and is listed in ***Table 21.7***. This risk increases if the surgery is performed as an emergency. Often, the underlying condition requiring surgery itself may be associated with an increased risk of complications. For example, a patient with severe peripheral vascular disease resulting from heavy smoking may need a femoral–popliteal bypass graft and can be expected also to have significant COPD and IHD.

Moreover, when mortality by type of surgery is adjusted for patient risk factors, the apparent hierarchy of surgical risk may change. The average mortality risk for an individual patient undergoing thoracic surgery, for example, is likely to be higher than the average risk for that same patient undergoing vascular surgery. Complications associated with the latter are nevertheless more frequent because vascular patients have greater medical risk factors (***Table 21.8***).

TABLE 21.6 Patient factors that predispose to high risk of morbidity and mortality.

- Previous severe cardiorespiratory illness, e.g. acute myocardial infarction, COPD or stroke
- Late-stage vascular disease involving the aorta
- Age >70 years with limited physiological reserve in one or more vital organs
- Extensive surgery for carcinoma
- Acute abdominal catastrophe with haemodynamic instability (e.g. peritonitis)
- Acute massive blood loss >8 units
- Septicaemia
- Positive blood culture or septic focus
- Respiratory failure: PaO_2 <8 kPa or F_iO_2 >0.4 or mechanical ventilation >48 hours
- Acute renal failure: urea >20 mmol or creatinine >260 mmol/L

COPD, chronic obstructive pulmonary disease; F_iO_2, fraction of inspired oxygen; PaO_2, arterial oxygen partial pressure.

Based on clinical criteria used by Shoemaker and colleagues, modified by Boyd.

Risk prediction

The key to managing patients effectively is the identification and accurate quantification of the risk, and subsequent measures taken to minimise it.

Realistic estimates of risk are the cornerstone of informed patient consent and shared decision making. The patient and the surgeon may choose a less extensive or even a non-surgical option when the risks of the definitive procedure are deemed to be too high or unacceptable. The Royal College of Surgeons of England has recommended that patients who are predicted to have >5% mortality risk should have active consultant input in all stages of their management. Surgical procedures in those with predicted mortality of >10% should be conducted under the direct supervision of a consultant surgeon or anaesthetist, unless the consultants are satisfied with the seniority and competence of the staff managing these patients. Moreover, those with a mortality >10% should be managed in the critical care facility postoperatively. The identification of patients who will benefit the most from these interventions is important, not only for the improvement of outcomes but also for the effective allocation of resources.

A number of scoring systems have been developed over the years with the aim of identifying high-risk patients (***Table 21.9***).

American Society of Anesthesiologists system

The ASA scoring system is widely used. Although not designed to be used as a risk prediction score, it has a quantitative association with the predicted percentage of postoperative mortality (***Table 21.10***). However, it does not account for the patient's age or the nature of the surgery and the term 'systemic disease' in ASA grading introduces an element of 'subjectivity'. Examples of each physical status added in 2015 aim to reduce this.

The POSSUM score

The POSSUM (Physiologic and Operative Severity Score for the enUmeration of Mortality and Morbidity) and its modifications (P-POSSUM, CR-POSSUM) are used to predict all-cause mortality in postoperative critical care patients as well as non-cardiac morbidity.

TABLE 21.10 Operative mortality by American Society of Anesthesiologists (ASA) grade.

ASA grade	Description	30-day mortality (%)
I	Healthy	0.1
II	Mild systemic disease, no functional limitation	0.7
III	Severe systemic disease, definite functional limitation	3.5
IV	Severe systemic disease, constant threat to life	18.3
V	Moribund patient unlikely to survive 24 hours with or without operation	93.3
E	Emergency operation	–

Lee Goldman, b. 1948, Dean of Health Sciences and Medicine, Columbia University, New York, NY, USA, since 2006. He developed his index in 1977.

Lee's Revised Cardiac Risk index

Lee's Revised Cardiac Risk index (RCRI) uses objective indices based on weighted scores pertaining to surgery and comorbidity. This stratifies cardiac risk but is not designed to predict mortality (***Table 21.11***).

TABLE 21.11 The Revised Cardiac Risk index of Lee.

Risk factors	Risk of major cardiac complications (%)
History of ischaemic heart disease History of compensated or prior heart failure History of cerebrovascular disease Diabetes mellitus Renal insufficiency (creatinine >177 μmol/L) High-risk surgery	Number of factors 0 = 0.4 1 = 0.9 2 = 7.0 3+ = 11.0

ACS NSQIP score

The American College of Surgeons (ACS) National Surgical Quality Improvement Program (NSQIP) surgical risk score estimates the chance of a complication or death after surgery for more than a thousand different surgical procedures. It compares the patient's risk with an average person's risk. It is a Web-based tool done preoperatively. The risk is calculated based on surgical procedure and 19 patient-specific preoperative risk factors.

Choosing the right operation for the high-risk patient

There are situations in which the selection of one surgical technique over another may be significantly influenced by patient risk factors. Some procedures are not primarily high risk but may become so in unsuitable patients. Laparoscopic surgery, for example, has come of age as a preferred technique for patients predisposed to postoperative respiratory complications, but its effect on cardiac physiology means that the same may not apply to patients at risk of cardiac complications. The expanding demand and indications for minimal access surgery are now pushing the boundaries of intraoperative physiological tolerance. Robotic prostatectomy and some laparoscopic colorectal procedures require a pneumoperitoneum with steep Trendelenburg (head down) positioning for several hours (***Figure 21.10***). This can be associated with adverse cardiovascular and neurological complications, such as myocardial ischaemia and increased intracranial pressure in the high-risk group. This risk may be minimised by attention to patient selection.

Figure 21.10 Robotic surgery

Role of critical care and outreach services

Reports from the National Confidential Enquiry into Patient Outcome and Death (NCEPOD) show that the majority of postoperative deaths in the UK occur more than 5 days after surgery. Admission to a critical care unit allows for early treatment of complications and a level of care that is difficult to deliver in the ward environment during this crucial period. Common complications include myocardial ischaemia, cardiac, respiratory or renal failure and sepsis.

Perioperative MI is associated with a high mortality (15–25%). Critical care uses invasive cardiac monitoring and vasoactive drugs to help provide cardiac stability postoperatively to minimise ischaemia and guide fluid management to prevent cardiac failure.

Postoperatively, 1.5% of patients develop lower respiratory tract infection after surgery, with a 30-day mortality of >20%. Respiratory failure, which is defined as PaO_2 <8 kPa in air, PaO_2/F_iO_2 (the ratio of arterial oxygen partial pressure to the fraction of inspired oxygen) <40 kPa or the inability to extubate a patient 48 hours after surgery, is by far the most significant of these and is associated with a mortality of 27–40%. Elective non-invasive ventilation, chest physiotherapy and incentive spirometry should be considered for patients at increased risk of respiratory complications. These are commonly delivered on the critical care unit (***Figure 21.11***).

The high-risk surgical population accounts for 80% of postoperative deaths, but only about 15–30% of high-risk surgical patients are admitted to a critical care unit at any time following surgery. Work by the National Emergency Laparotomy Audit in the UK is seeking to standardise treatment of this high-risk group with many recommendations, including admission to critical care where predicted mortality is >5%.

In the last decade, the role of critical care has been expanded to the concept of 'critical care without walls'. The intensive care outreach services (ICORS) grew from a recognition that

Thomas H Lee, Professor of Medicine, Harvard Medical School, Professor of Health Policy and Management, Harvard School of Public Health, Boston, MA, USA.
Friedrich Trendelenburg, 1844–1924, successively Professor of Surgery at Rostock (1875–1882), Bonn (1822–1895) and Leipzig, (1895–1911), Germany. The Trendelenburg position was first described in 1885.

Figure 21.11 A high-risk patient admitted to critical care postoperatively.

there were many patients in hospital who are at risk of being critically ill and that early identification of these patients using 'early warning scores' could allow for early intervention. The outreach team functions to bridge the gap between the critical care unit and ward.

ARRANGING AN ELECTIVE THEATRE LIST

The date, place and time of operation should be matched with the availability of appropriately skilled personnel. Appropriate equipment and instruments should be made available. The operating list should be distributed as early as possible to all staff who are involved in making the list run smoothly (***Table 21.12***). If this is done electronically, familiarity with the computer system is required. A critical care bed should be prearranged for high-risk cases.

Elective list order should prioritise patients who are vulnerable to long starvation times, e.g. children and patients with diabetes. For a prompt theatre start, planning a straightforward case first can utilise time waiting for preprocedure imaging on the second case, e.g. breast wire insertion, or confirmation of a postoperative critical care bed for a high-risk case. List planning using a surgeon's average operation times for a procedure rather than generic estimates leads to better list utilisation. Staggering admission times can improve patient satisfaction but reduces flexibility for 'on the day' changes to list order.

TABLE 21.12 Perioperative teams.

- Radiology and pathology involvement
- Rehabilitation and social care workers
- Administration and scheduling team
- Specific personnel in individual cases, e.g. cardiac devices team

PREOPERATIVE ASSESSMENT FOR EMERGENCY SURGERY

In emergency surgery the principles of preoperative assessment should be the same as in elective surgery, except that the opportunity to optimise the condition of the patient is limited by time constraints. The urgency of surgery should be graded, e.g. by using the NCEPOD classification of intervention, and emergency theatre cases should be prioritised accordingly, i.e. immediate (within minutes), urgent (within hours), expedited (within days) or elective (timing to suit patient, hospital and staff). Medical assessment and treatments should be started even if there is no time to complete them before the start of a time-critical surgical procedure. Some risks may be reduced but some may persist; whenever possible, these need to be discussed with the patient during the consent process. Optimisation before urgent surgery can be more effective in a critical care environment and patients may need to be admitted to critical care preoperatively. The likelihood of a high-risk emergency patient requiring postoperative critical care should be identified and discussed with the duty critical care physician.

Summary box 21.3

Preoperative assessment for emergency surgery

- **Start**. Similar principles to that for elective surgery
- **Constraints**. Time, facilities available
- **Consent**. May not be possible in life-saving emergencies
- **Organisational efforts**. For example, local/national algorithms for the treatment of patients with multiple injuries

PART 3 | Perioperative care

CHAPTER
22 Day case surgery

Learning objectives

To understand:

- The key components of the day surgery pathway
- Which surgical procedures can be done as day surgery
- Patient selection and preparation for day surgery
- Basic principles of anaesthesia and surgery for day surgery
- How to achieve successful discharge after day surgery

DAY SURGERY

In the UK the definition of day surgery is the admission of selected patients to hospital for a planned surgical procedure, returning home on the same day. 'True day surgery' patients are day case patients who require full operating theatre facilities and/or a general anaesthetic, and any day cases not included as outpatients or undergoing endoscopy. Surgery that requires a 23-hour stay, including an overnight stay, is *not* classed as day surgery.

Day surgery offers benefits for patients and hospitals. Patients often prefer to recover in the comfort of their own home, and day surgery may cause less disruption to their domestic situation. It also reduces their risk of a hospital-acquired infection. For the hospital, it can provide greater patient satisfaction and increase the number of inpatient beds available for patients who need to be cared for in hospital.

Successful delivery of day surgery requires the day surgery service to be considered a priority by the hospital, with key enablers in all areas of the pathway providing effective implementation, refinement and progression. There must be a high-quality pathway (***Figure 22.1***) staffed by experienced/expert members of the multidisciplinary team with the equipment and resources they need. This will ensure that there is a well-prepared patient who is in receipt of high-quality day case anaesthesia and surgery and who subsequently has a safe and successful day case discharge.

SELECTION CRITERIA

Surgical

Surgical techniques have progressed significantly and now cause less physiological disruption and stress to patients; therefore, they have a lower postoperative complication profile and a faster recovery rate. The British Association of Day Surgery's (BADS) Directory of Procedures (DOP) lists over 200 procedures that are now considered to be suitable as a day case (***Table 22.1***).

Traditionally day surgery was limited to cases that lasted less than 1 hour but surgical procedures lasting 3–4 hours are now being routinely performed as successful day cases.

Day surgery surgical criteria include the following:

- There must be a low risk of significant immediate postoperative complications, e.g. catastrophic bleeding or airway compromise.
- The patient should be able to eat and drink or take oral nutrition postoperatively.
- Postoperative pain needs to be managed by oral painkillers, which may be in conjunction with local anaesthetic infiltration or peripheral nerve block.
- The patient should be able to mobilise postoperatively with or without aid.

If these criteria are met then the surgeon booking the procedure should add the patient to a day surgery pathway.

TABLE 22.1 Examples from British Association of Day Surgery *Directory of Procedures*, 6th edn (2019).

Specialty	Procedure	Recommended day case rate (%)
Breast	Simple mastectomy	75
Ear–nose–throat	Tonsillectomy	90
General surgery	Laparoscopic cholecystectomy	75
Gynaecology	Vaginal hysterectomy	60
Orthopaedics	Arthroscopy of knee or shoulder	99
Urology	Ureteroscopic extraction of calculus from the ureter	70
Vascular surgery	Transluminal operations on the iliac and femoral arteries	85

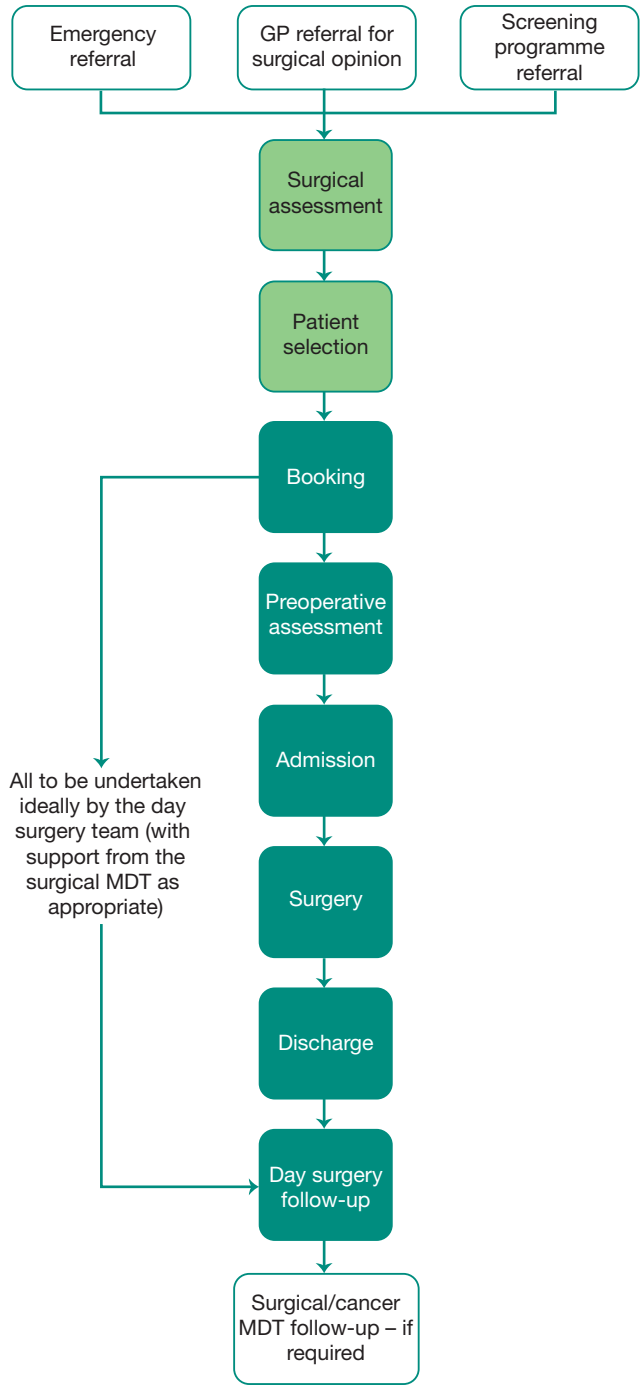

Figure 22.1 Day surgery pathway. GP, general practitioner; MDT, multidisciplinary team.

Medical

With the developments of anaesthesia and surgery, there should be very few restrictions to patients having day surgery (***Table 22.2***). Every effort should be made to optimise a patient's health so that they can be treated as a day case.

There should be no arbitrary cut-offs according to age, weight or criteria specified by the American Society of Anesthesiologists. A patient's suitability for day surgery should be judged on their comorbidities and functional status. Older patients and patients with higher body mass index (BMI) benefit from awake surgery or short-acting anaesthetic agents with a good recovery profile.

TABLE 22.2 Medical exclusions to day surgery.

- Unstable ASA 3
- ASA 4 or 5
- Any poorly controlled abnormality/comorbidity

ASA, American Society of Anesthesiologists.

Diabetes

Patients with diabetes are often better at managing their own diabetes than healthcare professionals. UK national guidance recommends that patients with well-controlled diabetes (haemoglobin A1c [HbA1c] <69 mmol/mol) can be safely managed as a day case. Patients with poorly controlled diabetes have an increased risk of cardiovascular complications and poor wound healing. They should have their surgery delayed until their diabetes is well controlled. If surgery cannot wait or it is thought the underlying disorder (e.g. tooth infection) is causing the diabetes control to be disrupted then diabetic control should be optimised as much as possible prior to surgery.

Epilepsy

Patients with well-controlled epilepsy should not be excluded from day surgery. It is essential that normal medications are not missed. Poorly controlled epilepsy should be optimised prior to any elective surgery.

Obesity

Traditionally there has been caution treating patients who have a higher BMI as a day case. Guidance from the Association of Anaesthetists of Great Britain and Ireland/BADS in 2019 states that 'even morbidly obese patients can be safely managed in expert hands, with appropriate resources'.

Preoperative assessment of patients should routinely include STOP-BANG (Snoring, Tiredness, Observed apnoeas, Pressure [hypertension], Body mass index, Age, Neck circumference, Gender) to identify undiagnosed OSA (obstructive sleep apnoea). The Society for Obesity and Bariatric Anaesthesia (SOBA) Guideline for Anaesthesia of the obese patient identifies a number of risk factors that may make day surgery unsuitable, e.g. poor functional capacity, oxygen saturation <94% on air, STOP-BANG ≥5 (***Figure 22.2***; see also tools.farmacologiaclinica.info, riskcalculator.facs.org/RiskCalculator and www.stopbang.ca). Obese patients considered suitable for day surgery should receive a short-acting anaesthetic, avoiding long-acting opiates, with allowance for the additional time that may be required anaesthetically, surgically and for recovery.

Social

Social criteria for day surgery include:

- Adequate housing conditions such as heating, an inside toilet and access to a phone.

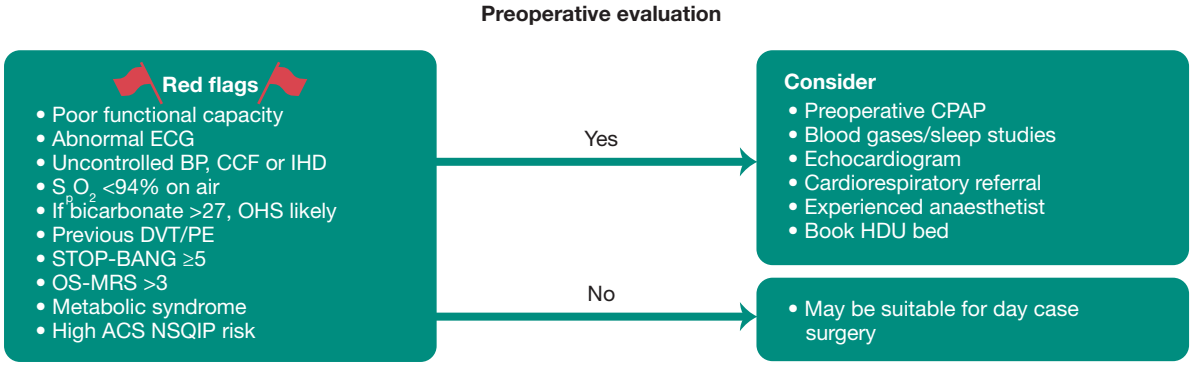

Figure 22.2 Society of Bariatric Anaesthesia (SOBA) red flags. BP, blood pressure; CCF, congestive cardiac failure; CPAP, continuous positive airway pressure; DVT, deep vein thrombosis; ECG, electrocardiogram; HDU, high-dependency unit; IHD, ischaemic heart disease; ACS NSQIP, American College of Surgeons National Surgical Quality Improvement Program; OHS, obesity hypoventilation syndrome; OS-MRS, obesity surgery mortality risk score; PE, pulmonary embolism; S_pO_2, oxygen saturation; STOP-BANG, Snoring ,Tiredness, Observed apnoeas, Pressure (hypertensive), Body mass index, Age, Neck circumference, Gender.

- The patient should live within a 1-hour drive of a hospital.
- A responsible adult should be able to stay with the patient for 24 hours after a regional anaesthetic/general anaesthetic.

The first two points are generally achievable as the patient needs to be 1 hour from 'a hospital' that can treat them rather than the hospital where surgery was performed.

With respect to the responsible adult, there have been two solutions introduced for this by centres in the UK:

1. The Torbay and South Devon NHS Foundation Trust model provides carers into the patient's home.
2. Norfolk and Norwich University Hospital model allows some patients home without carers after certain procedures (***Figure 22.3***).

Both pathways have been in place for a number of years with excellent patient satisfaction and no adverse outcomes.

TABLE 22.3 Benefits of dedicated day surgery facilities.

- All members of the multidisciplinary team are focused on day surgery
- Nurses with expertise in day surgery
- Nurses not distracted by inpatients
- Activity can continue even during a time of pressures on inpatient beds
- Fewer cancellations because activity can continue even when there are pressures on inpatient beds
- Can be made a COVID secure area – protected from COVID-positive areas of hospital
- Higher chance of successful day case discharge
- Separation from inpatient activity and so patients are more likely to be motivated to get up and go home if they see this as the 'norm'
- Higher patient satisfaction
- Higher quality outcomes

COVID, coronavirus disease.

DELIVERY OF DAY SURGERY

Facilities

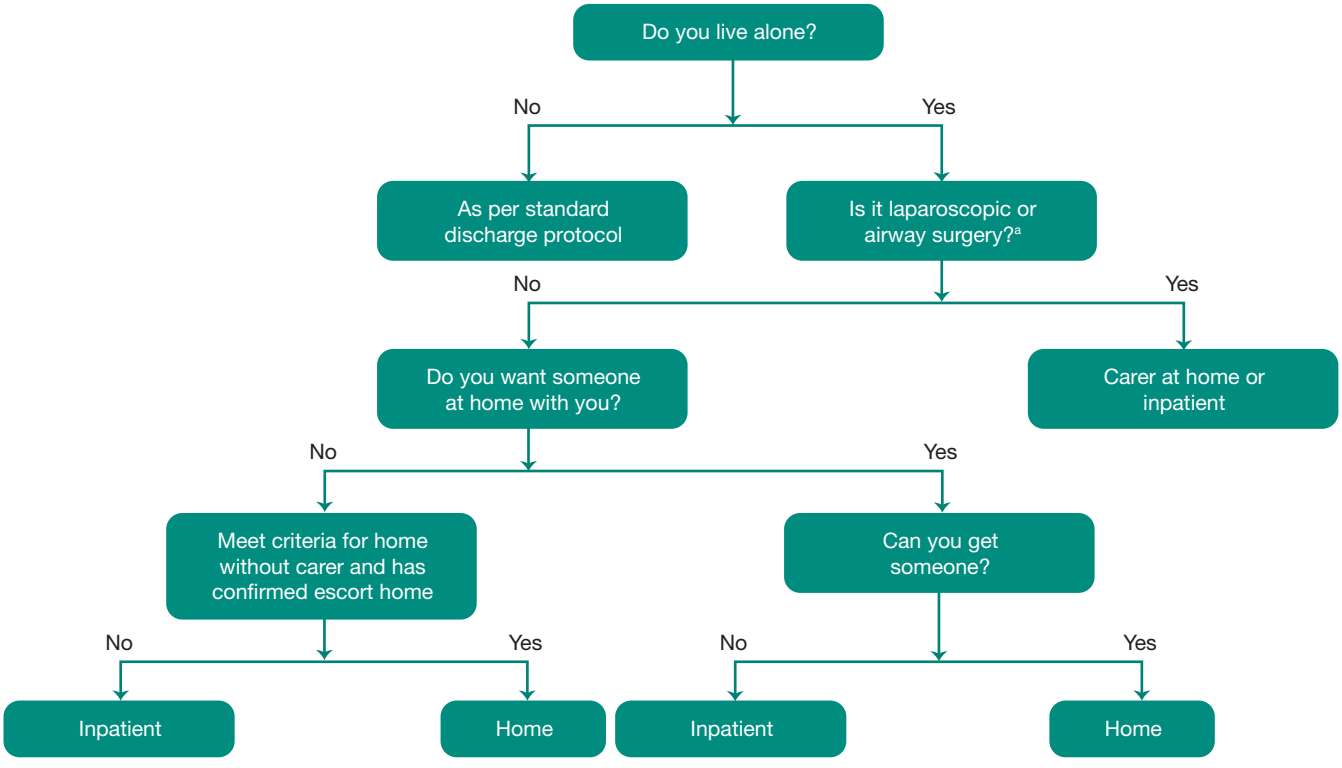
National guidance from the Royal College of Anaesthetists, Royal College of Surgeons and BADS recommends that, ideally, day surgery should be performed in a dedicated unit with its own admission area, operating theatres and discharge ward. As a minimum a dedicated day surgery ward is required. This offers a number of benefits, as listed in ***Table 22.3***.

It is important to remember that to deliver high-quality successful day surgery the appropriate equipment, drugs and expertise are essential.

Preoperative assessment

A key component to successful day surgery is a well-informed, well-prepared patient. It is essential that the day surgery message starts at the time of referral by the primary care doctor and continues throughout the pathway by all staff who the patient interacts with.

Preoperative assessment should follow the same principles as for any other patient and should be nurse led (see ***Chapter 21***). The anaesthetist should review the patient's notes where appropriate and the suitability of the patient for day case surgery should be discussed with the day surgery lead to optimise day case rates.



Key preassessment considerations specific to day surgery include:

- Can surgery be delayed until the medical condition is optimised and then plan as a day case?
- Can social factors be addressed for the patient to become a suitable day case?

Admission and list planning

Day surgery patients should follow the same starvation guidance as any other elective patient. All patients, but especially day surgery patients, should be encouraged to walk to theatre.

Consider the list order to optimise successful day surgery and therefore put operations with longer recovery times or patients who take longer to recover early on the lists

All patients must have a responsible adult escort for the journey home

[a]Airway surgery includes nasal and neck procedures and other surgery that may cause bleeding or swelling around the airway

Please discuss with an anaesthetist if the patient has multiple comorbidities or you have any concerns

Figure 22.3 The Norfolk and Norwich Day Surgery Home Alone flowchart. (Reproduced with the permission of The Norfolk and Norwich Day Surgery Team.)

(***Table 22.4***). This needs to be balanced with patients who would benefit from being first on the list, such as patients with insulin-dependent diabetes and patients with learning difficulties who would struggle to wait for long periods of time.

Anaesthesia and surgery

It is not expected that there should be any difference in surgical technique. Surgeons should perform their usual operation, which should be appropriate for rapid recovery and should be performed well. Drains should generally be avoided or, if used, clear plans of when they should be removed and by whom made clear. Any specific postoperative care or discharge information should be documented in theatre to avoid delay to discharge.

Appropriate day surgery anaesthesia requires meticulous attention to ensuring good pain relief and avoidance of postoperative nausea and vomiting. This should include premedication and a multimodal approach. Short-acting general anaesthesia agents, day case spinals or regional anaesthesia techniques should be used to enable rapid recovery. Use of long-acting opioids such as intravenous morphine is discouraged because they can delay recovery owing to increased sleepiness or nausea.

TABLE 22.4 List planning.

Operation with potentially longer recovery times	Types of patients who might need longer recovery time
Tonsillectomy	Very elderly
Knee replacement	High BMI
Hip replacement	
Complex laparoscopic cholecystectomy	

BMI, body mass index.

Discharge

The expectation by the patient and healthcare team should be that the patient will be going home the same day. Therefore, unless there has been an unexpected anaesthetic or surgical issue the patient should routinely have a nurse-led discharge. Patients should meet any pre-agreed general criteria (***Table 22.5***) as well as any surgery-specific criteria prior to discharge. In general, there should be no time restriction except for certain procedures, e.g. patients should remain in hospital until 6 hours after tonsillectomy.

TABLE 22.5 Discharge criteria.

- Vital signs stable for at least 1 hour
- Correct orientation as to time, place and person if appropriate
- Adequate pain control with supply of oral analgesia
- Understands how to use oral analgesia supplied
- Ability to dress and walk where appropriate
- Minimal nausea, vomiting or dizziness
- Has taken oral fluids
- Minimal bleeding or wound drainage
- Has passed urine (if appropriate)
- Has a responsible adult to take them home
- Written and verbal instructions given about postoperative care
- Knows when to come back for follow-up (if appropriate)
- Emergency contact number supplied

The patient should receive written and verbal postoperative instructions and a phone number to contact should they have a problem out of hours. This must be a phone with a suitable person to advise and not an answerphone.

Take-home medications should provide adequate pain relief and may include an antiemetic. These should be prescribed when the patient is in theatre and pre-packs of common analgesics should be used to improve the efficiency of prescribing and reduce delays to discharge.

All day surgery patients should be telephoned the day after surgery to provide support and to check that they have no problems. This call can also be used to collect valuable audit data, which can be used to refine the day surgery pathway.

EMERGENCY DAY SURGERY

Many emergency surgical procedures are minor and non-life-threatening. Patients may be considered low priority for surgical intervention and can therefore end up waiting hours or days for a slot on the emergency theatre list, resulting in prolonged starvation times and inpatient stay.

With appropriate planning and preparation these patients could have surgery performed as a day case. This has become reasonably commonplace in orthopaedics for many upper limb traumas and in gynaecology for the evacuation of retained products of conception (ERPC). It has also increasingly been recognised for many other surgical procedures, as listed in the BADS DOP (***Table 22.6***).

For certain procedures that can wait more than 24 hours patients can follow an 'elective pathway'. They can be swabbed and isolate as per current coronavirus 2019 (COVID-19) requirements and then attend via an 'elective green pathway'. Alternatively, they can be discharged home and then return to an acute surgical admission area to be added to a suitable list or be first on the emergency list (priority slot) and discharged the same day.

Contraindications to being discharged must be identified, e.g. systemic sepsis, unstable diabetes, major comorbidities, if parenteral pain relief is needed or if patients are deemed unsafe to mobilise.

TABLE 22.6 Common procedures suitable for an emergency day surgery pathway.

Procedure	Suggested BADS DOP day case rate (%)
Evacuation of retained products of conception	95
Incision and drainage of a perianal abscess	95
Appendicectomy	15
Reduction of a fracture of the zygomatic complex of bones	60
Repair of hand or wrist tendon	95
Primary reduction and open fixation of the ankle	25
Primary reduction and open fixation of the wrist	60

PART 3 | Perioperative care

CHAPTER 23

Anaesthesia and pain relief

Learning objectives

To gain an understanding of:

- Techniques of anaesthesia and airway maintenance
- Methods of providing pain relief
- Local and regional anaesthesia techniques
- The management of chronic pain and pain from malignant disease

HISTORY

Anaesthesia, as we know it today, was first successfully demonstrated by William Morton, a local dentist, at the Massachusetts General Hospital, Boston, MA, USA on 16 October 1846 when he administered ether to Gilbert Abbot for an operation on a vascular tumour on his neck. Earlier Horace Wells had used nitrous oxide in 1844 for painless extraction of teeth successfully.

Simpson, at Edinburgh University, overcame some of the technical difficulties of ether administration by introducing chloroform. The benefits of anaesthesia were then universally recognised and antagonism by religious leaders was countered when Queen Victoria accepted chloroform from John Snow during the birth of Prince Leopold in 1853.

KEY PRINCIPLES OF ANAESTHESIA

Optimum patient care is dependent on a collaborative approach by the anaesthetic and surgical teams. The importance of multidisciplinary collaboration has been clearly demonstrated by national audits such as the National Confidential Enquiry into Patient Outcome and Death (NCEPOD) and the Confidential Enquiry into Maternal Deaths in the UK. These audits have led to changes in clinical and non-clinical practice to improve morbidity and mortality.

The use of a safety checklist in operating theatres in the form of the World Health Organization's (WHO) 'WHO Surgical Safety Checklist' has shown a reduction in the incidence of perioperative untoward events.

The role of the modern anaesthetist has evolved from just being responsible for the patient in the operating suite into a 'perioperative physician' who optimises the patient for surgery, assesses and minimises risk, cares for the patient during the operation and then manages both pain and homeostasis in the postoperative period.

Summary box 23.1

Ground rules for anaesthesia

- Safe surgery is achieved by close teamwork between the surgeon and the anaesthetist
- Safety checklists ensure that things are not forgotten
- Risk assessments allow the best strategy to be chosen
- Anaesthetists are extending their care into the pre- and postoperative phases

PREPARATION FOR ANAESTHESIA

A surgeon's role is to carry out, in cooperation with the anaesthetist, a thorough preoperative assessment that recognises medical and anaesthetic risk factors and facilitates the optimisation of the patient's condition (see ***Chapter 21***).

Anaesthesia; the name was suggested by Oliver Wendell-Homes, first appeared in Bailey's *An Universal Etymological English Dictionary* in 1751.
William Thomas Gren Morton, 1819–1868, dentist who practised in Boston, MA, USA.
Horace Wells, 1815–1848, Harvard, CT, USA, dentist who pioneered the use of nitrous oxide anaesthesia to prevent pain during dental procedures.
Sir James Young Simpson, 1811–1870, Professor of Midwifery, Edinburgh, UK.
John Snow, 1813–1858, general practitioner, London, UK, was one of the pioneers of anaesthesia.
Humphrey Davy, 1800, suggested that nitrous oxide inhalation might be used to relieve the pain of surgical operations and named it 'laughing gas'.
Henry Edmund Gaskin Boyle, in 1917, got his gas-oxygen machine, which became the first 'Boyle apparatus'.
The first examination for a **Diploma in Anaesthesia** was held in London in 1935.
The **First Chair in Anaesthesia**: Ralph Waters, Wisconsin, USA, in 1933 and RR Macintosh in Oxford, UK, in 1937.
During the First World War **Sir Ivan Magill** and **Stanley Rowbotham**, while working with Harold Gillies (pioneer of plastic surgery), developed tracheal intubation. Sir Magill is also remembered for his laryngoscope, Magill attachment and laryngeal forceps.

A careful preassessment, multidisciplinary approach and standardised care pathway with a carefully chosen anaesthetic and analgesic technique is the cornerstone of the 'enhanced recovery programmes' that have been introduced recently across the surgical specialties.

GENERAL ANAESTHESIA

General anaesthesia is commonly described as the triad of unconsciousness, analgesia and muscle relaxation.

Summary box 23.2

The general anaesthetic triad

- Amnesia: loss of awareness
- Analgesia: pain relief
- Muscle relaxation

Induction of general anaesthesia is most frequently done by intravenous agents. Propofol has replaced thiopentone as the most widely used induction agent and can be used for maintenance of anaesthesia. Other infrequently used intravenous agents include etomidate and ketamine. Newer agents based on a benzodiazepine receptor agonist, etomidate derivatives and fospropofol are still in the experimental stage.

Inhalational induction using agents such as non-pungent sevoflurane is useful in children, needle-phobic adults and those in whom a difficult airway is anticipated. These patients will have a higher risk of developing airway obstruction. *Figure 23.1* shows a commonly used anaesthetic machine.

Figure 23.1 Anaesthetic machine.

Summary box 23.3

Key features of commonly used intravenous anaesthetic agents

- **Propofol (di-isopropyl phenol)**: smooth induction, better haemodynamic stability, blunting of autonomic reflexes and ability to use as a continuous infusion
- **Thiopentone (barbiturate)**: rapid induction, myocardial depression. A reduced metabolic rate and lowering of intracranial pressure is useful in neurosurgical patients but the drop in blood pressure can have detrimental effects
- **Etomidate (steroid derivative)**: good haemodynamic stability, brief duration of action, but concern over adrenocortical depression
- **Ketamine (phencyclidine derivative)**: preservation of blood pressure and respiratory reflexes together with excellent analgesia makes it an ideal choice for field anaesthesia. Emergence delirium is associated with administration of ketamine

Rapid sequence induction (RSI) using a predetermined dose of intravenous anaesthetic agent together with a rapidly acting muscle relaxant is used in those with a high risk of regurgitation in order to secure the airway quickly. Commonly needed in emergency surgery, it is also a technique of choice in any non-emergency surgery in a patient with delayed emptying of the stomach.

Total intravenous anaesthesia (TIVA) is becoming popular following the introduction of propofol and the ultra-short-acting opioid remifentanil. The lack of cumulative effect, better haemodynamic stability, excellent recovery profile and concerns over environmental effects of inhalational agents have made TIVA an attractive choice. TIVA is routinely used in neurosurgery, airway laser surgery, during cardiopulmonary bypass and for day case anaesthesia.

Summary box 23.4

Special terms in anaesthesia

- RSI is a technique that allows the airway to be rapidly secured. It is used when there is a high risk of regurgitation that may lead to pulmonary aspiration
- TIVA is becoming increasingly popular

Maintenance of anaesthesia can be done using a continuous infusion of intravenous agent (propofol) or an inhaled vapour such as isoflurane, sevoflurane or desflurane.

The use of nitrous oxide is declining, despite its analgesic and weak anaesthetic properties, because of concerns over postoperative nausea and vomiting. It also increases the size

of air bubbles, causing adverse effects, for example, in eye, ear and abdominal surgery. Finally it is possibly mutagenic and is a powerful greenhouse gas.

Management of the airway during anaesthesia

Loss of muscle tone as a result of general anaesthesia means that the patient can no longer keep their airway open. Therefore, patients need their airway to be maintained for them. The use of muscle relaxants will mean that they will also be unable to breathe for themselves and so will require artificial ventilation. Head tilt, chin lift and jaw thrust manoeuvres along with adjuncts such as oropharyngeal airways (***Figure 23.2***) are used to facilitate bag–mask ventilation while induction agents exert their full effect. A laryngeal mask airway or endotracheal tube is then inserted, and the patient is allowed to breathe spontaneously or is ventilated during the procedure.

The addition of a cuff to the endo-tracheal tube facilitates positive pressure ventilation and protects the lungs from aspiration of regurgitated gastric contents.

Supraglottic airways

- **Laryngeal mask airway (LMA)**. Developed by Dr Archie Brain in the UK, the original LMA® is a first-generation supraglottic airway. The mask with an inflatable cuff is inserted via the mouth and produces a seal around the glottic opening, providing a very reliable means of maintaining the airway. Its placement is less irritating and less traumatic to a patient's airway than endotracheal intubation. The technique can be easily taught to non-anaesthetists and paramedics and can be used as an emergency airway management tool. Several varieties of first-generation LMAs are available, including the classic LMA and the flexible LMA. Further advancements have led to the development of second-generation supraglottic devices, such as the ProSeal® LMA and the i-gel® (***Figure 23.3***). These devices usually have an in-built 'bite block' and oesophageal drain tube. They can be used for ventilation of the lungs at higher inflation pressures and are more suitable for patients with a higher body mass index. There are also modified versions of the LMA, including the ILMA (intubating LMA), that allow a blind technique, aiding insertion of a tracheal tube in difficult conditions. There is increasing evidence that second-generation devices have a good safety and efficacy profile and should be replacing all first-generation devices.
- **Difficult intubation**. Endotracheal intubation is feasible in most patients, but in a certain proportion of patients it may be difficult or impossible. However, if it is compounded by an inability to ventilate and therefore maintain oxygenation of the patient by bag–mask, the consequence can be catastrophic hypoxia. Many devices have been developed to aid intubation if difficulty is anticipated (e.g. McGrath® blade, Airtraq®, C-MAC® video laryngoscope) (***Figures 23.4 and 23.5***); similarly, protocols have been created by specialised societies to deal

Figure 23.2 Oropharyngeal airways.

Figure 23.3 i-gel® supraglottic airway.

Figure 23.4 Single-use laryngoscope.

Archie Brain, b. 1942, formally an anaesthetist, whose patent application for the laryngeal mask airway was granted in 1982.

Figure 23.5 Airtraq® intubating device.

Figure 23.6 Fibreoptic intubating bronchoscope.

with such situations. One specialised method for intubation in difficult situations is the use of the fibreoptic intubating bronchoscope (***Figure 23.6***), facilitated by topical local anaesthetic in awake patients or using general anaesthesia. The anaesthetist places the endotracheal tube in the trachea by threading the tube over the bronchoscope, and so places the tube in the trachea under direct bronchoscopic vision. An awake intubation requires careful patient selection, as it may not be a suitable technique for all patient groups.

Double-lumen tubes and endobronchial tubes are used in procedures such as thoracoscopic, pulmonary and oesophageal surgery to allow collapse of one lung (while ventilating the other) for ease of surgery. Their use is also essential to isolate the healthy lung in empyema and in the case of a bronchopleural fistula.

Ventilating bronchoscopes and endobronchial catheters can be used to maintain oxygenation during laryngotracheal surgery or bronchoscopy by using intermittent jets of oxygen.

Summary box 23.5

Techniques for maintaining an airway

- Chin lift and jaw thrust: suitable for the short term when no aid is available
- Guedel airway: holds the tongue forward but does not prevent aspiration
- Supraglottic device: easy insertion, reliable airway, allows ventilation
- Endotracheal intubation: secure and protected airway

Summary box 23.6

Complications of intubation

- Failed intubation
- Accidental bronchial intubation
- Trauma to teeth, pharynx or larynx
- Aspiration of gastric contents during intubation
- Disconnection, blockage or kinking of tube
- Delayed tracheal stenosis

Muscle relaxation and artificial ventilation

Pharmacological blockade of neuromuscular transmission by neuromuscular blocking agents provides relaxation of muscles, allowing easy surgical access. However, the patient will need artificial ventilation. Neuromuscular blocking agents are broadly classified into depolarising and non-depolarising groups according to their mode of action (***Table 23.1***).

Suxamethonium is the most commonly used depolarising agent. It binds to the nicotinic acetylcholine receptors, resulting in opening of the cation channel, leading to depolarisation and rapid relaxation of muscles. Despite its adverse effects such as hyperkalaemia, muscle pain, anaphylaxis and potentially life-threatening malignant hyperthermia, suxamethonium is still widely used because of its quick onset and short duration of action. These properties are useful when rapid endotracheal intubation is necessary to protect the patient's airway or when short duration surgery is performed.

Non-depolarising muscle relaxants act by competitive blockade of postsynaptic receptors at the neuromuscular junction. They provide longer, predictable activity but require careful monitoring, appropriate timing and reversal of their action by agents such as neostigmine and sugammadex at the end of the procedure. A peripheral nerve stimulator is routinely used to monitor the depth of neuromuscular block and also to confirm satisfactory recovery of muscle power prior to extubation. With the increasing availability and evidence of the use of sugammadex, the non-depolarising muscle relaxant rocuronium is an alternative to suxamethonium in the 'rapid-sequence' induction as it allows reversal of its actions with sugammadex in a rapid manner.

Arthur Ernest Guedel, 1883–1956, Clinical Professor of Anesthesiology, University of Southern California, Los Angeles, CA, USA.

TABLE 23.1 Properties of commonly used muscle relaxants

	Advantages	Disadvantages
Suxamethonium	• Quickest onset, very short duration, spontaneous recovery • Ideal for rapid intubation and for short procedures	• Muscle pain, hyperkalaemia, prolonged apnoea and life-threatening malignant hyperthermia
Vecuronium	• Long acting • Minimal cardiovascular effect and less allergic reaction	• Dependent on hepatic metabolism and renal clearance; hence, caution if hepatic and renal impairment
Atracurium	• Intermediate acting • Non-enzymatic Hofmann degradation • Suitable in renal and hepatic failure	• Histamine release and allergic reactions
Rocuronium	• Rapid onset, intermediate action • Suitable for rapid intubation • Rapid reversal possible using sugammadex	• Allergic reactions • Excreted unchanged via bile and urine

Ventilation during anaesthesia

Mechanical ventilation is required when the patient's spontaneous ventilation is inadequate or when the patient is not breathing because of the effects of the anaesthetic, analgesic agents or muscle relaxants.

In volume control ventilation, a preset volume is delivered by the machine irrespective of the airway pressure. The pressure generated will be, in part, dependent on the resistance and compliance of the airway. In laparoscopic surgery requiring the Trendelenburg position (the patient is positioned head down), morbidly obese patients and those with lung disease, this may result in excessive pressures being developed, which may lead to barotrauma (pneumothorax).

In pressure control mode the ventilator generates flow until a preset pressure is reached. The actual tidal volume delivered is variable and depends on airway resistance, intra-abdominal pressure and the degree of relaxation.

Positive end-expiratory pressure (PEEP) is often applied to help maintain functional residual capacity. This avoids lung collapse by opening collapsed alveoli and maintains a greater area of gas exchange, so reducing vascular shunting.

Monitoring and care during anaesthesia

A minimum basic monitoring of cardiovascular parameters is required during surgery. This includes:

- vascular
  - electrocardiogram (ECG);
  - blood pressure;
- adequacy of ventilation:
  - inspired oxygen concentration;
  - oxygen saturation by pulse oximetry;
  - end-tidal carbon dioxide concentration.

Monitors of temperature, ventilation parameters and delivery of anaesthetic agents are also routinely used, while measurement of urine output and central venous pressure are recommended for major surgery.

Summary box 23.7

Intermittent positive-pressure ventilation

- Volume controlled, which ensures adequate gas entry but risks high-pressure damage
- Pressure controlled, which avoids high-pressure damage but risks inadequate ventilation
- PEEP reduces alveolar collapse and reduces vascular shunting so improving perfusion

LOCAL ANAESTHESIA

Local anaesthetic drugs (*Table 23.2*) may be used to provide anaesthesia and analgesia, as a sole agent or as adjuncts to general anaesthesia. Available techniques include topical anaesthesia, local infiltration, regional nerve blocks and central neuraxial blocks (spinal and epidural anaesthesia).

TABLE 23.2 The common local anaesthetic drugs.

Name	Maximum dose	Comments
Lidocaine	3 mg/kg (7 mg/kg with adrenaline [epinephrine])	Early onset, short acting, good sensory block
Bupivacaine	2 mg/kg	Long lasting, more cardiotoxic, must never be used intravenously
Prilocaine	6 mg/kg (9 mg/kg with adrenaline)	Least systemic toxicity, causes methaemoglobinaemia
Ropivacaine	3–4 mg/kg	Less cardiotoxic, greater sensory–motor separation
Levobupivacaine	2 mg/kg	Isomer of bupivacaine with fewer cardiotoxic properties

Local anaesthesia techniques can lead to complications that may be local, such as infection or haematoma, or systemic, as a result of overdose or accidental intravascular injection.

Friedrich Trendelenburg, 1844–1924, successively Professor of Surgery at Rostock (1875–1882), Bonn (1822–1895) and Leipzig (1895–1911), Germany. The Trendelenburg position was first described in 1885.

The systemic effects of local anaesthetic agents are dose dependent and manifest as cardiovascular (cardiac arrhythmia, cardiac arrest) or neurological (depressed consciousness, convulsions). Prilocaine overdose causes methaemoglobinaemia, whereas bupivacaine overdose causes treatment-resistant ventricular arrhythmia and cardiac arrest.

The addition of adrenaline (epinephrine) to local anaesthetic solutions hastens onset, prolongs the duration of action and permits a higher upper dose limit. The use of adrenaline is contraindicated in patients with cardiovascular disease, those taking tricyclic and monoamine oxidase inhibitors and in end-arterial locations.

Appropriately skilled personnel, resuscitation equipment and oxygen should always be available with local anaesthetic use because of the potential risks of life-threatening complications.

Regional anaesthesia

Regional anaesthesia involves central neuraxial or peripheral nerve or plexus blocks using local anaesthetic drugs. It has a clear advantage when general anaesthesia carries a higher risk of morbidity and mortality, such as in patients with debilitating respiratory and cardiovascular disease and obstetric cases. It also provides excellent pain relief in the postoperative period, reducing the need for analgesics such as opioids.

As with general anaesthesia, venous access should be established and vital parameters should be monitored during regional anaesthesia.

Localising nerves using anatomical landmarks and eliciting paraesthesia alone carries a high risk of nerve damage and intravascular injection and has a lower success rate. The use of nerve stimulators to localise nerves improves the success rate and reduces risks. Ultrasound-guided regional anaesthesia allows the visualisation of nerves and the spread of local anaesthetics, enabling the use of a smaller dose of local anaesthetic agents with improved success rates and safety.

Summary box 23.8

Types of anaesthesia

- General anaesthesia may be more acceptable to patients
- Regional anaesthesia has major advantages in obstetrics and patients with respiratory compromise
- Local blocks have been transformed by nerve stimulators and ultrasound guidance
- All require full resuscitation and monitoring equipment to be available

Common local anaesthesia techniques

Topical anaesthesia

- **EMLA (eutectic mixture of local anaesthetics)**. This is a mixture of lidocaine and prilocaine for application to the skin for venepuncture in children.
- **Cocaine**. It may be called Moffett's solution (with an added mixture of adrenaline and sodium bicarbonate) and used in nasal surgery for anaesthesia and vasoconstriction.
- **Lidocaine 2/4/10%**. Spray to anaesthetise the airway during awake fibreoptic intubation.

Nerve blocks

An interscalene approach to brachial plexus for shoulder surgery produces excellent postoperative analgesia. Complications include phrenic nerve block, Horner's syndrome and accidental intravascular and spinal injection. Supraclavicular, infraclavicular or axillary approaches to the brachial plexus can be used as the sole anaesthetic technique for upper limb surgery (***Figure 23.7***). Femoral and sciatic nerve blocks are often used for anaesthesia and analgesia for lower limb surgery.

Local anaesthetic blocks have been described that block the nerves closer to the joint so that motor blockade of the whole lower limb can be minimised. An example of this type of block is the iPACK (infiltration between the popliteal artery and capsule of the knee) block, which targets the genicular nerves supplying the knee joint by using ultrasound-guided injection posterior to the knee joint.

Transversus abdominis plane/quadratus lumborum and erector spinae plane block are examples of fascial plane blocks, which have grown rapidly in popularity. Local anaesthetic is injected in the fascial planes containing the nerves from abdominal or chest wall structures. Transversus abdominis plane (TAP) block has been claimed to provide effective

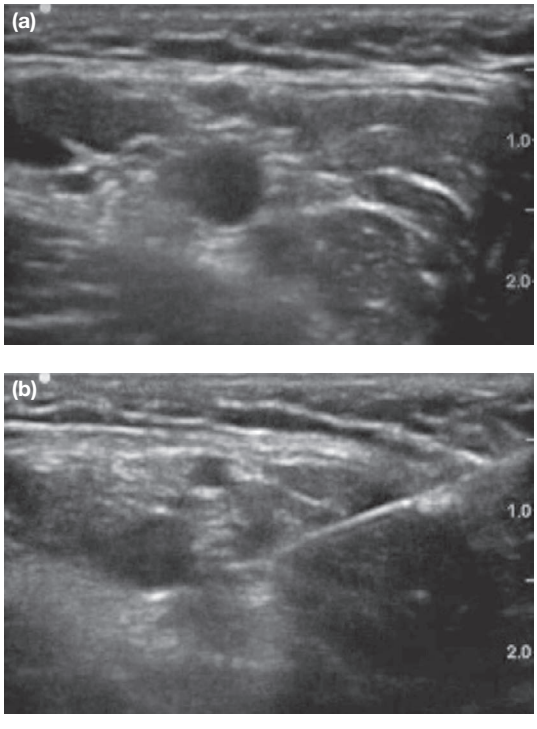

Figure 23.7 (a, b) Ultrasonic picture of brachial plexus block.

Johann Friedrich Horner, 1831–1886, Professor of Ophthalmology, Zurich, Switzerland, described this syndrome in 1869.
Major A. J. Moffett of the Royal Army Medical Corps first described its use in 1941. He modified it in 1946 to include 2 mL of 8% cocaine, 2 mL of 1% sodium bicarbonate, and 1 mL of 1:1000 adrenaline.

analgesia after a wide range of abdominal surgery. The T6–L1 segmental nerves enter the plane between the internal oblique muscle and the transverse abdominis muscle just medial to the anterior axillary line. Injection of local anaesthetic into the fascial plane between the internal oblique and transversus abdominis muscles allows a block of all these nerves, and excellent anaesthesia of the anterior abdominal wall. Quadratus lumborum block also aims to target abdominal nerves as they pass in front of the quadratus lumborum muscle. Erector spinae block aims to block the spinal nerves at various sites, depending on the site of injection. Local anaesthetic is deposited underneath the erector spinae group of muscles as they lie over the transverse process of the vertebra.

Intravenous regional anaesthesia (Bier's block)

Bier's block produces excellent anaesthesia for short surgery, particularly for the upper limb (e.g. carpal tunnel release). In this technique local anaesthetic is injected intravenously to produce anaesthesia of the upper limb. A double tourniquet is used on the side of surgery. An intravenous cannula is sited into a vein on the back of the hand on the side that is being operated on. The upper limb is then exsanguinated using an Esmarch bandage. The proximal cuff of the double tourniquet is inflated, followed by intravenous injection of prilocaine into the cannula. After 20 minutes the distal cuff of the tourniquet is inflated and then the proximal cuff is deflated. Even if surgery is finished, the tourniquet should be left inflated until the local anaesthetic has bound to tissues (20 minutes) so that release of local anaesthetic into the systemic circulation does not occur. Lidocaine can be used with caution (consider the safe dose of lidocaine and the time of tourniquet inflation) but bupivacaine should never be used for Bier's block.

Spinal anaesthesia

Spinal anaesthesia alone or in combination with general anaesthesia or sedation is used extensively for lower limb, obstetric and pelvic surgery. Injection of a 'single-shot' local anaesthetic agent intrathecally produces intense and rapid block for surgery. The addition of opioids provides prolonged postoperative analgesia but carries the risk of late respiratory depression.

Autonomic sympathetic blockade produces hypotension, particularly if the level of block is above the T10 spinal dermatome. Caution is needed in patients with hypovolaemia and cardiovascular disease.

The incidence of dural puncture headache can be minimised by limiting the number of punctures and using fine-bore pencil-tip needles that are designed to split rather than cut the dura.

Epidural anaesthesia

Epidural anaesthesia is slower in onset than spinal but has the advantage of prolonged analgesia by multiple dosing or continuous infusion through a catheter placed in the epidural space. Being slower in onset, the resulting hypotension from sympathetic blockade can be better controlled and can reduce blood loss.

Continuous infusion (with a patient-controlled bolus) of weak local anaesthetic combined with opioids (such as fentanyl) is routinely used for postoperative analgesia. Placement of an epidural catheter in the high thoracic region provides excellent analgesia for a wide variety of upper abdominal and thoracic surgical operations, enabling early mobilisation and reducing respiratory complications.

Epidural anaesthesia is technically more difficult than spinal anaesthesia; it has a higher failure rate and carries the risk of nerve damage, spinal injuries, accidental spinal injection of a large volume of local anaesthetic, infection and epidural haematoma.

Summary box 23.9

Local anaesthetics

- EMLA cream for children needing injections
- Regional and nerve blocks for limb surgery
- Spinal anaesthesia offers a quick onset and a short duration of anaesthesia
- Epidurals are more difficult but can then be topped up postoperatively and used as a continuous infusion

PAIN

Pain is defined as 'An unpleasant sensory and emotional experience associated with, or resembling that associated with, actual or potential tissue damage.' Most patients will experience pain after surgery. This is usually managed by a combination of painkillers and local anaesthetic techniques (multimodal analgesia). The common painkillers that are used are regular paracetamol, non-steroidal anti-inflammatory drugs (NSAIDs) and opioids. Opioids can be weak, such as codeine, or stronger opioids, such as morphine and oxycodone. Opioids are associated with a high incidence of side effects (nausea and vomiting, respiratory depression, itching). By combining opioids with other drugs, the dose of opioid can be minimised, thus side effects can be reduced.

Paracetamol and non-steroidal anti-inflammatory drugs

Paracetamol was first synthesised in 1878 by Morse and was introduced for medical usage in 1883. However, because of misinterpretation of its safety profile, its use was limited until the 1950s, when the chemically similar, and until then preferred analgesic, phenacetin was withdrawn owing to renal toxicity. Paracetamol is probably now the most commonly used drug worldwide; it is available over the counter, used in almost all ages and forms step 1 of the WHO analgesic ladder. It is first-line treatment for pyrexia and pain, plays an important role in multimodal analgesia and is considered to possess a generally excellent safety profile, except in significant overdose, with only a few drug interactions. Oral and rectal administration can produce analgesia within 40 minutes, with maximal effect at

August Karl Gustav Bier, 1861–1949, Professor of Surgery, Bonn (1903–1907) and Berlin (1907–1932), Germany.

1 hour, but because of variability in bioavailabilities (in the range 63–89% for oral and 24–98% for rectally administered preparations) the timing of onset can be unpredictable. The introduction of its intravenously administered preparation within the last decade overcomes this issue.

NSAIDs are used in the treatment of acute pain for their opioid-sparing effects, as part of a multimodal analgesic regimen. However, it is important to recognise that long-term usage and an increase in prescription may be associated with significant morbidities. Increased risk of perioperative bleeding, gastrointestinal bleeding and ulceration, thrombotic events such as myocardial infarction and stroke, renal impairment, fluid retention and exacerbation of asthma are some of the side effects of NSAIDs, suggesting cautious usage.

Intravenous opioids administered as patient-controlled analgesia (PCA) for pain relief is a useful technique. The patient is trained to give a bolus dose of drug by pressing a control button on a machine, the functions of which have been regulated by medical staff. The strength, frequency and total dose of drug in a given time are all limited by computer. This method is popular with patients as they have control and prevents delays in administration of doses.

Chronic pain

Chronic pain is defined as pain that persists or recurs for more than 3 months. In chronic pain syndromes, pain can be the sole or a leading complaint and requires special treatment and care. This could be 'chronic primary pain', which may be conceived of as a disease in its own right, for example in conditions such as fibromyalgia or non-specific low-back pain. In six other subgroups, pain is secondary to an underlying disease: chronic cancer-related pain, chronic neuropathic pain, chronic secondary visceral pain, chronic post-traumatic and postsurgical pain, chronic secondary headache and orofacial pain and chronic secondary musculoskeletal pain. These conditions are summarised as 'chronic secondary pain', in which pain may at least initially be conceived as a symptom.

In surgical practice, patients with chronic pain may present for treatment of the cause (e.g. pancreatitis, malignancy) or concomitant benign pathology. Almost 50 years ago, using gate theory, Melzeck and Wall proposed pain to be not only subjective but also a multidimensional experience that incorporates sensory/discriminative, motivational/affect and cognitive aspects. Recent guidance from the International Association for the Study of Pain highlights that the multidimensional aspect is one of the key components, hence the treatment of chronic pain involves a multidisciplinary multimodal approach.

Mechanistically, chronic pain may be classified into:

- **Nociceptive pain**, which may result from musculoskeletal disorders or cancer activating cutaneous nociceptors (pain receptors). Prolonged ischaemic or inflammatory processes result in sensitisation of peripheral nociceptors and altered activity in the central nervous system, leading to exaggerated responses in the dorsal horn of the spinal cord. The widened area of hyperalgesia and increased sensitivity (allodynia) have been attributed to increased transmission in the central nervous system.
- **Neuropathic (or neurogenic) pain** is dysfunction in the peripheral or central nerves (excluding the 'physiological' pain due to noxious stimulation of the nerve terminals). It is classically of a 'burning', 'shooting' or 'stabbing' type and may be associated with allodynia, numbness and diminished thermal sensation. It is poorly responsive to opioids. Examples include trigeminal neuralgia, postherpetic neuropathy and diabetic neuropathy.

Principles of chronic pain management

Non-pharmacological treatment

This involves a multidisciplinary approach targeting the biopsychosocial model of health (***Figure 23.8***). Early assessment and engagement with physiotherapy and exercise are key contributors in successful management. Psychological interventions such as counselling, cognitive behaviour therapy and mindfulness are recognised strategies for pain control. 'Pain management programmes' lay out a logical structure for this.

Pharmacological treatment

Drugs in chronic non-malignant pain

Paracetamol and NSAIDs are the mainstays of musculoskeletal pain treatment. The tricyclic antidepressant drugs and anticonvulsant agents are often useful for the pain of nerve injury, although side effects can prove troublesome and reduce compliance. Both pregabalin and gabapentin reduce spontaneous neuronal activity by their action on the $\alpha_2\delta$ subunit of the calcium channel. They are now routinely used for managing neuropathic chronic pain. In more severe and debilitating non-malignant chronic pain, opioid analgesic drugs are used in slow release oral preparations (morphine and oxycodone) and transcutaneous patches (fentanyl and buprenorphine).

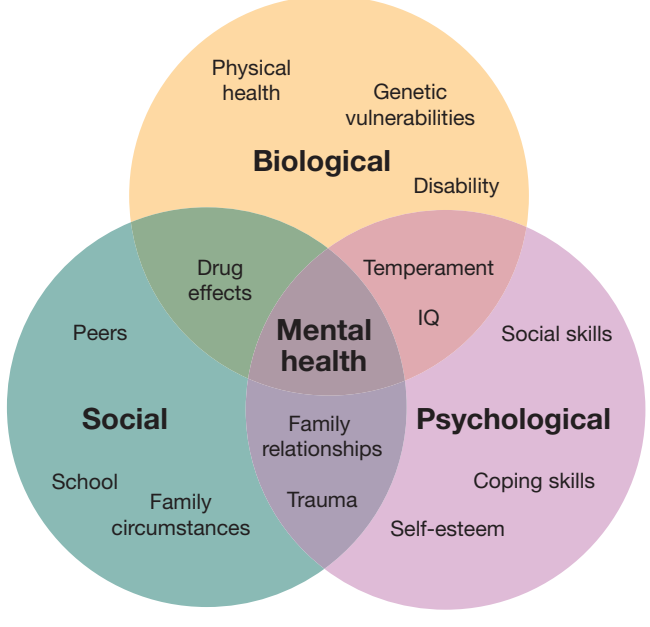

Figure 23.8 Biopsychosocial model of health.

Summary box 23.10

Commonly used terms in chronic pain

Term	Definition
Allodynia	Pain due to a stimulus that does not normally provoke pain. Allodynia involves a change in the quality of a sensation, whether tactile, thermal or of any other sort
Analgesia	Absence of pain in response to stimulation that would normally be painful
Central sensitisation	Increased responsiveness of nociceptive neurones in the central nervous system to their normal or subthreshold afferent input. The net effect is that innocuous stimuli will be interpreted as painful
Epidural space	The space (or potential space) between the ligamentum flavum (or vertebral wall) and the dura, just outside the spinal canal, extending from the foramen magnum to the sacrum. Leads and catheters may be placed in this space via a needle
Hyperalgesia	Abnormally heightened sensitivity to pain. For pain evoked by stimuli that usually are not painful, the term allodynia is preferred, while hyperalgesia is more appropriately used for cases with an increased response at a normal threshold or at an increased threshold
Hypoalgesia	Decreased sensitivity to painful stimuli. Hypoalgesia can be caused by exogenous chemicals such as opioids, as well as by chemicals produced by the body in phenomena such as fear- and exercise-induced hypoalgesia
Intrathecal space	The cerebrospinal fluid-filled space around the spinal cord, protected by the dura mater, into which certain medicines may be delivered to achieve their most potent effect
Nociception	Sensory response to certain harmful or potentially harmful stimuli. Nociception triggers a variety of biological and behavioural responses and may also result in a subjective experience of pain
Neuropathic pain	Neuropathic pain is defined as pain caused by a lesion or disease of the somatosensory nervous system
Nociceptive pain	Pain that arises from actual or threatened damage to non-neural tissue and that is due to the activation of nociceptors
Noxious stimulus	An actual or potential tissue-damaging event
Off-label	When a prescription drug is prescribed for uses other than what Australia's Therapeutic Goods Administration, the USA's Food and Drug Administration or the UK's Medicines and Healthcare products Regulatory Agency has approved and published in the drug's package insert
Pain	An unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage
Pain threshold	The minimum amount of a stimulus with which pain begins to be felt. It is an entirely subjective phenomenon
Paraesthesia	Abnormal cutaneous sensations such as tingling, tickling, pricking or burning with no apparent physical cause. Often described as 'pins and needles' or of a limb 'falling asleep'
Peripheral neuropathic pain	Pain caused by a lesion or disease of the peripheral somatosensory nervous system

Tapentadol, with its dual action on the opioid and noradrenaline (norepinephrine) selective reuptake inhibition pathway, may provide relief in patients with both a neuropathic and nociceptive element to their pain. Combinations of drugs often prove useful to achieve the optimum of efficacy with minimal side effects.

Treatment of pain dependent on sympathetic nervous system activity

Even minor trauma and surgery (often of a limb) can provoke excessive sympathetic adrenergic activity, inducing vasoconstriction and abnormal nociceptive transmission. This can lead to chronic burning pain, allodynia, trophic changes and resultant disuse.

Management includes antineuropathic pain medications (pregabalin, gabapentin, amitriptyline) as part of multimodal analgesia with a multidisciplinary pain management approach. This includes considerable input from psychological services and targeted physiotherapy. Interventional treatment may include local anaesthetic injection of the stellate ganglion for upper limb symptoms. Percutaneous chemical lumbar sympathectomy with local anaesthetic is used for relief of rest pain in advanced ischaemic disease of the legs.

Interventional pain management for chronic pain

Local anaesthetic and steroid injections can be effective around an inflamed nerve and they reduce the cycle of constant pain transmission with consequent muscle spasm. Transforaminal

selective root blocks in the epidural space are used for the pain of nerve root irritation associated with or without minor disc prolapse, followed by active physiotherapy and rehabilitation to promote mobility.

Nerve stimulation procedures such as acupuncture and transcutaneous nerve stimulation increase endorphin production in the central nervous system. Nerve decompression craniotomy rather than percutaneous coagulation of the ganglion is now performed for trigeminal neuralgia.

Spinal cord stimulation (SCS) by dorsal column stimulation is now a recognised and effective management of intractable neuropathic pain (***Figure 23.9***). This involves placement of electrodes in the posterior epidural space to allow dorsal column stimulation through an implantable pulse generator inserted in the body. In the UK this has been recommended by National Institute for Health and Care Excellence (NICE) guidance for intractable neuropathic pain management. Robust evidence exists for its clinical and health economic benefit in failed back surgery syndrome, in which patients have undergone previous spinal surgery. Early use of SCS in surgery-naive patients might lead to better outcomes. National guidelines in the UK do not recommend disc replacements or spinal fusions in patients with lower back pain unless the latter are part of a trial, rendering a large part of the patient population ineligible for surgery. In these instances, SCS could prove to be an effective solution.

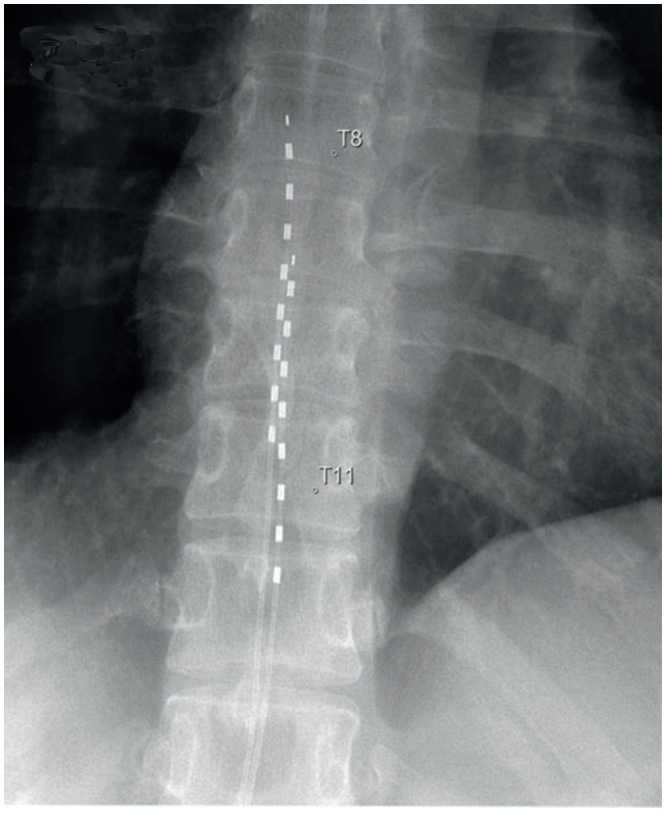

Figure 23.9 Dual-lead spinal cord stimulator in the epidural space.

Pain control in malignant disease

Pain is a common symptom associated with cancer, even more so during the advanced stages. In intractable pain, the underlying principle of treatment is to encourage independence of the patient and an active life in spite of the symptom. WHO advises use of the 'WHO analgesic ladder':

- first step: simple analgesics – paracetamol, NSAIDs, tricyclic drugs or anticonvulsant drugs;
- second step: intermediate-strength opioids – codeine, tramadol;
- third step: strong opioids – morphine (pethidine has now been withdrawn).

Oral opiate analgesia is necessary when the less powerful analgesic agents no longer control pain on movement or enable the patient to sleep. Opioids may exhibit both dependence and addiction with long-term use. It is important to distinguish between addiction and dependence; the former is a psychosocial phenomenon whereas the latter is a purely physiological response to a given drug. Some patients experience 'breakthrough pain' (acute, excruciating and incapacitating), which occurs either spontaneously or in relation to a specific predictable or unpredictable trigger experienced by patients who have relatively stable and adequately controlled background pain. Opioid rotation or switching may be considered if a patient obtains pain relief with one opioid and has severe adverse effects.

Oral morphine, which is often used for chronic pain, can be prescribed in short-acting liquid or tablet form and should be administered regularly every 4 hours until an adequate dose of drug has been titrated to control the pain over 24 hours. Once this is established, the daily dose can be divided into two separate administrations of enteric-coated, slow-release morphine tablets (MST morphine) every 12 hours. Additional short-acting opioids (morphine/fentanyl) can then be used to cover episodes of 'breakthrough pain'. Nausea treated using antiemetic agents does not usually persist, but constipation is a frequent and persistent complication requiring regular prevention by laxatives.

Infusion of subcutaneous, intravenous, intrathecal or epidural opiate drugs

The infusion of an opiate is necessary if a patient is unable to take oral drugs. Subcutaneous infusion of diamorphine is effective and simple to administer. Epidural infusions of diamorphine with an external pump can be used in mobile patients. Intrathecal infusions with pumps programmed by external computers are used; however, there is a possibility of the patient developing an infection with catastrophic effects. Intravenous narcotic agents may be reserved for acute crises, such as pathological fractures.

Neurolytic techniques in cancer pain

These should only be used if life expectancy is limited and the diagnosis is certain. The useful procedures are:

- subcostal phenol injection for a rib metastasis;
- coeliac plexus neurolytic block with alcohol for the pain caused by pancreatic, gastric or hepatic cancer;
- intrathecal neurolytic injection of hyperbaric phenol;

- percutaneous anterolateral cordotomy to divide the spinothalamic ascending pain pathway; this is a highly effective technique in experienced hands, selectively eliminating pain and temperature sensation in a specific limited area.

Alternative strategies include:

- the development of anti-pituitary hormone drugs, such as tamoxifen and cyproterone, has enabled effective pharmacological therapy for the pain of widespread metastases instead of pituitary ablation surgery;
- palliative radiotherapy can be most beneficial for the relief of pain in metastatic disease; adjuvant drugs such as corticosteroids to reduce cerebral oedema or inflammation around a tumour, which may be useful in symptom control; tricyclic antidepressants, anticonvulsants and flecainide are also used to reduce the pain of nerve injury.

Summary box 23.11

Approximate equianalgesic potencies of opioids for oral administration

	Potency	Equivalent dose to 10 mg oral morphine
Codeine phosphate	0.1	100 mg
Dihydrocodeine	0.1	100 mg
Hydromorphone	5	2 mg
Morphine	1	10 mg
Oxycodone	1.5	6.6 mg
Tapentadol	0.4	100 mg

Adapted from the British National Formulary.

PART 3 | Perioperative care

CHAPTER 24

Postoperative care including perioperative optimisation

Learning objectives

To understand:

- The integrated approach to caring for patients in the perioperative period
- Common postoperative problems seen in the immediate postoperative period
- How to predict, recognise, prevent and treat common postoperative complications
- The principles of enhanced recovery

INTRODUCTION

Perioperative care is integrated care delivered to the patient by a multidisciplinary team before, during and after surgery.

The multidisciplinary perioperative team comprises doctors from various specialties, such as surgery, anaesthesia, acute medicine, care of the elderly and cardiology, along with nurses, physiotherapists and occupational therapists. The aim of this is to bring together the patient and the care team in the perioperative period to improve the patient's outcome and reduce healthcare-related costs. The input from the multidisciplinary team will vary depending on the medical condition of the patient and the complexity of the surgery.

Many patients coming for surgery will have long-term health problems that are at risk of worsening in the perioperative period. The time period between a decision to operate and the actual surgery can be used by the perioperative team to risk assess the patient and identify medical problems and treat them accordingly to ensure an optimal medical state prior to surgery. This will stop deterioration in long-term health problems perioperatively and will prevent a delay in discharge. Risk assessment may involve simple blood tests to identify health problems, e.g. heart or renal failure, or more sophisticated tests, such as cardiopulmonary exercise testing (CPET), to assess the patient's level of fitness. Providing high-quality care during surgery is essential and expected. Preventing harm by medical errors is also important. Checklists, such as the World Health Organization's (WHO) 'Surgical Safety Checklist', are now routinely used to prevent surgical errors. Postoperative pain can delay the patient's recovery, increase the risk of chest complications and chronic pain and contribute to a poor patient experience. A well-trained perioperative team led by an anaesthetist can develop a plan for managing pain.

Increasingly patients are coming for surgery with complex medical problems that require management from the multidisciplinary team of physicians. This role is now taken over by anaesthetists as they have a better understanding of complications occurring in the perioperative setting.

After complex surgery, many patients will need more intensive monitoring of their physiological parameters than is possible on a normal surgical ward, but they do not necessarily need all of the facilities available on an intensive care unit. In such a case, patients are admitted for a period of 24–48 hours to an 'overnight intensive recovery unit' or 'postanaesthesia care unit' (PACU), where this facility can be provided. After this time period patients are transferred to either a surgical ward or critical care unit depending on how they are recovering from surgery or according to the level of cardiac or respiratory support they need.

Hospital beds are a finite and expensive resource. The beds can be utilised efficiently if the patient can be discharged home quickly and safely. Good communication between hospital and care givers in the community will facilitate a smooth transition to home.

PREHABILITATION

The functional capacity of a patient can be reduced following major surgery. This can have a significant negative impact on the recovery of patients with poor functional reserve prior to surgery. Prehabilitation is a process of improving the functional capacity of patients prior to major surgery in order to improve postoperative outcomes.

The time period between the decision to operate and the surgery date itself is used for prehabilitation. The patient is medically optimised by asking them to, for example, stop smoking, reduce their alcohol intake or lose weight. Anaemia should be treated and blood sugar can be effectively controlled in patients with diabetes during this period. Existing medication should be reviewed and modified if necessary to better control

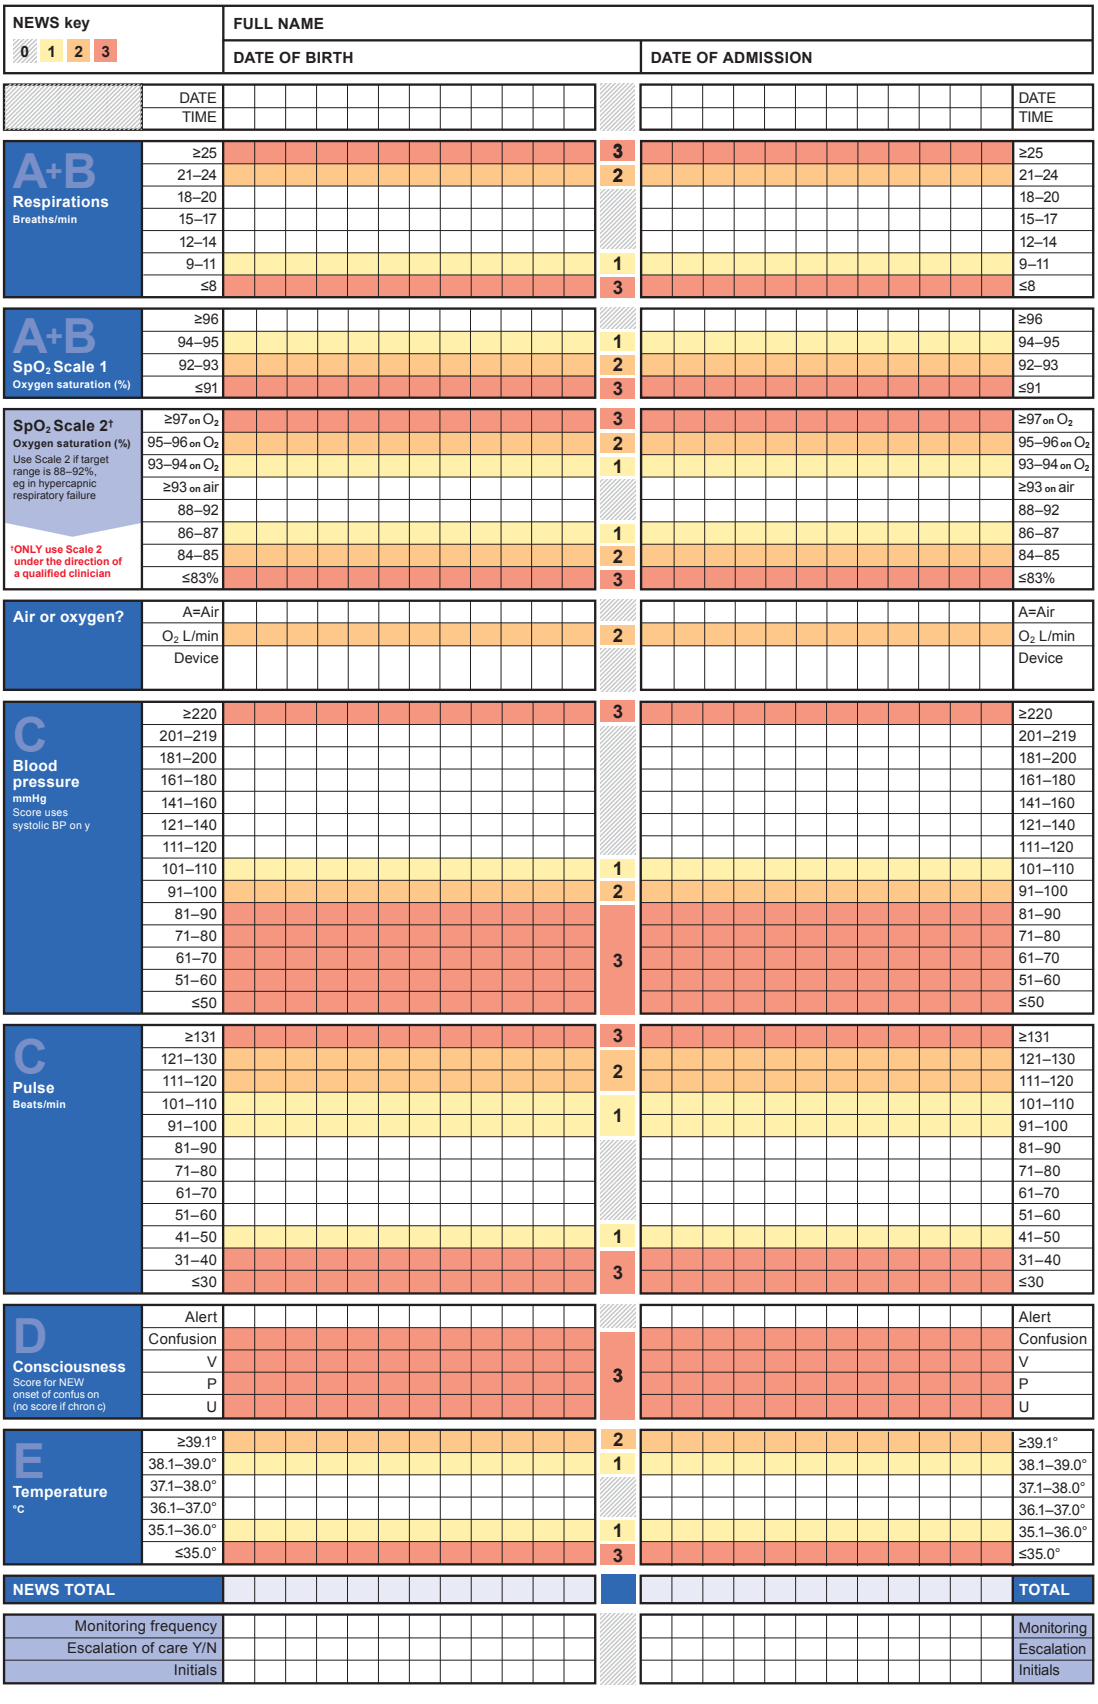

Figure 24.1 An example of an early warning system using patient observations: the National Early Warning System (NEWS) from the Royal College of Physicians. (Reproduced from Royal College of Physicians. *National Early Warning Score (NEWS) 2: Standardising the assessment of acute-illness severity in the NHS*. Updated report of a working party. London: RCP, 2017.)

chronic health conditions such as diabetes, asthma and hypertension. Functional capacity can be assessed formally using either CPET or the 6-minute walk test. Patients should be encouraged to undertake strength and aerobic exercises in formal programmes or as far as possible to improve their physical fitness. A poor preoperative nutritional state leads to poorer outcomes, and correcting nutritional imbalances will help the recovery of the patient. Psychological interventions to reduce anxiety prior to surgery and improve the patient's motivation to recover after surgery will benefit the patient greatly.

Preoperative assessment, including assessment of high-risk surgical patients, has been covered in ***Chapter 21***. Anaesthesia and pain relief has been covered in ***Chapter 23***.

The postoperative phase begins at the end of surgery when the patient is transferred to 'recovery' or 'PACU'. At the end of surgery, a 'sign out' is performed as part of the WHO checklist. The theatre team should then formally hand over the care of the patient to the PACU staff. The information provided should include the patient's name and age, the surgical procedure, the anaesthetic and analgesics given, fluid replacement, blood loss, urine output, any surgical/anaesthetic problems encountered or expected, existing medical problems and allergies. A plan for the management of pain and nausea or vomiting should also be conveyed.

POSTOPERATIVE OBSERVATIONS

The patient's vital signs (including pulse, blood pressure and pulse oximetry reading), level of consciousness, pain and hydration status are monitored in the recovery room and supportive treatment is given. In recent years, patient observations have been collated in recording systems designed to provide an early warning of clinical deterioration (***Figure 24.1***). The recording of observations as an 'early warning system' begins in recovery and is continued on the ward until the patient is discharged from the hospital.

The following six simple physiological parameters, which are routinely measured, are used to calculate the score:

1. respiration rate;
2. oxygen saturation;
3. systolic blood pressure;
4. pulse rate;
5. level of consciousness or new-onset confusion, disorientation and/or agitation;
6. temperature.

Each measured parameter is allocated a score depending on how much it varies from a normal value. Two points are added if the patient needs supplemental oxygen. The score is then aggregated. An aggregate score places patients in different risk categories (low to high risk) that trigger an appropriate clinical response, as seen in ***Figure 24.2***. Depending on the risk categories patients may need level 2 or level 3 care. Patients who are in the high-risk category of clinical deterioration will need urgent assessment by staff with critical care experience and airway skills.

Surgery-specific observations, such as Doppler flow for a free flap, regular neurological evaluation and laboratory tests, such as blood gas analysis, should also be performed when necessary.

The patient can be discharged from PACU when they fulfil the following criteria:

- they are fully conscious;
- respiration and oxygenation are satisfactory;
- they are normothermic, not in pain and not nauseous;
- cardiovascular parameters are stable;
- oxygen, fluids and analgesics have been prescribed;
- there are no concerns relating to the surgical procedure.

However, as discussed above, some patients who have had complex surgery or who have severe chronic health conditions will stay for a period of 24–48 hours on PACU or an overnight intensive recovery unit until they are discharged to either a surgical ward or critical care unit.

NEW score	Clinical risk	Response
Aggregate score 0–4	Low	Ward-based response
Red score Score of 3 in any individual parameter	Low–medium	Urgent ward-based response*
Aggregate score 5–6	Medium	Key threshold for urgent response*
Aggregate score 7 or more	High	Urgent or emergency response**

* Response by a clinician or team with competence in the assessment and treatment of acutely ill patients and in recognising when the escalation of care to a critical care team is appropriate.

**The response team must also include staff with critical care skills, including airway management.

Figure 24.2 Risk category from the National Early Warning (NEW) score and response. *Response by a clinician or team with competence in the assessment and treatment of acutely ill patients and in recognising when the escalation of care to a critical care team is appropriate. **The response team must also include staff with critical care skills, including airway management. London: RCP, 2017.)

Summary box 24.1

Postoperative period

- All anaesthetised patients should be recovered in a dedicated PACU
- All vital parameters should be monitored and documented according to local protocols
- Treat pain and nausea/vomiting
- Observe for complications

POSTOPERATIVE COMPLICATIONS

Postoperative complications are an important cause of morbidity, mortality, extended hospital stay and increased costs. Most patients at increased risk of developing postoperative complications can be identified prior to surgery at the preoperative assessment clinic using a variety of scoring systems (for example the American College of Surgeons National Surgical Quality Improvement Program surgical risk calculator for a patient's risk of postoperative complications [ACS NSQIP], as discussed in ***Chapter 21***). Early identification of risk allows for targeted, appropriate, anticipatory and supportive medical care, which will reduce both the incidence and severity of such complications when they occur.

The Clavien–Dindo classification of postoperative complications (***Table 24.1***) is used to objectively and reproducibly measure the impact of surgical complications on the outcome of the procedure. Complications are graded according to the treatment they require. This eliminates subjective bias and prevents complications from being downgraded.

TABLE 24.1 Clavien–Dindo classification of postoperative complications.

Grade	Definition
I	• Any deviation from the normal postoperative course without the need for pharmacological treatment or surgical, endoscopic or radiological intervention • Acceptable therapeutic regimens are: drugs as antiemetics, antipyretics, analgesics, diuretics and electrolytes and physiotherapy. This grade also includes wound infections opened at the bedside
II	Requiring pharmacological treatment with drugs other than such allowed for grade I complications. Blood transfusions and total parenteral nutrition are also included
III	Requiring surgical, endoscopic or radiological intervention
IIIa	Intervention not under general anaesthesia
IIIb	Intervention under general anaesthesia
IV	Life-threatening complication (including CNS complications, e.g. brain haemorrhage, but excluding TIAs) requiring ICU management
IVa	Single-organ dysfunction (including dialysis)
IVb	Multiorgan dysfunction
V	Death of a patient

CNS, central nervous system; ICU, intensive care unit; TIA, transient ischaemic attack.

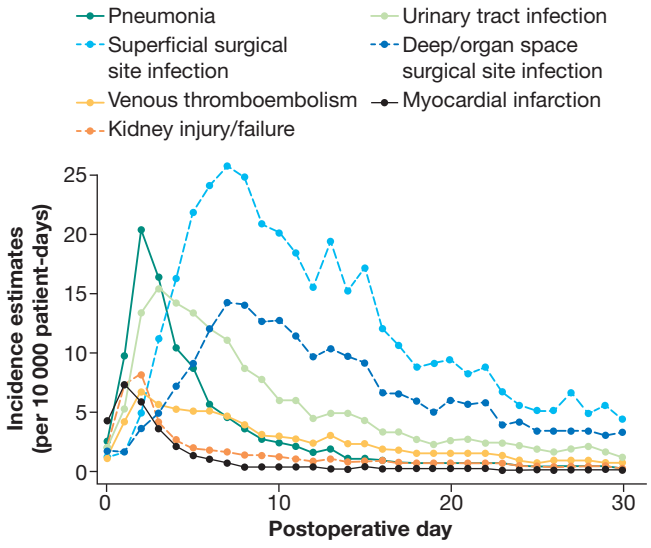

Figure 24.3 Timing and incidence of postoperative complications. Modified from Hyder JA, Wakeam E, Arora V *et al*. Investigating the "Rule of W," a mnemonic for teaching on postoperative complications. *J Surg Educ* 2015; **72**(3): 430-7.

Complications can occur throughout the postoperative period. However, certain complications are more common earlier in the postoperative period than others, as shown in ***Figure 24.3***.

Postoperative complications can be further classified into system-specific and surgery-specific complications.

SYSTEM-SPECIFIC COMPLICATIONS

Respiratory system

Early detection of respiratory complications is facilitated by periodic assessment of airway patency, respiratory rate and routine oxygen saturation measurement, performed during emergence and recovery as described earlier. Postoperative respiratory complications can occur immediately on PACU or later when a patient is on the surgical ward or is discharged home.

Immediate respiratory complications on PACU

Airway

Upper airway obstruction is one of the commonest immediate postoperative complications and can be due to laryngospasm, persisting relaxation of airway muscles, soft-tissue oedema, haematoma, vocal cord dysfunction or a foreign body. Vigilance and early intervention are necessary to prevent harm to the patient. Most interventions are simple and involve manual support of the jaw or insertion of an oral or nasal airway.

Pierre-Alain Clavien, contemporary, professor, University Hospital Zurich, Zurich, Switzerland.
Daniel Dindo, contemporary, surgeon, Centre for Surgery, Zurich, Switzerland.

Hypoventilation

The residual effects of anaesthetic drugs (neuromuscular blockers, anaesthetic agents, opioids) can contribute to reduced or impaired adequacy of ventilation postoperatively. Continuous pulse oximetry and respiratory rate evaluation can identify respiratory compromise and consequent hypoxia early. Supplemental oxygen should be given to all patients on PACU until adequate respiration and oxygenation are restored.

Hypoxaemia

This may occur, in addition to the situations already described above, as a consequence of acute pulmonary oedema (fluid overload, cardiac failure, postobstructive), bronchospasm, pneumothorax (***Figure 24.4***), aspiration and, rarely, pulmonary embolism (PE) (***Figure 24.5***). *De novo* pneumonia is very unusual in the immediate postoperative period. Hypoxaemia develops most quickly in patients with obstructive sleep apnoea (OSA), lung disease and obesity; these patients should therefore be closely observed.

Patients with hypoxaemia should be treated urgently. If the patient is breathing spontaneously, oxygen should be administered at 15 L/min using a non-rebreathing mask. A head tilt, chin lift or jaw thrust should relieve obstruction related to reduced muscle tone. Suctioning of any blood or secretions and insertion of an oropharyngeal airway may be needed. Early anaesthetic intervention may be required.

Vocal cord palsy (as a consequence of recurrent laryngeal nerve injury), neck haematoma and post-tonsillectomy bleeding are recognised as life-threatening complications of head and neck surgery, which need immediate medical attention for safe resolution.

Although the above respiratory complications are more common on PACU, they can occur after discharge from PACU as well.

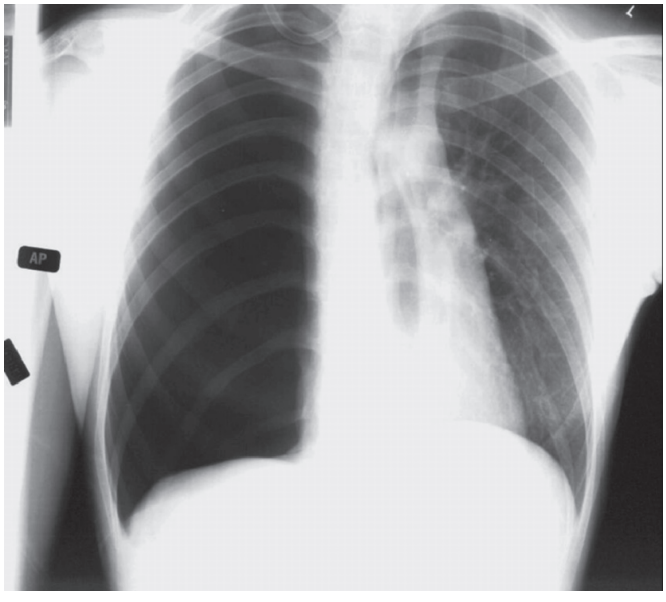

Figure 24.4 Radiograph showing a right tension pneumothorax with tracheal deviation to the left (courtesy of Professor Stephen Eustace, Dublin, Ireland).

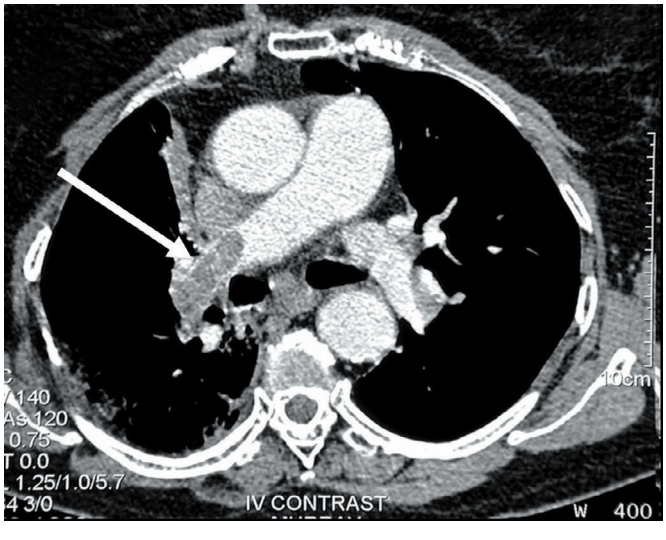

Figure 24.5 Computed tomography scan showing a pulmonary artery blood embolism (arrow) (courtesy of Professor Stephen Eustace, Dublin).

Respiratory complications after discharge from PACU

Postoperative pulmonary complications are a significant cause of postoperative morbidity and mortality (figures vary between 5% and 70%). Complications include fever (due to microatelectasis), cough, dyspnoea, bronchospasm, hypercapnia, atelectasis (***Figure 24.6***), pneumonia (***Figure 24.7***), pleural effusion, pneumothorax and respiratory failure. The risk of each varies with the patient and the type of surgery being performed. Thoracic or abdominal surgery carries the highest risk. The majority of patients at risk (obese, smokers, chronic lung disease, OSA, poor nutritional status) can be identified

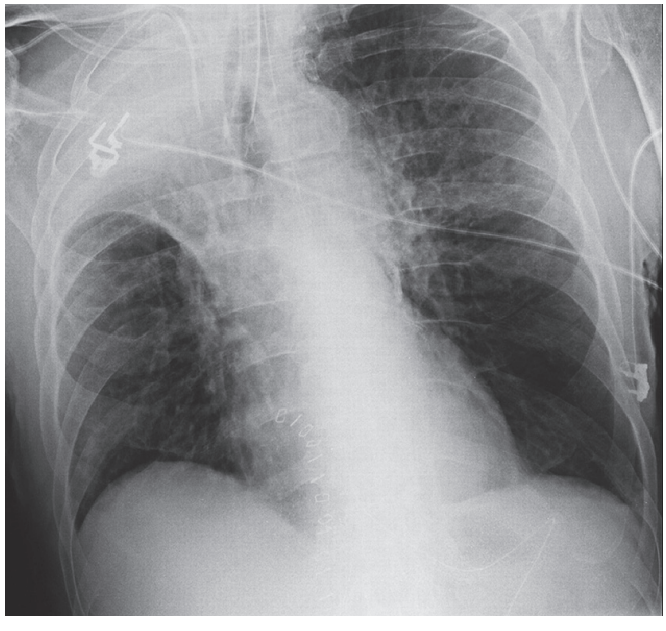

Figure 24.6 Radiograph showing right upper lobe atelectasis (courtesy of Professor Stephen Eustace, Dublin, Ireland).

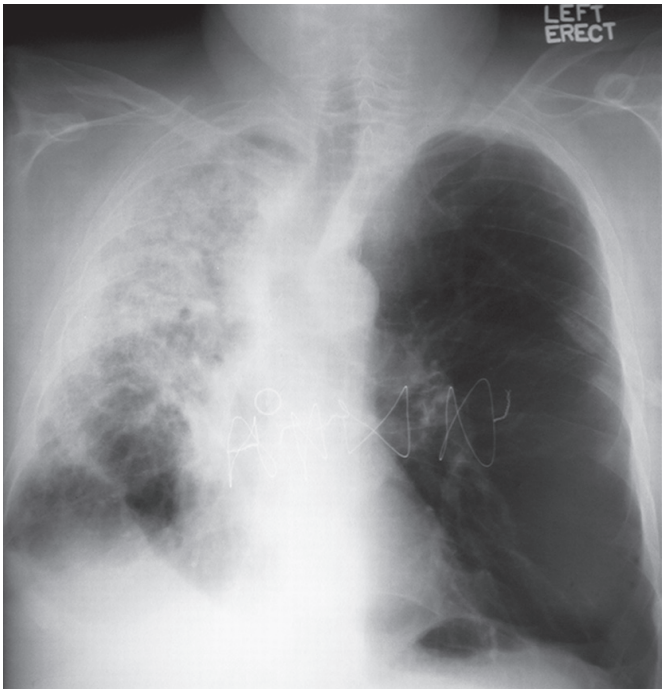

Figure 24.7 Radiograph showing classical Staphylococcus aureus pneumonia (courtesy of Professor Stephen Eustace, Dublin, Ireland).

preoperatively, facilitating the development of strategies that will reduce the impact of surgery on the individual patient.

Table 24.2 shows risk factors for developing a postoperative pulmonary complication.

Summary box 24.2

Respiratory complications

- Respiratory complications can occur either immediately or a few days later on the ward
- Obesity, smoking, chronic lung disease, poor nutritional status and OSA predispose to a higher risk of respiratory complications
- Early intervention and multidisciplinary involvement can prevent life-threatening respiratory complications

Cardiovascular system

Thirty per cent of patients undergoing non-cardiac surgery will have at least one cardiovascular risk factor. In this group 30-day mortality is 0.5–2% as a result of cardiac complications.

Routine pulse, blood pressure and electrocardiogram (ECG) monitoring will detect cardiovascular complications, reduce adverse outcomes and should be recorded during emergence from, and recovery after, anaesthesia. There are certain categories of patient and procedure for which routine cardiovascular monitoring may be required for 24 hours or longer, usually on a PACU or high-dependency unit.

Hypotension

In the immediate postoperative period this is associated with adverse outcomes. Hypotension may be due to hypovolaemia, myocardial impairment or vasodilatation from subarachnoid and epidural anaesthesia. Other causes of hypotension such as

TABLE 24.2 Risk factors for developing a postoperative pulmonary complication.

Patient factors	Procedure-related factors	Laboratory testing
Non-modifiable • Age • Male sex • ASA grade >II • Frailty • Acute respiratory infection within 1 month of surgery • Impaired cognition/sensorium/stroke • Malignancy • Weight loss >10% (within 6 months • Long-term steroid use • Prolonged hospitalisation	Non-modifiable • Type of surgery • Upper abdominal or vascular surgery • Emergency surgery • Long-duration surgery (>2 hours) • Reoperation or multiple surgery	Increased urea and creatinine • Low albumin • Preoperative low saturation (<96%) or abnormal chest radiograph • Preoperative anaemia (<10 g/dL) • FEV_1/FVC <0.7 and FEV_1 <80% predicted
Modifiable • Smoking • COPD/asthma • OSA • BMI <18.5 or >40 • Hypertension • Chronic heart failure • Chronic liver failure/ascites • Renal failure • Diabetes mellitus • Alcohol • GORD • Preoperative sepsis and shock	Modifiable • Use of general anaesthesia versus regional anaesthesia • Use of neuromuscular blocking agents • Mechanical ventilation strategy • Open versus laparoscopic surgery • Intraoperative blood transfusion	

ASA, American Society of Anesthesiologists; BMI, body mass index; COPD, chronic obstructive pulmonary disease; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; GORD, gastro-oesophageal reflux disease; OSA, obstructive sleep apnoea.

Modified from Miskovic A, Lumb AB. Postoperative pulmonary complications. *Br J Anaesth* 2017; **118**(3): 317–34.

surgical bleeding, sepsis, arrhythmias, tension pneumothorax, PE, pericardial tamponade and anaphylaxis should also be considered in the differential diagnosis.

A high prevalence of diastolic dysfunction is seen in middle-aged patients having non-cardiac surgery. These patients are susceptible to exaggerated hypotension following hypovolaemia and pulmonary oedema in response to fluid overloading.

Treatment should be aimed at the cause. Postoperative hypotension leading to end-organ dysfunction (e.g. decreased urine output <0.5 mL/kg/h, decreased level of consciousness, myocardial ischaemia, capillary refill >2 seconds) needs immediate management with fluid and may require the use of vasopressors and inotropes.

Hypertension

Hypertension is also common. It may be due to pain, agitation, anxiety, bladder spasm secondary to urinary catheterisation or pre-existing poorly controlled hypertension. The consequences include bleeding from vascular suture lines, cerebrovascular haemorrhage and myocardial ischaemia or infarction.

Myocardial ischaemia

Patients with a history of cardiovascular disease or with known cardiac risk factors undergoing major surgery are at risk of major adverse cardiac events (MACE). The spectrum of myocardial damage can range from injury (myocardial injury after non-cardiac surgery [MINS]) to ischaemia or infarction. Symptoms can include retrosternal pain radiating into the neck, jaw or arms, nausea, dyspnoea or syncope, but many events in the perioperative period are silent.

ECG changes can include ST elevation in two continuous leads, new left bundle branch block or an arrhythmia. In the case of a non-ST segment myocardial infarction, only a rise in serial troponin levels will clarify the diagnosis. Cardiologists should be involved early and may start coronary reperfusion therapy in the form of primary percutaneous coronary intervention or thrombolysis. These should be discussed with the surgical team because of the risk of bleeding after major surgery.

Arrhythmias

When they occur in the postoperative period, arrhythmias can cause hypotension, myocardial ischaemia and cardiac arrest. Treatment should be guided by the Resuscitation Council UK's peri-arrest guidelines.

Tachycardia (sinus or supraventricular, including atrial fibrillation) may occur as a result of anxiety, pain, myocardial ischaemia or infarction, hypovolaemia, sepsis, electrolyte imbalance or hypoxia in the postoperative period. Consideration should be given to correction of the underlying causes and the rate controlled with β-blockers, amiodarone or cardioversion, depending on the state of the patient.

Sinus bradycardia may be normal in athletes, but it may also be associated with hypoxia, preoperative β-blockers, digoxin and increased intracranial pressure. Pharmacological options include glycopyrrolate or atropine intravenously.

A prolonged QT interval may be seen in the perioperative period. It is multifactorial in origin with most patients having predisposing risk factors, such as long QT syndrome or electrolyte abnormalities.

Summary box 24.3

Cardiovascular complications

- Hypotension and hypertension in the postoperative period can be multifactorial and result in serious morbidity
- Arrhythmias can be prevented and corrected by treating hypotension and electrolyte imbalance
- Arrhythmias, myocardial ischaemia/infarction and stroke will need management with the help of cardiologists and neurologists

Renal and urinary system

Acute kidney injury

Renal failure occurring during the perioperative period is associated with considerable mortality and morbidity. About one-quarter of cases of hospital-acquired renal failure occur in the perioperative period and are associated with high mortality, especially after cardiac and major vascular surgery. Several definitions of acute kidney injury have been proposed that use changes in serum creatinine and urine output to stage kidney injury. One of the more recent examples is KDIGO (Kidney Disease: Improving Global Outcomes), which is shown in ***Table 24.3***.

Certain groups of patients with comorbidities such as diabetes or those undergoing emergency surgery or certain high-risk procedures such as cardiac/transplantation surgeries are more susceptible. ***Table 24.4*** lists the causes of perioperative acute kidney injury.

To prevent acute kidney injury in the perioperative period it is important to identify patients who are more susceptible to it. Normovolaemia and normal blood pressure should be maintained during surgery. Avoiding nephrotoxic agents and unnecessary blood transfusions and treating infections promptly will also help to avoid acute kidney injury.

Urine output is reduced during surgery and does not correlate with renal function. Fluids should not be given excessively to treat oliguria.

TABLE 24.3 KDIGO: Kidney Disease: Improving Global Outcomes.

Stage 1	Increased sCr × 1.5–1.9 of baseline that is known or presumed to have occurred within the preceding 7 days or sCr increase ≥0.3 mg/dL within 48 hours or Urine output <0.5 mL/kg/h for 6–12 hours
Stage 2	Increased sCr × 2–2.9 of baseline or Urine output <0.5 mL/kg/h for ≥12 hours
Stage 3	Increased sCr × 3 of baseline or sCr ≥4 mg/dL or initiation of RRT or GFR decrease to <35 mL/min/1.73 m^2 in patients <18 years old or Urine output <0.3 mL/kg/h for ≥24 hours or anuria for ≥12 hours

GFR, glomerular filtration rate; RRT, renal replacement therapy; sCr, serum creatinine.

TABLE 24.4 Causes of perioperative acute kidney injury.

Prerenal	• Hypovolaemia due to third space losses and bleeding • Sepsis • Cardiac failure • Low cardiac output due to anaesthesia and cardiopulmonary bypass • Increased intra-abdominal pressure • Cirrhosis, hepatorenal syndrome • Aortic cross-clamp
Renal	• Inflammation and sepsis • Chronic kidney disease and comorbidities, e.g. diabetes, obesity • Endogenous (e.g. myoglobin) and exogenous (e.g. radiocontrast dyes) toxins • Blood transfusions • Chloride-rich solution and hydroxyethyl starch
Post renal	• Surgery • Tumour • Benign prostatic hypertrophy • Neurogenic bladder

Urinary retention

Inability to void after surgery is common after anaesthesia and surgery with the incidence ranging from 5% to 70%. Risk factors include age >50 years, male sex, certain surgeries such as hernia, anorectal and pelvic surgery, a history of benign prostatic hypertrophy and neurological disease. Neuraxial anaesthesia and certain drugs given during anaesthesia such as anticholinergic medications, α-/ β-blockers, sedatives and fluids increase the risk. The diagnosis of retention may be confirmed by clinical examination and by using ultrasound imaging. Urinary retention needs treatment as it can cause not only discomfort but also long-term bladder dysfunction. Catheterisation should be performed prophylactically when an operation is expected to last 3 hours or longer, or when large volumes of fluid are administered.

Urinary infection

Urinary infection is one of the most commonly acquired infections in the postoperative period. Patients may present with dysuria and/or pyrexia. Immunocompromised patients, patients with diabetes and those with a history of urinary retention are known to be at higher risk. Treatment involves adequate hydration, proper bladder drainage and antibiotics depending on the sensitivity of the microorganisms.

Summary box 24.4

Renal and urinary complications

- Postoperative renal failure is associated with high mortality
- Prophylactic measures to prevent renal failure should be taken in high-risk cases
- Urinary retention and infection are common problems postoperatively

Central nervous system

Postoperative delirium and postoperative cognitive dysfunction

Postoperative delirium (POD) is characterised by a reduced awareness of the environment and a disturbance in attention accompanied by either hallucinations or disorientation or temporary memory loss.

Postoperative cognitive dysfunction (POCD) refers to deterioration in cognition temporally associated with surgery.

POD can occur during recovery from anaesthesia or a few days after surgery. The overall incidence of POD is 5–50%. It occurs more frequently in elderly orthopaedic patients and those undergoing emergency surgical procedures. Delirium is associated with increased all-cause morbidity, mortality and discharge to a nursing home. There are two types of delirium: hyperactive (restlessness, incoherent speech, agitation, hallucinations) and hypoactive (withdrawn, poorly responsive to the environment, depressed). Preoperative risk factors for POD include pre-existing cognitive impairment, dementia, frailty, Parkinson's disease, severe illness, renal impairment and depression. Precipitating factors include surgery, intraoperative administration of narcotics and benzodiazepines, change of medications, electrolyte and fluid abnormalities, constipation, catheterisation and an unfamiliar environment (***Table 24.5***).

Correcting any reversible cause, involving relatives or friends whom the patient knows and pain control can all contribute to reducing the impact and duration of delirium. As a last option, haloperidol may be given in titrated doses according to local protocols.

TABLE 24.5 Causes of delirium.

Renal	• Renal failure/uraemia • Hyponatraemia and electrolyte disorders • Urinary tract infection • Urinary retention
Respiratory	• Hypoxia, e.g. chest infection • Atelectasis
Cardiovascular	• Pulmonary embolism • Dehydration • Septic shock • Myocardial infarction • Chronic heart failure • Arrhythmia
Drugs	• Opiates including heroin • Hypnotics • Cocaine • Alcohol withdrawal • Hypoglycaemia
Neurological	• Epilepsy • Encephalopathy • Head injury • Cerebrovascular accident
Idiopathic (rare)	• Hypothyroidism • Hyperthyroidism • Addison's disease

James Parkinson, 1755–1824, general practitioner of Shoreditch, London, UK, published *An essay on the shaking palsy* in 1817.
Thomas Addison, 1795–1860, physician, Guy's Hospital, London, UK, described the effects of disease of the suprarenal capsules in 1849.

Stroke

Stroke is a recognised complication of carotid endarterectomy surgery both early (secondary to emboli) and later (secondary to cerebral hyperperfusion syndrome). It is also a recognised consequence of both hypotension and hypertension. Thrombolysis may be indicated but the neurology and surgical teams must discuss together the risks and benefits of such a treatment plan.

Seizures

These are uncommon except in those patients with known poorly controlled epilepsy. They may occur as a complication of neurosurgery.

GENERAL POSTOPERATIVE COMPLICATIONS

Bleeding

Postoperative haemorrhage is most common in the immediate postoperative period. It may be caused by an arterial or venous leak, but also by a generalised ooze or a coagulopathy. Slow bleeds may go undetected for hours and then the patient suddenly decompensates. All patients must have their vital signs (pulse rate, blood pressure, oximetry, central venous pressure, if available, and urine output) monitored regularly. Dressings and drains should be inspected regularly in the first 24 hours after surgery. If haemorrhage is suspected, blood samples should be taken for a full blood count, coagulation profile and cross-match. A large-bore intravenous cannula should be sited and fluid resuscitation commenced. If the source of bleeding is in doubt and the patient is stable, an ultrasound or computed tomography (CT) scan may be required to determine the nature of the bleed (most commonly if a haematoma is suspected in the days following surgery). If the patient's cardiovascular system is unstable or compromised in any way (for example neck haematoma or bleeding tonsil) they should be taken back to the operating theatre immediately.

The treatment of haemorrhage is both to stop the bleeding and supportive. Supportive treatment includes oxygen and fluid resuscitation. It may require correction of coagulopathy. All patients will require close observation. Blood transfusion carries risks (acute haemolytic transfusion reaction, sensitisation, fluid overload, hyperkalaemia, transfusion-related lung injury and transmission of blood-borne infection). There is much published about what is the right transfusion trigger and how to balance the need for adequate tissue perfusion and the risks of transfusion. According to the Joint United Kingdom (UK) Blood Transfusion and Tissue Transplantation Services Professional Advisory Committee transfusion should be considered if the haemoglobin (Hb) level is below 8g/dL. The decision to transfuse should be based on the clinical condition of the patient with acceptance of higher thresholds in individual cases. If the Hb level is below 7g/dL transfusion is usually indicated (see also ***Chapter 2***).

Patients who are symptomatic of anaemia, e.g. having chest pain, orthostatic hypotension or tachycardia unresponsive to fluid resuscitation, or who have congestive heart failure may need transfusion at a higher threshold.

All hospitals should have a 'major haemorrhage protocol' in place. The consultant surgeon, anaesthetist and haematologist should all be involved early on in the care of unstable patients.

Summary box 24.5

Postoperative bleeding

- All hospitals should have a major haemorrhage protocol in place
- The need to transfuse blood in the absence of continued bleeding, guided by the Hb level, should be weighed against the risks

Deep vein thrombosis

Deep vein thrombosis (DVT) is a well-known and, when complicated by pulmonary embolus, potentially fatal complication of surgery (***Table 24.6***). All hospitals must have a process for screening all surgical patients to identify those at risk and for implementing prophylactic measures to avoid this dreaded complication. Risk assessment should occur within 24 hours of admission. Risk should be reviewed if the clinical situation changes. Methods of prevention are guided by the risk score and include the use of compression stockings, calf pumps and pharmacological agents, such as low-molecular-weight heparin. Compression stockings are not offered to patients who have suspected or proven peripheral arterial disease or neuropathy. They are also avoided or used with caution in those with sensitive or broken skin and in those who are allergic to the material used, have severe leg oedema or have a leg deformity.

The symptoms and signs of DVT include calf pain, swelling, warmth, redness and engorged veins. However, most will show no physical signs. On palpation the muscle may be tender and there may be a positive Homans' sign (calf pain on dorsiflexion of the foot), but this test is neither sensitive nor specific. Use the two-level DVT Wells score to assess the probability of DVT (***Table 24.7***).

TABLE 24.6 Stratification of surgical procedure and the associated risk of deep vein thrombosis.

Low
• Maxillofacial surgery
• Neurosurgery
• Cardiothoracic surgery
Medium
• Inguinal hernia repair
• Abdominal surgery
• Gynaecological surgery
• Urological surgery
High
• Pelvic elective and trauma surgery
• Total knee and hip replacement

John Homans, 1877–1954, Professor of Clinical Surgery, Harvard Medical School, Boston, MA, USA.
Philip Wells, contemporary, physician, University of Ottawa, Ottawa, Ontario, Canada.

TABLE 24.7 Two-level deep vein thrombosis (DVT) Wells score.

Clinical features	Points
Active cancer (treatment ongoing, within 6 months or palliative)	1
Paralysis, paresis or recent plaster immobilisation of the lower extremities	1
Recently bedridden for 3 days or more, or major surgery within 12 weeks requiring general or regional anaesthesia	1
Localised tenderness along the distribution of the deep venous system	1
Entire leg swollen	1
Calf swelling at least 3 cm larger than asymptomatic side	1
Pitting oedema confined to the symptomatic leg	1
Collateral superficial veins (non-varicose)	1
Previously documented DVT	1
An alternative diagnosis is at least as likely as DVT	–2
Clinical probability simplified score	**Points**
DVT likely	2 points or more
DVT unlikely	1 point or less

TABLE 24.8 Two-level pulmonary embolism (PE) Wells score.

Clinical features	Points
Clinical signs and symptoms of DVT (minimum of leg swelling and pain with palpation of the deep veins)	3
An alternative diagnosis is less likely than PE	3
Heart rate more than 100 beats per minute	1.5
Immobilisation for more than 3 days or surgery in the previous 4 weeks	1.5
Previous DVT/PE	1.5
Haemoptysis	1
Malignancy (on treatment, treated in the last 6 months or palliative)	1
Clinical probability simplified score	**Points**
PE likely	More than 4 points
PE unlikely	4 points or less

DVT, deep vein thrombosis.

If DVT is suspected, duplex Doppler ultrasound and venography can be used to assess flow and the presence of a thrombosis. If DVT is unlikely by Wells's score then d-dimer testing can be done. A negative d-dimer test makes DVT unlikely; however, patients should be told about the signs and symptoms of PE and how to seek medical help if necessary.

If a significant DVT is found (one that extends above the knee), treatment with parenteral anticoagulation initially, followed by longer term warfarin or a new oral anticoagulant (refer to national guidance, e.g. National Institute for Health and Care Excellence [NICE]; see ***Further reading***) is necessary. In some patients with a large DVT, a caval filter may be required to decrease the possibility of PE.

Pulmonary embolus

PE is not usually an immediate complication but can present in the early postoperative period. Thrombus can arise from DVT in the legs/pelvis, venae cavae or the right atrium. Signs and symptoms depend on the size of the embolus and may range from dyspnoea, cough and pleuritic chest pain to sudden cardiovascular collapse. Diagnosis of PE begins with the history (including risk factors and recent surgery) and a physical examination (which may include signs of DVT). The two-level Wells PE score (***Table 24.8***) can be used to determine the probability of PE.

Depending on the presentation, investigations may include ECG, chest radiograph, blood tests (arterial blood gas and d-dimer) and radiological tests (usually CT pulmonary angiography).

If the presentation includes cardiovascular collapse, resuscitation will be needed. Thrombolysis can be considered with massive PE causing cardiovascular collapse, but this should include senior clinical opinion and would generally follow appropriate guidelines. The patient may need inotropes and admission to the intensive care unit. In less severe cases of PE, supportive measures include oxygen therapy and analgesia. After initial resuscitation, the patient will need anticoagulation – initially parenteral anticoagulation – followed by long-term oral anticoagulation (refer to national guidance, e.g. NICE; see ***Further reading***). A vena cava filter may be needed if anticoagulation is not possible or if the patient has an embolism while anticoagulated (see ***Further reading***).

Fever

About 40% of patients develop pyrexia after major surgery; however, in most cases no cause is found. The inflammatory response to surgical trauma may manifest itself as fever, and so pyrexia does not necessarily imply sepsis. However, in all patients with a pyrexia, a focus of infection should be sought.

The causes of a raised temperature postoperatively include:

- atelectasis of the lung;
- superficial and deep wound infection;
- chest infection, urinary tract infection and thrombophlebitis;
- wound infection, anastomotic leakage, intracavitary collections and abscesses.

The possible causes of pyrexia of a non-infective origin include:

- DVT;
- transfusion reactions;
- wound haematomas;

Christian Johann Doppler, 1803–1853, Professor of Experimental Physics, Vienna, Austria, enunciated the 'Doppler principle' in 1842.

- atelectasis;
- drug reactions.

Patients with a persistent pyrexia need a thorough review. Relevant investigations include full blood count, urine culture, sputum microscopy and blood cultures.

Summary box 24.6

Fever

- A very common problem postoperatively
- Consider infection in the lung, urine and wound

Wound dehiscence

Wound dehiscence is disruption of any or all of the layers in a wound. Dehiscence may occur in up to 3% of abdominal wounds, increases the risk of postoperative mortality and is very distressing to the patient.

Wound dehiscence most commonly occurs from the fifth to the eighth postoperative day when the strength of the wound is at its weakest. It may herald an underlying abscess and usually presents with a serosanguinous discharge. The patient may have felt a popping sensation during straining or coughing. Most patients with a full thickness dehiscence of an abdominal wound will need to return to the operating theatre for resuturing. In patients in whom tissues are suspected to be infected, of poor quality or under excessive tension, it may be appropriate to leave the wound open and treat with dressings or vacuum-assisted closure pumps.

Summary box 24.7

Risk factors in wound dehiscence

General

- Malnourishment
- Diabetes
- Obesity
- Renal failure
- Jaundice
- Sepsis
- Cancer
- Treatment with steroids
- Emergency surgery

Local

- Inadequate or poor closure of wound or closure of a wound under tension
- Poor local wound healing, e.g. because of infection, haematoma or seroma
- Increased intra-abdominal pressure, e.g. in postoperative patients with chronic obstructive airway disease, during excessive coughing

Pressure sores

Patients undergoing surgery for a prolonged period of time are vulnerable to the development of a pressure sore or to worsening of a pre-existing sore as a result of prolonged immobility during, and sometimes after, the operation. Careful positioning and padding of the patient are standard practice intraoperatively to reduce the risk. Pressure sores occur as a result of friction or persisting pressure on soft tissues. They particularly affect the pressure points of a recumbent patient, including the sacrum, greater trochanter and heels. Risk factors are poor nutritional status, dehydration, lack of mobility and nerve block anaesthesia technique. Early mobilisation of the patient and regular inspection of pressure points by the nursing team can act to prevent pressure sores. High-risk patients may be nursed on an air mattress, which automatically relieves the pressure areas.

Pressure ulcers can be graded according to an internationally recognised grading system based on the extent of skin loss. Category 1 ulcers involve non-blanching erythema with intact skin. Category 2 ulcers have partial thickness skin loss and appear as a shallow open ulcer with a red-pink wound bed or an intact or ruptured serum-filled blister. Category 3 ulcers have full thickness skin loss, with subcutaneous fat visible in the wound, but not bone, tendon or muscle. Category 4 ulcers have full thickness loss with exposed bone, tendon or muscle; osteomyelitis may develop at these sites.

Summary box 24.8

Preventing pressure sores

- Recognise patients at risk
- Address nutritional status
- Keep patients mobile or regularly turned if bed-bound

SURGERY-SPECIFIC COMPLICATIONS

This section provides an overview of selected important complications, rather than a comprehensive account of all possible complications. The reader is advised to consult chapters where specific procedures are described in more detail.

Abdominal surgery

The abdomen should be examined daily for excessive distension, tenderness or drainage from wounds or drain sites. In certain operations, such as those for intestinal obstruction or oesophageal and gastric procedures, a nasogastric tube may be required. This is of particular value in those patients with ileus or a marked level of altered consciousness, who are therefore liable to aspirate.

Paralytic ileus

Paralytic ileus may present with nausea, vomiting, loss of appetite, bowel distension and absence of flatus or bowel movements. Following laparotomy, gastrointestinal motility temporarily decreases. Treatment is usually supportive, with maintenance of adequate hydration and electrolyte levels. However, intestinal complications may present as prolonged ileus and so should be actively sought and treated. It is important to note that nutrient absorption from the gut will be impaired in the context of paralytic ileus, and parenteral

nutrition will therefore need to be considered in any patient with prolonged ileus.

Return of function of the intestine occurs in the following order: small bowel, large bowel and then stomach. This pattern allows the passage of faeces despite continuing lack of stomach emptying and, therefore, vomiting may continue even when the lower bowel has already started functioning normally.

Localised intra-abdominal infection or anastomotic leakage

Intra-abdominal infection may develop from a complication such as anastomotic leakage or persistent abscess following a laparotomy for a perforated viscus, as well as from less common causes such as iatrogenic perforation of a viscus during an elective operation. Intra-abdominal infection may be localised, presenting with focal tenderness, a spiking fever, raised inflammatory markers and sometimes positive blood cultures and a prolonged ileus. These patients can often be managed by radiological drainage, if accessible, and appropriate antibiotic treatment. In some patients the leak may be more widespread, causing generalised peritonitis and severe sepsis and necessitating urgent laparotomy (see also ***Chapters 64 and 75***).

Bleeding

Postoperative bleeding is a well-recognised complication but can still sometimes be overlooked. Hb levels may not always decrease in patients who are bleeding because of the relative haemoconcentration, and drains may not demonstrate significant blood loss if blocked with clot. It is important to have a high index of suspicion for bleeding and a low threshold for appropriate intervention for any postoperative patient with a drop in blood pressure, tachycardia, demonstrable bleeding in the drains, progressive distension of the abdomen or a drop in Hb.

Summary box 24.9

The main complications after abdominal surgery

- Paralytic ileus
- Localised infection or anastomotic leakage
- Bleeding

Orthopaedic surgery

Neurovascular supply to the extremity

Patients who have undergone extremity surgery, for example open reduction and internal fixation of a fracture, require regular neurovascular observations, both in recovery and on the ward (this will usually follow a local or national guideline). Moreover, if a tourniquet has been used, the restoration of the distal neurovascular supply should be established. Careful documentation of findings before and after surgery will allow comparison. Concern about the neurovascular status requires urgent and experienced surgical review and further management. Circumferential casts can be split and dressings cut down to skin to improve the blood supply to the limb.

Compartment syndrome

Raised pressure in an osseofascial compartment can manifest after surgical intervention to a limb and can prevent adequate tissue perfusion. Patients with compartment syndrome complain of pain that is (i) out of proportion to that expected, (ii) increasing in intensity, and (iii) worse on passive stretching of the muscles in the affected compartment. Other symptoms that relate to pressure on nerves (paralysis, paraesthesia) and blood vessels (pallor and pulselessness) may only be noticed after irretrievable injury to the limb has occurred from the ischaemia. Extreme vigilance and early intervention is necessary to identify and manage compartment syndrome. When suspected, prompt senior input is required. In terms of initial management, circumferential casts can be split, dressings cut down to skin and the limb elevated. Further management will require experienced judgement and may include compartment pressure monitoring and/or fasciotomies. Compartment syndrome is considered more extensively in ***Chapters 3 and 32***.

Summary box 24.10

Compartment syndrome symptoms and signs

- Pain out of proportion to that expected
- Pain that is increasing
- Pain on passive stretching of the muscles in the affected compartment
- Paralysis, paraesthesia, pallor and pulselessness generally occur late

Neck surgery

Patients undergoing neck surgery, e.g. thyroid surgery, must be observed for accumulation of blood in the wound, which may obstruct the airway and cause rapid asphyxia. This potentially life-threatening complication necessitates systems for early detection and prompt evacuation (see guidelines from the Difficult Airway Society, the British Association of Endocrine and Thyroid Surgeons and the British Association of Otorhinolaryngology, Head and Neck Surgery). Another potential but less dangerous complication is damage to the recurrent laryngeal nerve, which can produce voice change (see also ***Chapter 55***).

Thoracic surgery

Careful fluid management is important in patients undergoing a lobectomy or pneumonectomy as they are susceptible to fluid overload in the first 24–48 hours postoperatively. Chest drains require regular review. If the fluid in a chest drain swings then the drain has been correctly inserted into the pleural cavity. Bubbling of the chest drain confirms the release of air from the pleural cavity; however, if the bubbling persists, this may represent a bronchopleural fistula. A haemothorax or pleural effusion will reveal itself as a prolonged loss of blood or fluid, respectively, into the drain. Cardiac patients require continuous ECG monitoring postoperatively (see also ***Chapter 60***).

Neurosurgery

Postoperatively the patient should be kept under close observation. A rise in intracranial pressure may be signalled by a deterioration in the state of consciousness, as well as by neurological signs. Urgent imaging and intervention are likely to be necessary in these cases to avoid the risk of mortality from complications such as an intracranial haematoma. Some patients may have an intracranial monitoring device to allow for more sensitive monitoring.

Vascular surgery

The patency of grafts and anastomoses, for example femoropopliteal bypasses and abdominal aneurysm, needs to be checked by regular clinical assessment of the limbs and by Doppler ultrasound in the postoperative phase.

Plastic surgery

The viability of flaps is crucial and the perfusion needs to be monitored regularly. The blood supply may be compromised by position, dressings or collection of fluids or blood beneath the flap.

Urology

Catheter patency must be checked regularly following urological surgery. In patients who have undergone transurethral resection of the prostate, continuous bladder irrigation may be used. More generalised complications can occur, for example transurethral resection syndrome, and are discussed further in the appropriate section.

GENERAL POSTOPERATIVE PROBLEMS AND MANAGEMENT

This section provides an overview of selected important postoperative problems and the principles of their management. It does not set out to describe such problems relating to the vast array of all surgical techniques and procedures. The reader is advised to consult chapters where specific procedures are described in more detail. Moreover, when considering postoperative problems, the importance of pain control and fluid management should be appreciated, and the reader is directed to ***Chapters 23 and 25***.

Drains

Drains are used to prevent accumulation of blood and serosanguineous or purulent fluid. In clean surgery, such as joint replacement, blood collected in drains can be transfused back into the patient provided that an adequate volume is collected rapidly and that a specifically designed drain and filter system is used.

The use of surgical drains has decreased in recent years as the evidence for their benefits has been questioned. Complications of drains include trauma to surrounding tissues and infection. The quantity and character of drain fluid can be used to identify an abdominal complication such as fluid leakage (e.g. bile or pancreatic fluid) or bleeding.

Drains should be removed as soon as it is considered safe to do so. The timing of drain removal is related to the volume and nature of fluid being evacuated (e.g. a drain may be left longer to evacuate a pancreatic leak, but removed earlier if only serous fluid is draining) and balanced against the risk of leaving the drain in place (such as damage to the surrounding tissues).

Wound care

Within hours of the wound being surgically closed, the dead space fills up with an inflammatory exudate. Within 48 hours of closure a layer of epidermal cells from the wound edge bridges the gap. Consequently, sterile dressings applied in theatre should not be removed before this time.

Wounds should be inspected only if there is a concern about their condition or the dressing needs changing. Inspection of the wound should be performed under sterile conditions. If the wound looks inflamed, a wound swab can be taken and sent for microbiological examination, but this can be unreliable. Infected wounds and haematomas may need treatment with antibiotics or even wound washout. If a surgical procedure is performed it gives an opportunity to collect samples for bacteriology (before any antibiotics, if the patient's general condition allows), to excise dead tissue and to control any bleeding. Depending on location, the wound may require packing if it is contaminated or if non-viable tissue remains. The dressing should then be changed regularly until the wound is clean.

Skin sutures or clips are usually removed between 6 and 10 days after surgery. The period can be shorter in wounds on the face or neck, or longer for tougher tissues such as the back. Wound healing is delayed in patients who are malnourished or in those who have vitamin A and C deficiency. Steroids also inhibit the adequate healing of wounds as they inhibit protein synthesis and fibroblast proliferation. Poorly controlled diabetes delays wound healing and increases the risk of infection at the surgical site (see also ***Chapter 3***).

DISCHARGE OF PATIENTS

Patients discharged home need a 'discharge letter' detailing the postoperative plan. The discharge letter should include details of the final diagnosis, the treatment and any complications that may have occurred. There should be advice for referring the patient back to hospital and indications for readmission if specific problems do occur. The general practitioner (GP) should be informed of the subsequent care plan, including follow-up, physiotherapy and other support needed. Pathology results should be included if available, and the basis of these in the subsequent care plan should be described along with the prognosis if appropriate.

Summary box 24.11

Discharge letter

- Diagnosis
- Treatment
- Laboratory results
- Complications
- Discharge plan
- Support needed
- Follow-up

Follow-up in clinic

Patients should be reviewed in clinic if a key decision on management needs to be made. The findings and the care plan agreed with the patient at the clinic appointment should be included in a letter to the patient's GP, as well as in a clear entry in the notes or electronic patient record. This should include advice on how to recognise the onset of complications and what to do if there is concern. Patients should be discharged from clinic as soon as no further input from the surgical team is required and their GP or they themselves can manage their care.

ENHANCED RECOVERY

Enhanced recovery is an approach to the perioperative care of patients undergoing surgery. It is designed to speed clinical recovery of the patient and reduce both the cost and the length of stay of the patient in the hospital. It is achieved by optimising the health of the patient before surgery through prehabilitation and then delivering evidence-based best care in the perioperative period.

Postoperative strategies advocated by enhanced recovery protocols include:

- early planned physiotherapy and mobilisation;
- early oral hydration and nourishment;
- opioid-sparing analgesia regimens that include the use of regional blocks, regular non-steroidal anti-inflammatory drugs and paracetamol;
- early discharge planning (started even before the patient is admitted to hospital and involving support from stoma care nurses, physiotherapists and other community care workers).

Early mobilisation is encouraged to reduce the risks of DVT, urinary retention, atelectasis, pressure sores and faecal impaction. Telephone follow-up is carried out to make sure that the patient is recovering well.

PART 3 | Perioperative care

CHAPTER 25

Nutrition and fluid therapy

Learning objectives

To understand:

- The importance of assessment of perioperative nutritional status and fluid balance
- The nutritional requirements of surgical patients and the effects of intestinal resection on nutrition
- The causes and complications of malnutrition and their management
- The options for nutritional intervention and the indications for enteral versus parenteral nutritional support

INTRODUCTION

Optimal nutritional status, both pre- and postoperatively, is a key factor in reducing perioperative complications and improving surgical outcomes. However, the pathologies requiring surgical intervention often contribute to malnutrition, and a lack of appreciation of preoperative nutritional status can unnecessarily increase the risk of the operation and compromise recovery from surgery (***Figure 25.1***). Some operations, particularly abdominal operations, can compromise absorption from the gastrointestinal tract, at least temporarily if not permanently. It is therefore imperative that the effects of surgical intervention on the patient's nutritional status are taken into consideration perioperatively, and appropriate intervention taken as early as possible to correct any nutritional deficits.

Figure 25.1 Severely malnourished patient with evidence of fat and muscle wasting.

Appreciation of the importance of nutritional status is becoming more widespread within the healthcare profession and many tools have been developed to help identify poor nutritional status. These assessment tools and the availability of improved options for both enteral and parenteral delivery of nutrients allows any nutritional deficiency to be expeditiously identified and corrected until normal intestinal absorption can resume.

PHYSIOLOGICAL RESPONSES TO NUTRITIONAL IMPAIRMENT

Metabolic response to fasting or starvation

The constant need for glucose by metabolically active tissues in the body, such as the brain, red and white blood cells and the renal medulla, necessitates homeostasis of blood glucose levels even during periods of fasting. During short-term fasting periods, when insulin levels fall and glucagon levels rise, glycogenolysis is the main source of glucose, whereby glycogen stores from the liver and skeletal muscle are converted to glucose via lactate (the Cori cycle). After approximately 24–40 hours of fasting, glycogen reserves are depleted and gluconeogenesis (the *de novo* synthesis of glucose from non-carbohydrate precursors such as the amino acids glutamine and alanine, as well as fructose,

Carl Ferdinand Cori, 1896–1984, Professor of Pharmacology and later Biochemistry, Washington University Medical School, St Louis, MI, USA, and his wife **Gerty Theresa Cori**, 1896–1957, also Professor of Biochemistry at the Washington University Medical School. In 1947, the Coris were awarded a share of the Nobel Prize in Physiology or Medicine for their discovery of how glycogen is catalytically converted.

lactate and glycerol) takes over as the predominant source of glucose production. The generation of amino acids occurs from catabolism of skeletal muscle, in amounts of up to 75 g per day for the average-sized individual.

Under conditions of even more prolonged fasting (>48 hours), glucose production is met by the breakdown of fat stores (lipolysis); this provides glycerol, which is then converted to fatty acids and glucose. Fatty acids can be converted to ketones, which can be used as a metabolic substrate by the majority of tissues in circumstances of extended fasting, reducing the need for muscle breakdown.

Resting energy expenditure levels significantly decrease in starvation, related in part to reduced conversion of inactive thyroxine (T_4) to active tri-iodothyronine (T_3). Nevertheless, this reduction is insufficient to obviate the need for metabolic substrates, leaving a glucose requirement of approximately 200 g per day even during conditions of prolonged fasting.

Summary box 25.1

Metabolic response to starvation

- Low plasma insulin
- High plasma glucagon
- Hepatic glycogenolysis
- Protein catabolism
- Hepatic gluconeogenesis
- Lipolysis: mobilisation of fat stores (increased fat oxidation) – overall decrease in protein and carbohydrate oxidation
- Adaptive ketogenesis
- Reduction in resting energy expenditure (from approximately 25–30 kcal/kg per day to 15–20 kcal/kg per day

Metabolic response to trauma and sepsis

This is described in greater detail in ***Chapter 1***, and covered briefly in ***Summary box 25.2***.

It is important to note that the metabolic response to trauma is influenced by the early and rapid rises in sympathetic nervous system activity and circulating catecholamines and elevated levels of glucocorticoids, glucagon and growth hormone, as well as insulin. Energy requirements often remain increased to allow tissue repair and inflammatory cell function. Elevated stress hormone levels can lead to net catabolism of tissue protein and thus a negative nitrogen balance. Ketone body production and utilisation may be impaired in the response to trauma, further exacerbating the catabolic response and protein breakdown.

The effect of the metabolic response to surgery on nutrition

The metabolic response to surgery is affected not only by the induced fasting period but also by the phenomenon of insulin resistance, which has been described in surgery and in other similar stresses, including trauma and burn injuries.

Summary box 25.2

Metabolic response to trauma and sepsis

- Increased counter-regulatory hormones: adrenaline (epinephrine), noradrenaline (norepinephrine), cortisol, glucagon and growth hormone
- Increased energy requirements (up to 40 kcal/kg per day)
- Increased nitrogen requirements
- Insulin resistance and glucose intolerance
- Preferential oxidation of lipids
- Increased gluconeogenesis and protein catabolism
- Loss of adaptive ketogenesis
- Fluid retention with associated hypoalbuminaemia

These stresses elicit combined hormonal and inflammatory responses to the triggers of pain, immobility, acidosis, tissue damage, hypoxia and impairment of homeostasis. Insulin resistance causes hyperglycaemia as a result of increased gluconeogenesis and reduced peripheral glycolysis. This is further worsened by reduced transport of glucose into muscle cells (the main tissue for uptake of insulin-mediated glucose) owing to reduced activation of the glucose transporter protein GLUT4. Instead, muscle protein is broken down to produce amino acids as substrates for gluconeogenesis, inducing a catabolic state with loss of lean muscle mass. The lack of response to insulin means that the catabolic processes induced by fasting or starvation are not resolved with the provision of glucose, and the inappropriate handling of peripheral glucose and breakdown of lean muscle continues for as long as the triggers for insulin resistance persist. Pre-existing comorbidities such as metabolic syndrome, diabetes, cancer and obesity have been shown to contribute to perioperative insulin resistance, which in turn is associated with an increased risk of major complications, in particular severe postoperative infection. Increased awareness of perioperative insulin resistance has led to the incorporation of specific interventions such as preoperative high-carbohydrate drinks to increase insulin sensitivity, adoption of minimally invasive surgery where appropriate (more invasive surgery appears to trigger a greater degree of insulin resistance) and early mobilisation protocols to minimise the impact and duration of insulin resistance on postoperative outcomes and recovery.

NUTRITIONAL ASSESSMENT

The nutritional status of an individual can be assessed by the ABCD of anthropometry, biochemistry, clinical evaluation and dietary assessment.

Anthropometry

Anthropometry uses several different parameters to obtain an estimate of body composition as a surrogate for nutritional status. These parameters can include weight and percentage weight change, body mass index (BMI) (weight [kg]/height^2 [m^2]), mid-upper arm circumference (MUAC), skinfold thickness (TSF) and mid-arm muscle circumference (MAMC), where

MAMC = MUAC (cm) – 3.14 × TSF (cm). These measurements are indirect assessments of energy and protein stores and are not sufficiently accurate to facilitate planning of nutritional support regimens.

BMI, in particular, has often been used as a quick screening measure to identify those who are malnourished. A BMI of less than 18.5 kg/m^2 and unintentional weight loss greater than 10% within the last 3–6 months or a BMI of less than 20 kg/m^2 and unintentional weight loss greater than 5% within the last 3–6 months are indicators of a need for nutrition support. It is important to note, however, that both BMI and body weight can be altered by major changes in fluid balance, and thus may not be reliable indicators of nutritional status in critically ill patients.

Biochemistry

Biochemical tests can be used in conjunction with clinical history, examination, comorbidities and drug history. Albumin, C-reactive protein and white cell counts can be markers of infection or inflammation, which can compromise nutritional status. Hypoalbuminaemia can be associated with malnutrition; however, it is easily affected by fluid balance and is not a reliable parameter of nutritional status in the acute setting.

Haemoglobin levels can indicate the presence of anaemia related to a lack of appropriate vitamins. Glycated haemoglobin can reflect diabetes and blood glucose control. Electrolytes such as sodium and urea can reflect underlying renal function, while calcium and phosphate are useful baseline measurements in anticipation of potential refeeding syndrome (discussed in more detail later in this chapter). Specific micronutrient levels such as vitamin D levels can also be measured in the appropriate clinical contexts.

Clinical evaluation

Clinical assessment of nutritional status should begin by consideration of any important symptoms that may suggest malnutrition. Upper abdominal symptoms such as nausea and vomiting, early satiety, dysphagia, reflux or bloating as well as lower gastrointestinal symptoms of diarrhoea or constipation can all indicate inadequate nutritional intake or absorption.

A thorough assessment of the past medical history and comorbidities is also essential in assessing nutritional status, as conditions such as cancer, gastrointestinal pathologies (e.g. inflammatory bowel disease and liver disease) and neurological conditions (e.g. stroke, Parkinson's disease and dementia) can all contribute to affect nutritional status. Nutrient absorption can be impaired by conditions directly affecting the bowel such as short bowel syndrome, high-output stoma and enterocutaneous fistulae, and also by disorders more proximally in the gastrointestinal tract such as pancreatic insufficiency, in which absorption is impaired because of a lack of pancreatic enzyme secretion into the bowel. These conditions and the appropriate management are dealt with in the relevant chapters in this book.

Dietary assessment tools

The total daily calorie intake of an individual can be estimated via a diary of their food and fluid intake, taking into account the quality of the food or fluid consumed. For patients who are unwell, this needs to take into account any differences in current food and fluid consumption compared with their typical intake when well. Their caloric intake can be assessed against their calculated energy requirements, estimated with the calculation of 25–35 kcal/kg lean body weight and taking into account any metabolic stresses and activity level.

Patients whose caloric intake falls short of their caloric requirements or who are anticipated to eat little or nothing for over 5 continuous days in the near future (e.g. owing to upcoming abdominal surgery) are likely to require nutritional support.

The Malnutrition Universal Screening Tool (MUST), developed by the British Association for Parenteral and Enteral Nutrition (BAPEN), is a rapid screening tool that can be used in both hospitals and the community, and takes into account a combination of the above factors to identify those individuals at risk of malnutrition (***Figure 25.2***). Patients who are found to be likely to be malnourished require referral to a dietician or nutritional support team, with regular reviews to ensure sustained improvement in nutritional status.

FLUID AND ELECTROLYTE REPLACEMENT

Daily fluid balance

Fluid intake consists of liquid ingested in the form of oral fluids as well as fluid released during oxidation of consumed food. ***Table 25.1*** shows the average daily fluid balance for a healthy adult.

It must be noted that insensible losses can increase in conditions of pyrexia, exertion or warm environments. Patients with a tracheostomy can lose a larger amount of fluid via insensible losses, emphasising the importance of humidification of inspired air. In addition, fluid loss via the faecal route will inevitably increase in diarrhoea or more chronic bowel pathologies, such as high-output stoma, short bowel syndrome and enterocutaneous fistulae.

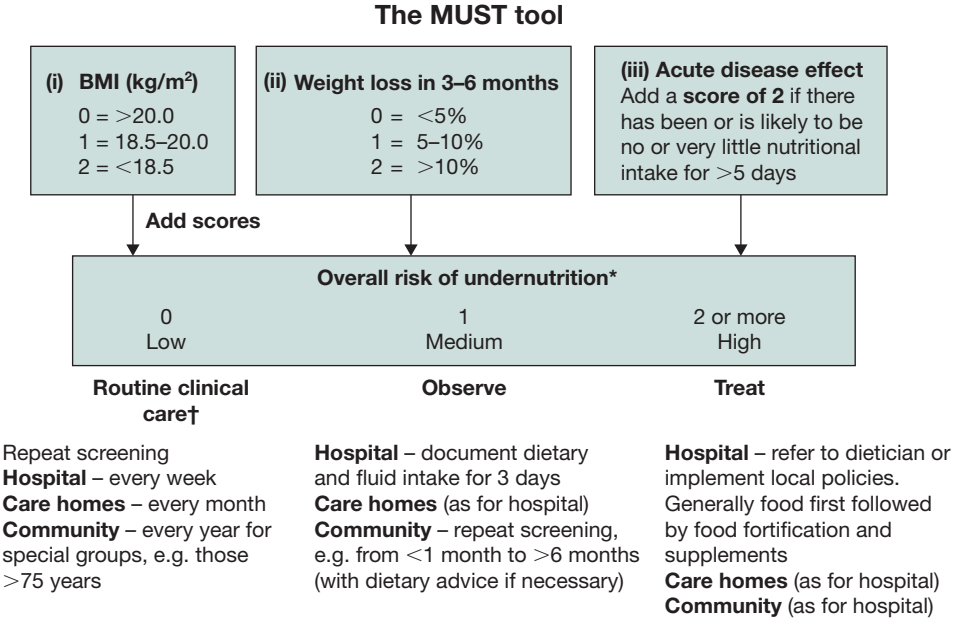
TABLE 25.1 Estimated daily fluid balance for a healthy 70-kg adult in a temperate climate.

Intake (L)		Output (L)	
Water from beverages	1.2	Urine	1.5
Water from food	1.0	Insensible losses (skin and lungs)	0.9
Metabolic processes of oxidation	0.3	Faeces	0.1

James Parkinson, 1755–1824, general practitioner of Shoreditch, London, UK, published *An essay on the shaking palsy* in 1817.

Prescription of maintenance fluids should aim to restore fluid losses and provide sufficient water and electrolytes to maintain the intracellular and extracellular fluid compartments, and to enable the kidneys to excrete waste products. The normal volume of water required for daily maintenance in a healthy 70-kg adult is approximately 2.2 litres or 30 mL/kg per day. Accurate assessment of maintenance fluid volumes requires both intake and output to be taken into account, in addition to the patient's body weight.

Fluid replacement should also encompass replacement of key electrolytes. The approximate daily requirements of the main electrolytes are as follows:



- sodium: 0.9–1.2 mmol/kg per day
- potassium: 1 mmol/kg per day
- calcium: 5 mM per day
- magnesium: 1 mM per day

Replacement of fluid and electrolytes should be by the simplest and safest route of administration. Where feasible the oral route should be used via oral rehydration solutions. In patients whose ability to swallow is impaired, fluid may be replaced via feeding nasogastric tubes or nasojejunal tubes, provided intestinal absorptive function is maintained.

Intravenous fluid replacement solutions

Intravenous fluid replacement may be necessary in conditions of gastrointestinal absorptive impairment or large fluid losses that cannot be quickly replaced via the enteral route. The specific type of fluid replacement therapy will be determined by the individual patient's needs. ***Table 25.2*** shows the composition of some commonly used intravenous fluid replacement solutions, in contrast to the average composition of the same components in plasma.

In addition to the crystalloid fluid solutions above, fluid can also be replaced with colloid solutions, which usually contain a form of modified gelatin. Examples of these include Gelofusine® or Volplex®, which both contain 4% w/v succinylated gelatin, or Voluven®, which contains hydroxyethyl starch. These solutions are often used as plasma expanders as the larger molecules are thought to be slower to diffuse into the extravascular space. Colloids are therefore sometimes used for fluid resuscitation in preference to crystalloids, but they can cause renal failure or coagulopathy. There is ongoing controversy regarding the use of crystalloids or colloids in the setting of fluid resuscitation. Albumin solutions have also been used

***If height, weight or weight loss cannot be established**, use documented or recalled values (if considered reliable). When measured or recalled height cannot be obtained, use knee height as a surrogate measure.
If neither can be calculated, obtain an overall impression of malnutrition risk (low, medium, high) using the following:
(i) Clinical impression (very thin, thin, average, overweight);
(iia) Clothes and/or jewellery have become loose fitting;
(iib) History of decreased food intake, loss of appetite or dysphagia up to 3–6 months;
(iic) Disease (underlying cause) and psychosocial/physical disabilities likely to cause weight loss.

† Involves treatment of underlying condition, and help with food choice and eating when necessary (also applies to other categories).

Figure 25.2 The Malnutrition Universal Screening Tool (MUST) for adults. (Adapted from Elia M (ed.). *The MUST Report. Nutritional screening of adults: a multidisciplinary responsibility. Development and use of the 'Malnutrition Universal Screening Tool' ('MUST') for adults*. A report by the Malnutrition Advisory Group of the British Association for Parenteral and Enteral Nutrition. Report no. 152. Redditch: BAPEN, 2003. ISBN 1 899467 70 X.)

TABLE 25.2 Composition of plasma in comparison with commonly used intravenous fluid replacements.

	Plasma	0.9% saline	Hartmann's solution	5% dextrose
Sodium (mmol/L)	135–145	154	131	0
Chloride (mmol/L)	95–105	154	111	0
Potassium (mmol/L)	3.5–5.3	0	5	0
Bicarbonate (mmol/L)	24–32	0	29	0
Calcium (mmol/L)	2.2–2.6	2	2	0
Magnesium (mmol/L)	0.8–1.2	0	0	0
Glucose (mmol/L)	3.5–5.5	0	0	227.8 (50 g)
Lactate (mmol/L)	0.5–1.0	0	29	0
pH	7.35–7.45	4.5–7.0	5.0–7.0	3.5–5.5
Osmolality (mOsmol/L)	275–295	308	273	278

in the past for fluid resuscitation; however, increasing evidence shows no benefit for the use of albumin outside of certain specific indications such as replacement of ascitic fluid losses or in the context of liver insufficiency. It is important to remember that if fluid loss is related to haemorrhage then the best form of fluid replacement is blood.

It must be noted that, as seen in ***Table 25.2***, none of the different intravenous fluid replacement solutions have electrolyte levels that completely mirror plasma levels, and thus there is no single ideal fluid replacement therapy. The specific choice of fluid replacement should take into account the nature of fluid losses and the amount of fluid replacement necessary in a specific patient.

Such an assessment would include:

- measurement of the pulse, blood pressure and, if available, the central venous pressure, as an estimate of intravascular fluid depletion;
- accurate intake and output charts, especially in inpatients in the acute care setting, taking into account urine output as well as losses from drains, fistulae, nasogastric tubes and faecal losses;
- measurement of serum electrolytes and haematocrit.

The choice of fluid replacement will also be guided by the time of gastrointestinal fluid loss, as the composition of gastrointestinal secretions varies with anatomical location (***Table 25.3***).

TABLE 25.3 Composition of gastrointestinal secretions (mmol/L).

	Sodium	Potassium	Chloride	Bicarbonate
Saliva	10	25	10	30
Stomach	50	15	110	–
Duodenum	140	5	100	–
Ileum	140	5	100	30
Pancreas	140	5	75	115
Bile	140	5	100	35

NUTRITIONAL REQUIREMENTS

Patients who are considered to be unable to consume enough nutrition via dietary means will need to be considered for either enteral or parenteral nutrition. Provision of enteral and parenteral nutrition should take into account not only macronutrients, such as carbohydrate, fat and protein, but also vitamins, trace elements, electrolytes and water. Planning of the feeding regimen will require the patient's weight as well as daily energy and protein requirements, which can be calculated based on standard tables. These regimens will need to be assessed on a daily basis and adjusted according to any changes in requirements, as overfeeding is one of the most common causes of complications regardless of the route of nutrient delivery. Regular biochemical monitoring is also mandatory as electrolyte and nutrient requirements can vary based on plasma levels (***Table 25.4***).

TABLE 25.4 Recommended schedule for monitoring feeding regimens.

Daily[a]	Observations including: • pulse, blood pressure and temperature • body weight • fluid balance, including volume of urine and/or urine and intestinal losses • quantity and type of food consumed, if allowed to eat Plasma levels: • sodium, potassium, urea and creatinine • blood glucose • magnesium and phosphate (if at risk of refeeding syndrome) • liver function tests • C-reactive protein
Weekly to fortnightly	Plasma levels: • full blood count • calcium, zinc, copper • plasma proteins including albumin • thiamine • triglycerides • vitamin B12 • folic acid
3–6 monthly	• Ferritin • Selenium, manganese • 25-hydroxyvitamin D

[a]Could be converted to weekly once the patient is established on a stable feeding regimen.

Macronutrient requirements

Total energy intake

In a normal state of health, the basal metabolic rate (BMR) can be calculated using the Harris–Benedict equation:

Men

$$BMR = (10 \times \text{weight in kg}) + (6.25 \times \text{height in cm}) - (5 \times \text{age in years}) + 5$$

Women

$$BMR = (10 \times \text{weight in kg}) + (6.25 \times \text{height in cm}) - (5 \times \text{age in years}) - 161$$

In the unwell patient population (acute or chronic disease), a degree of hypermetabolism exists, but no more than 120% of the predicted values. Stable patients with a normal or only moderately increased nutritional need should therefore be provided with a corresponding energy intake of 20–30 kcal for every kilogram of ideal body weight per day. Daily energy expenditure and thus requirements can be severely overestimated in obese patients, hence the ideal body weight should be used in these calculations rather than the actual body weight.

Nutrient requirements may increase to 30 kcal/kg ideal body weight per day under conditions of severe stress. However, the introduction of nutrition should be cautious in these patients as well as in those at risk of refeeding syndrome; nutrition should be started at no more than 50% of the estimated target energy needs. This can be increased to the full requirement over 24–48 hours, according to tolerance. Patients at risk of refeeding syndrome (discussed in more detail in ***Refeeding syndrome***) should have a maximum of 50% of their target requirements for the first 48 hours; this is subsequently increased only if clinical and biochemical monitoring shows no evidence of refeeding syndrome.

Carbohydrate

Glucose is the main substrate for the central nervous system and certain haematopoietic cells, which require the equivalent of 2 g/kg of glucose per day. Dietary guidelines therefore recommend that carbohydrates form 45–65% of the total caloric intake per day.

Protein

In the ill patient population, daily nitrogen requirements increase from approximately 0.15 g/kg per day to 0.25 g/kg per day. This is equivalent to a daily protein intake of 1.5 g/kg ideal body weight or around 20% of total energy requirements, in order to reduce nitrogen losses at times of illness.

Fat

Dietary fat consists of triglycerides of saturated and unsaturated fatty acids. Of these, the unsaturated fatty acids linoleic acid and linolenic acid are particularly notable, as they cannot be synthesised *in vivo* from non-dietary sources and are therefore considered essential fatty acids. Emulsions of long-chain triglycerides are now routinely used in parenteral nutrition, in which a mixture of glucose (a minimum of 100–200 g per day) and fat (100–200 g per week) is delivered. The combination of fat and glucose delivery minimises metabolic complications associated with parenteral nutrition, improves substrate utilisation and reduces fluid retention and carbon dioxide production.

Vitamins, minerals and trace elements

Vitamins B and C are important in optimising recovery from illness, in particular for collagen formation and wound healing. Vitamin C requirement in the postoperative period increases to 60–80 mg per day. It is important to consider the need for supplemental vitamin B12, especially in patients who have undergone gastric surgery and in those with a history of alcohol dependence. Surgical procedures or medical conditions associated with a reduction in pancreatic or biliary enzymes in the intestinal tract (e.g. obstruction of the biliary or pancreatic ducts) will result in malabsorption of the fat-soluble vitamins A, D, E and K. Increased intestinal losses such as in chronic diarrhoea can cause hyponatraemia, hypokalaemia and hypophosphataemia, which will all need monitoring and replacement. Trace elements such as magnesium, zinc and iron are important cofactors in metabolic processes and may be reduced as part of the inflammatory response. Replacement of these elements is necessary to ensure appropriate utilisation of amino acids and avoidance of refeeding syndrome.

EFFECTS OF INTESTINAL RESECTION ON FLUID AND NUTRIENT ABSORPTION

The main role of the intestine is the absorption of fluid, nutrients and electrolytes, and as such it has a large capacity for adaptation to the loss of intestinal length by increasing the absorptive surface area as well as molecular changes increasing nutrient transporter levels. This may be due to either surgical resection or a reduction in functional capacity associated with severe cases of chronic inflammatory intestinal conditions such as Crohn's disease or ulcerative colitis. Patients with reduced functional intestinal length may therefore require supplemental parenteral nutrition, intravenous fluid or both, depending on the site and extent of affected bowel. Resection of the proximal jejunum can be compensated by the ileum and colon adapting to absorb the additional fluid and electrolyte load, hence these patients do not require supplemental nutrition. Resection of the ileum, however, may have more significant consequences. The ileum is responsible for bile salt reabsorption and loss of even 100 cm of ileum may cause steatorrhoea, which can be treated by the administration of cholestyramine for bile salt binding. If greater lengths of ileum are affected, dietary fat restriction may also be necessary. Ileal resection also increases

J Arthur Harris, 1880–1930, botanist and biometrician, head of the Department of Botany, University of Minnesota, St Paul, MN, USA (1924–1930).
Francis G Benedict, 1870–1957, American chemist, physiologist and nutritionist, developed a calorimeter and a spirometer used to determine oxygen consumption and measure metabolic rate.
Burrill Bernard Crohn, 1884–1983, gastroenterologist, Mount Sinai Hospital, New York, NY, USA, described regional ileitis in 1932.

gastric motility and intestinal transit, resulting in a greater volume of fluid and electrolytes reaching the colon, causing symptoms of diarrhoea. The greatest consequences of loss of functioning intestinal length occur in patients with remnant small intestine of less than 200 cm. This results in significantly reduced absorptive capacity, with the associated metabolic and nutritional consequences of short bowel syndrome.

Short bowel syndrome (discussed in more detail in ***Chapter 74***) is characterised by symptoms of diarrhoea, malnutrition and dehydration, with variable severity depending on the extent and function of the remaining small bowel. The acute stage of short bowel syndrome occurs in the first few weeks following the insult. It is characterised by high intestinal losses, gastric hypersecretion and hypergastrinaemia and can result in acute renal failure and acid–base imbalances. The subsequent adaptation stage occurs over 1–2 years and is a consequence of the structural and functional changes within the remnant bowel, allowing increased absorptive capacity and ameliorating some of the earlier symptoms. Sufficient recovery may occur in some patients to render parenteral nutrition no longer necessary; however, some features of intestinal insufficiency may still remain, requiring special diets, supplementation of nutrients and some pharmacological treatments. Intestinal rehabilitation programmes have been developed over the last decade to optimise intestinal function in short bowel syndrome as much as possible; however, recovery of function to allow weaning from home parenteral nutrition becomes unlikely beyond 3 years of onset. Intestinal transplantation is an option in those dependent on lifelong parenteral nutrition; this is covered in greater detail in ***Chapter 91***.

Patients who have less than 100 cm of total residual bowel have a particularly severe form of short bowel syndrome as they will lose more water and electrolytes from their bowel than consumed by mouth. Daily bowel losses can exceed 4 litres in a 24-hour period. Consumption of oral fluids with sodium concentrations of less than 90 mmol/L will result in a net efflux of sodium from plasma into the bowel lumen, hence hypotonic fluids should be restricted to less than 1 litre per day and patients should be encouraged to drink glucose and saline replacement solutions such as oral rehydration salts. Fluid balance needs to be carefully monitored; while some of the fluid intake will be covered by parenteral nutrition, further intravenous fluid supplementation may also be necessary in cases of particularly high bowel output.

ARTIFICIAL NUTRITIONAL SUPPORT

Given the importance of adequate nutrition in recovery from illness and surgery, consideration for artificial nutritional support should be given in any patient who has had inadequate nutritional intake for 5 days or more. In patients with pre-existing chronic malnutrition, this should be instituted earlier, and ideally in the preoperative period if feasible. Patients due to undergo major surgery for head and neck or abdominal cancers (such as laryngeal or pharyngeal resections, oesophagectomies, gastrectomies and pancreaticoduodenectomies) are more likely to have difficulty consuming any or sufficient oral nutrition postoperatively because of oedema, obstruction, delayed gastric emptying and paralytic ileus. These patients are also more likely to have nutritional depletion preoperatively owing to the effects of the underlying disease. Forethought should be given preoperatively in these patients regarding the placement of intravenous access, nasojejunal tubes or feeding jejunostomies intraoperatively to facilitate postoperative nutrient delivery (***Figure 25.3***).

Enteral nutrition

Enteral nutrition (the delivery of nutrients into the gastrointestinal tract) should always be the preferred route of administration of nutrition where possible. Benefits of enteral nutrition include preservation of the gut mucosal barrier and immunity and prevention of gut atrophy. The use of enteral nutrition is also associated with reduced infection rates, better wound healing and a reduced length of stay compared with parenteral nutrition. Supplementary enteral nutrition can be in the form of oral supplements as well as via tube-feeding techniques such as feeding gastrostomies or jejunostomies and nasogastric or nasojejunal tubes.

Enteral feeds contain variable nutrient formulations with respect to the content of energy, fat and nitrogen, as well as the osmolarity and nutrient complexity. In general, most feed formulations contain 1–2 kcal/mL and up to 0.6 g/mL protein.

Oral supplements

Many liquid oral supplements are commercially available, supplying around 200 kcal and 2 g of nitrogen per 200-mL carton. These can be used to increase daily caloric intakes in addition to that provided by diet alone, and are useful when weaning patients off tube-feeding regimens.

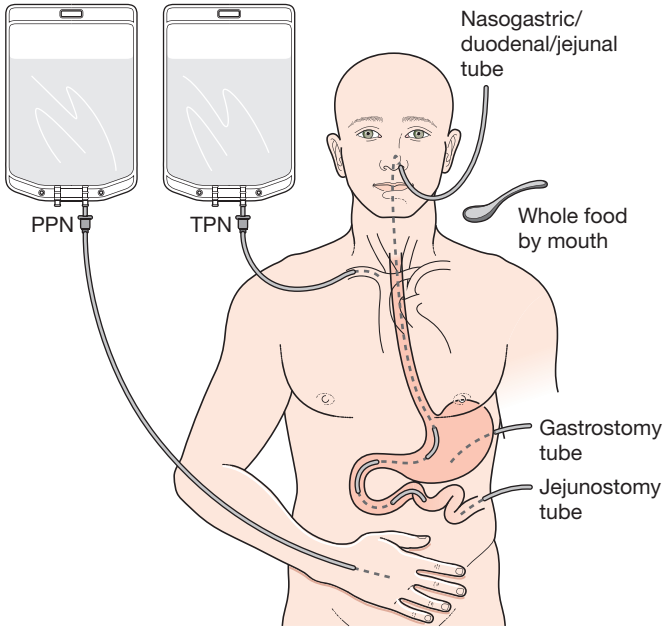


Figure 25.3 Routes available for delivery of artificial nutritional support. PPN, partial parenteral nutrition; TPN, total parenteral nutrition. (Redrawn with permission from Rick Tharp, rxkinetics.com.)

Tube feeding

Patients who are unable to maintain adequate nutritional intake with oral supplements will need administration of enteral feed via tube feeding. This can be prepyloric either via a conventional nasogastric (Ryle's) tube or a fine-bore feeding tube inserted into the stomach or via a surgical or endoscopically placed gastrostomy. Feed can also be delivered beyond the pylorus via a nasojejunal tube or surgical or endoscopic feeding jejunostomy.

The enteral feeding regime is best planned and managed by a trained dietician as administration of enteral feed requires calculation of the patient's nutritional requirements to allow caloric requirements to be met but at a sufficiently gradual rate of increase to prevent the onset of refeeding syndrome in the chronically malnourished patient. The rate of feeding typically starts at 10–20 mL/h and can increase to approximately 75 mL/h if tolerated.

Enteral feeding protocols should include aspiration of the tube, if of sufficiently wide calibre, to reduce the risk of nosocomial aspiration pneumonia by reducing or stopping the administration of enteral feed if aspirate volumes are high. Tube blockage is common and can be prevented by regular flushing with water daily. Specific agents such as chymotrypsin may be used to unblock a partially obstructed tube; however, guidewires should not be used because of the risk of perforation of the tube and thus damage to the lumen of the stomach or bowel. A radio-opaque nasogastric or Ryle's tube can be used for short-term feeding in the majority of patients and provides the advantage of also having a wide enough calibre to allow aspiration; however, the high-grade polyvinylchloride (PVC) material used can become brittle over time and thus should be changed every 2 weeks. For longer term feeding a fine-bore feeding tube (8–12Fr) may be preferable to minimise the risk of rhinitis, pharyngitis and gastric and oesophageal erosions. These tubes are also less likely to interfere with eating and drinking and are often better tolerated by patients.

Techniques for establishment of tube feeding

Insertion of nasogastric and nasojejunal feeding tubes

Nasogastric tubes can usually be inserted in the ward setting; however, in patients in whom there may be any concerns regarding the oropharyngeal or oesophagogastric anatomy, endoscopic insertion under direct visualisation may be needed. Patients are positioned in a semirecumbent position and the distance between the xiphisternum and the tip of the nose measured. The tube is inserted into the chosen nostril and advanced gently to the 10-cm point. Patients are then encouraged to swallow and the tube simultaneously advanced down the oesophagus with successive swallows until the distance measured to the xiphisternum is reached. The position of the nasogastric tube will need to be checked before feed is administered, either by pH testing (pH <5 is considered safe) or with a chest radiograph to confirm that the tip of the nasogastric tube is below the diaphragm and well past the bronchial bifurcation. Fine-bore feeding tubes can be inserted in a manner similar to above, but may require a guidewire within the tube to facilitate insertion; this must be confirmed to have been removed after insertion of the tube (***Figure 25.4***).

Feed can also be delivered directly to the jejunum via either tube feeding or surgically created jejunostomies. The advantage of this is that it bypasses the stomach and can thus overcome problems of delayed gastric emptying without necessitating the use of total parenteral nutrition (TPN). Nasojejunal feeding can also be used in patients who are unable to have a gastrostomy as this is the least invasive form of nutrient delivery into the jejunum. The siting of nasojejunal tubes requires either endoscopic or radiological (fluoroscopic) guidance; therefore, unlike nasogastric tubes, these cannot be inserted in the typical ward setting. Abdominal radiographs can confirm the position of the nasojejunal tube if there is any concern regarding proximal migration or displacement (***Figure 25.5***).

Gastrostomy

Gastrostomy tubes are generally reserved for patients who require longer term feeding. The decision for insertion of these tubes is increasingly discussed in the multidisciplinary context because of the long-term physical, psychological and lifestyle implications. Gastrostomy insertion can be endoscopic (percutaneous endoscopic gastrostomy [PEG]), radiological (radiologically inserted gastrostomy [RIG]) or surgical (***Figure 25.6***).

A PEG involves the insertion of the gastrostomy tube through the abdomen and stomach under vision via an endoscope, avoiding a surgical incision and a general anaesthetic. The endoscopist is able to visualise a cannula entering the

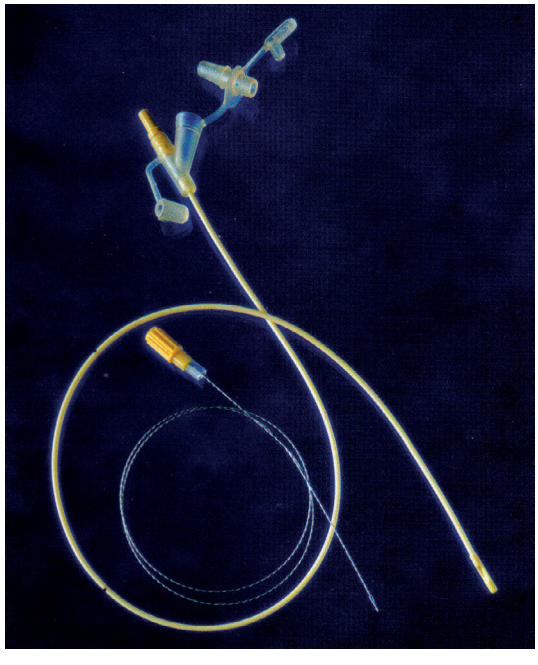

Figure 25.4 A fine-bore feeding tube with its guidewire.

John Alfred Ryle, 1889–1950, Regius Professor of Medicine, University of Cambridge, Cambridge, and later Professor of Social Medicine, University of Oxford, Oxford, UK, introduced the Ryle's tube in 1921.

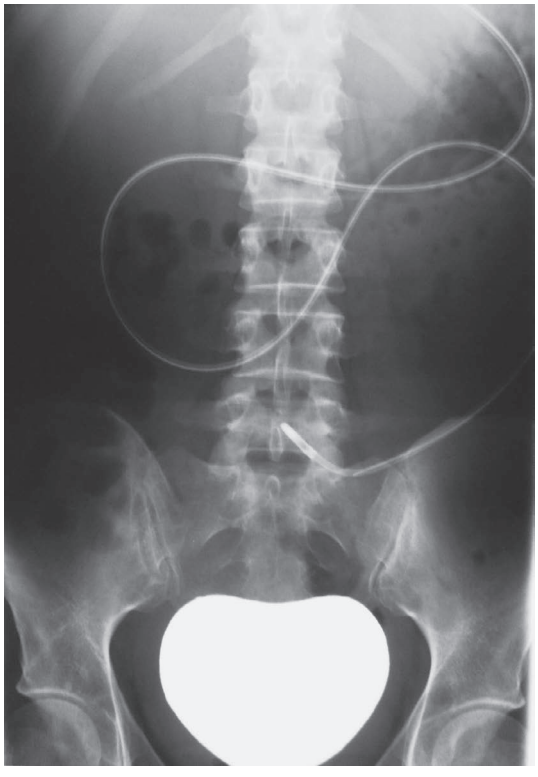

Figure 25.5 Abdominal radiograph confirming that the position of the tip of a nasojejunal feeding tube is past the duodenojejunal flexure.

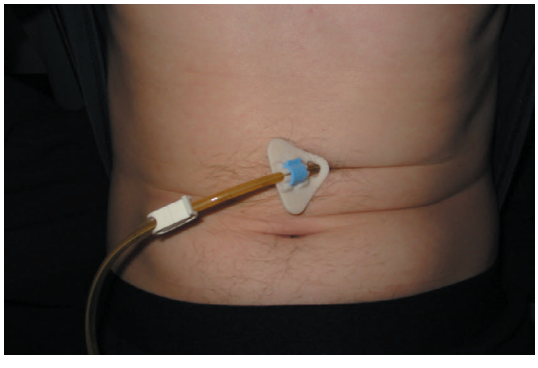

Figure 25.6 Percutaneous endoscopic gastrostomy tube, showing the external bumper and tube clamp

insufflated stomach via the anterior abdominal wall, through which a guidewire is passed. Then either the gastrostomy tube can be inserted through the anterior abdominal wall over the guidewire or the guidewire can be pulled out via the mouth and the tube secured to the guidewire, pulled down into the stomach and then pulled out through the abdominal wall. The stomach wall is pulled up to the anterior abdominal wall and held in place by a cuff, balloon or plastic bumper to minimise the risk of intraperitoneal leakage (***Figure 25.7***).

A RIG is an option in patients who are unable to have a PEG because of difficulty with oesophageal intubation, compromised respiratory function or oropharyngeal anatomy distortion such as from head and neck cancers. A nasogastric tube is inserted to insufflate the stomach and a cannula is

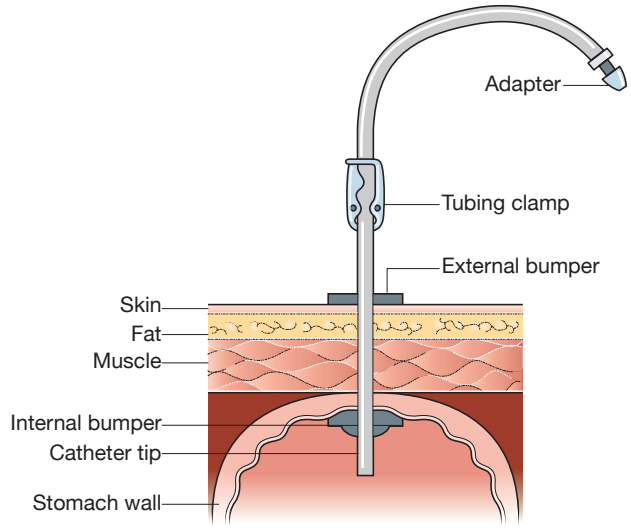

Figure 25.7 Cross-sectional appearance of a percutaneous endoscopic gastrostomy tube *in situ*, showing the abutment of the stomach to the abdominal wall to minimise risk of leakage and peritonitis.

inserted under radiographic guidance to facilitate insertion of the gastrostomy device, which is retained internally via a balloon or a pigtail. Contrast can be administered via the RIG to confirm the correct site of placement.

A surgical gastrostomy may be necessary in patients who are unable to have either a PEG or a RIG, most commonly because of distorted intra-abdominal anatomy, usually from previous surgical intervention. This will require either a laparotomy or a laparoscopy with a small gastrostomy to allow insertion of the feeding tube, which can be held in place either by insufflation of a balloon or by a plastic 'bumper'. The stomach wall is fixed to the anterior abdominal wall with sutures to minimise intraperitoneal leakage. Some gastrostomy devices also allow the fitting of jejunal extensions, thus allowing venting of stomach contents and simultaneous delivery of nutrients into the jejunum.

Complications of a gastrostomy, regardless of the technique of placement, include perforation, bleeding and peritonitis. Localised sepsis around the insertion site is very common and may require systemic antibiotics. Gastrostomies that have been in place for a long period are likely to develop a persistent gastric fistula on removal owing to epithelialisation of the tract, which may require surgical intervention for closure. Tube blockage may occur, as well as tube displacement.

Nasojejunal tubes and jejunostomies

Surgical jejunostomies are often created at the time of resection in patients undergoing major oesophagogastric surgery who are likely to have insufficient oral intake in the immediate postoperative period.

Jejunostomies require a general anaesthetic and either a laparotomy or a laparoscopy, facilitating the insertion of a feeding tube through the anterior abdominal wall into the proximal jejunum. The site of insertion in the jejunum is usually fixed to the anterior abdominal wall to further reduce the risk of leakage. A more recent development is the siting

of a jejunostomy via radiological guidance. The jejunum is punctured under image guidance and a guidewire inserted, over which the tract is dilated to allow a feeding jejunostomy tube to be passed. The position of the tube is confirmed with fluoroscopy and the tube anchored to the skin with sutures.

Complications of jejunostomy insertion in the perioperative period include bleeding or tube displacement and leakage causing peritonitis. In the longer term, granulation tissue formation or localised sepsis at the site of insertion is common.

Complications of enteral feeding

The complications of enteral feeding can be divided into three main groups and are outlined in ***Summary box 25.3***. The first group is that of complications related to the siting of tubes or creation of gastrostomies or jejunostomies, which have been covered individually in the sections above. The second group are gastrointestinal complications related to ongoing nutrient delivery. Enteral feeding is not appropriate in patients who are not likely to absorb the delivered nutrients. This includes patients who have an insufficient length of functioning intestine as well as patients with mechanical intestinal obstruction or paralytic ileus. These patients will require TPN as enteral nutrient delivery is likely to result in complications such as aspiration and failure to meet nutritional requirements. Enteral feeding can cause bloating and vomiting and is associated with diarrhoea in over 30% of patients, which can compromise nutritional uptake.

The third group refers to the development of metabolic or biochemical complications, and thus the establishment of feeding should be monitored carefully as rapid increases in nutrient delivery in patients with chronic malnutrition can cause electrolyte disorders and refeeding syndrome (see ***Refeeding syndrome***).

Summary box 25.3

Complications of enteral feeding

- Tube related
  - Malposition
  - Displacement
  - Blockage
  - Breakage/leakage
  - Local complications (e.g. erosion of skin/mucosa)
- Gastrointestinal
  - Diarrhoea
  - Bloating, nausea, vomiting
  - Abdominal cramps
  - Aspiration
  - Constipation
- Metabolic/biochemical
  - Electrolyte disorders, including refeeding syndrome
  - Vitamin, mineral, trace element deficiencies
  - Drug interactions

Parenteral nutrition

Indications and composition of parenteral nutrition

Nutrition may need to be delivered intravenously in patients in whom adequate feeding through the alimentary tract is not possible. This can be either in addition to enteral feeding (supplemental parenteral nutrition) or the sole source of nutrition (TPN). TPN is indicated in patients who are unable to meet their nutritional requirements via absorption of nutrients from their intestinal tract. The commonest cause for this is in patients with short bowel syndrome related to massive intestinal resection or a significant reduction in functional small bowel, often related to intestinal fistulation. In some cases the establishment of TPN is a temporary endeavour for a few days to minimise nutritional depletion until a route of enteral nutrition is established, e.g. awaiting the siting of a nasojejunal tube in patients with delayed gastric emptying.

Parenteral nutrition formulations have evolved over the years, but are currently commonly provided by the hospital pharmacy in the form of a 3-litre bag containing a lipid emulsion with a mixture of essential and non-essential amino acids, glucose, electrolytes, trace elements and vitamins. The energy content of parenteral nutrition is in the ratio of 150–250 kcal per gram of protein nitrogen, with usually 30–50% of the energy coming from fat. This ensures sufficient energy provision for amino acids to be utilised for tissue maintenance. Folic acid is supplemented in the solution once or twice a week at a dose of 15 mg and other vitamins are given daily. Patients requiring long-term parenteral nutrition (over many months) would also benefit from a single-dose injection of vitamin B12. Phosphate is an essential component of parenteral nutrition regimens: 20–30 mmol phosphate is required daily to ensure phosphorylation of glucose and prevent hypophosphataemia. The specific composition of parenteral nutrition can be changed daily to reflect the patient's needs and tailored to address any electrolyte deficiencies and ongoing energy requirements. This is guided by daily assessments (including weight and electrolytes). In addition, the protein content will differ in patients who are critically ill (requiring more protein) compared with those with chronic renal failure (requiring less protein). Micronutrients such as zinc, copper, selenium, ferritin, folate and vitamins B12 and D will need to be checked in patients on parenteral nutrition for more than 28 days and every 3 months in patients on long-term parenteral nutrition.

Administration of parenteral nutrition

Parenteral nutrition is usually administered directly into the central venous system (the superior vena cava [SVC] or the right atrium) to minimise the risk of venous thrombophlebitis, through either a peripherally inserted central catheter (PICC) or central venous catheter (***Figure 25.8***). PICC lines may be inserted through the basilic (most commonly used), cephalic, brachial or median cubital vein of the arm, and can be used for parenteral nutrition administration over several weeks to months. Femoral lines should be avoided for parenteral nutrition because of the high risk of infection at this site. Chest radiographs should be performed after PICC or central venous catheters are inserted to confirm the correct position of the line tip within the SVC or right atrium prior to commencing the parenteral feed (***Figure 25.9***).

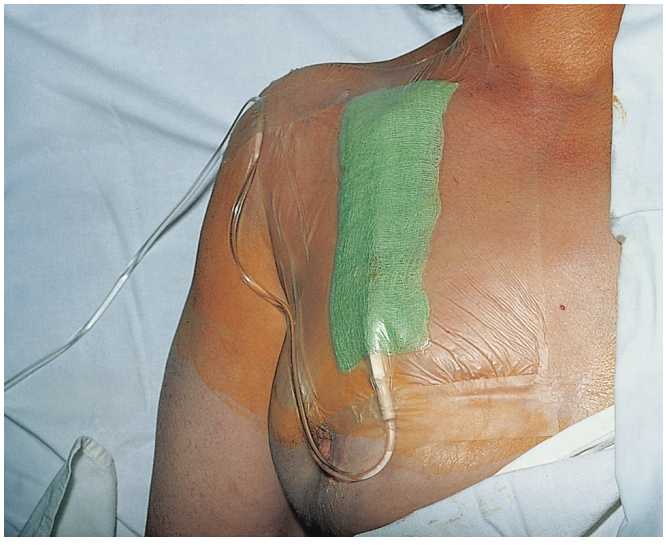

Figure 25.8 An example of a central venous line (in this case a subclavian line) used for administration of parenteral nutrition.

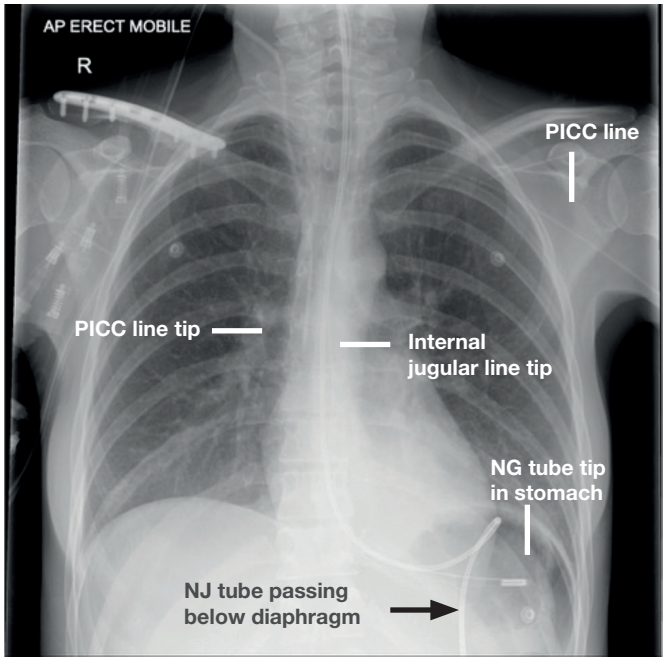

Figure 25.9 A chest radiograph showing correct positioning of the internal jugular and peripherally inserted central catheter lines within the superior vena cava, as well as the tip of the nasogastric (NG) tube in the stomach and the nasojejunal (NJ) tube passing into the abdomen.

In patients who are likely to require long-term parenteral nutrition, an implantable port or a Hickman line may be more appropriate. These are implanted via fluoroscopic or ultrasound guidance with a subcutaneous port or cuff and a catheter attachment sitting within the SVC.

Rarely, parenteral nutrition can be administered through a peripheral venous catheter; however, the high osmolarity of parenteral nutrition produces an increased rate of thrombophlebitis at these sites because of the narrower calibre and low rate of flow in peripheral veins, making it an appropriate option only where the duration of parenteral nutrition administration is less than 14 days. The risk of thrombophlebitis can be reduced to some extent by the use of soft polyurethane paediatric cannulae and using feeds of low osmolarity and neutral pH. The cannulae used will need to be changed every few days.

The parenteral nutrition bag should be covered at all times, including during infusion, with an opaque protective bag to prevent the vitamins from degradation. If the parenteral nutrition infusion is disconnected from the line for any reason during administration the bag will need to be discarded. It is important to remember that parenteral nutrition administration contributes to fluid intake, and thus the volume infused should be carefully recorded on the fluid balance chart to avoid fluid overload. In patients in whom parenteral nutrition is a temporary measure, oral nutritional input or enteral feeding should be monitored, and parenteral nutrition withdrawal planned in a stepwise manner and stopped once the patient is established on adequate oral or enteral support.

Complications of parenteral nutrition

The complications of parenteral nutrition are best considered to fall within one of three categories: insertion complications, line complications and metabolic complications (see ***Summary box 25.4***).

Summary box 25.4

Complications of parenteral feeding

- Insertion complications
  - Pneumothorax
  - Misplacement
- Line complications
  - Sepsis
  - Thrombosis
- Metabolic complications
  - Electrolyte disorders, including refeeding syndrome
  - Blood sugar derangement
  - Liver dysfunction
  - Metabolic bone disease
  - Vitamin deficiencies

Insertion complications

The most common complication of line insertion is an inadvertent pneumothorax, which occurs in around 0.5–1% of cases, most commonly during insertion of subclavian lines. It is managed by insertion of a chest drain, which can be removed once the pneumothorax has resolved. Line misplacement can also occur and is diagnosed on chest radiograph, which is mandatory following central line insertion. The line is considered to be in the correct place if the tip is in the inferior third of the SVC or at the atriocaval junction (see ***Figure 25.9***).

Robert O Hickman, 1926–2019, formerly paediatric nephrologist, Seattle Children's Hospital, Seattle, WA, USA.

Line complications

One of the most important line complications is line sepsis, which can occur in up to 15% of patients and is associated with significant morbidity and mortality. Insertion of the line and administration of parenteral nutrition requires strict aseptic technique as line infections can rapidly progress to septicaemia. Catheter entry sites should be checked daily. Patients with suspected line sepsis will need paired blood cultures taken from the line and a separate peripheral site and use of the line should be stopped until culture results are available. Positive cultures will require line removal and commencement of antibiotics. Fungal line infections in particular can be associated with uveitis and bacterial endocarditis.

Line thrombosis is not uncommon and can occasionally occur in major veins in association with line infection, causing serious complications such as SVC occlusion and pulmonary embolism. Treatment is by anticoagulation, rarely requiring fibrinolysis for acute SVC occlusion and endovascular intervention in the longer term. Line blockage is relatively common and can be prevented by regular line flushing after manipulation and the use of a dedicated parenteral nutrition line or, in the case of a multilumen centrally placed catheter, a dedicated lumen. Blocked lines can be unclogged by locking the affected line with heparin–saline or thrombolytic agents.

Metabolic complications

Refeeding syndrome. One of the most significant metabolic complications of both parenteral and enteral feeding is refeeding syndrome. This occurs in the first days after feeding is commenced in patients who have been severely malnourished. Patients due to start nutritional support need to be screened for the risk of refeeding syndrome. The degree of risk is related to their BMI, amount and rate of unintentional weight loss, period of starvation and electrolyte levels (see ***Summary box 25.5***).

The main underlying pathological process is one of hypophosphataemia, resulting in fluid and electrolyte shifts between the intra- and extracellular compartments. Patients may develop arrythmias, muscle weakness, respiratory or cardiac failure, oedema, lethargy or seizures; at its most severe the syndrome can be fatal. Laboratory tests will reveal low levels of phosphate, potassium, calcium and magnesium and a lactic acidosis. Nutritional support in this group of patients should be started at a maximum of 10 kcal/kg per day, aiming to increase levels slowly to meet full needs by 4–7 days. Frequent monitoring and replacement of the electrolytes listed above is essential. Nutritional support should include supplementary thiamine, vitamin B, multivitamins and trace elements.

Blood sugar derangement. In patients with diabetes and those with impaired blood glucose control owing to critical illness, administration of parenteral nutrition should coincide with a variable insulin infusion regimen to avoid hyperglycaemia. Conversely, insulin dosing should be reduced accordingly when parenteral nutrition is interrupted to avoid hypoglycaemia.

Liver dysfunction. Long-term use of parenteral nutrition is associated with derangement of liver function tests in at least 25% of patients. Fatty liver is a common complication. This is worse in children, and the degree can be reduced by modifying the parenteral nutrition solution, such as alternating the use of lipid-free parenteral nutrition solutions. A smaller percentage of patients may subsequently develop liver fibrosis and cirrhosis. Once liver disease is established in these patients the term 'intestinal failure-associated liver disease' (IFALD) is used, as these cholestatic changes in liver function profile are difficult to separate from the effects of short bowel syndrome. Factors such as a lack of colonic continuity, extreme short bowel, lack of enteral intake and high energy and fat content in feed have all been associated with a higher risk of the development of IFALD.

Metabolic bone disease and vitamin deficiencies. Osteoporosis or osteomalacia are both known complications of long-term parenteral nutrition, leading to fractures or kidney stones. Supplementation of calcium, phosphate, vitamin D and sometimes bisphosphonates can both prevent and treat this complication. Excess or deficiency of vitamins or trace elements may occur, manifesting with non-specific symptoms such as anaemia, hair loss or neurological symptoms. Regular measurements and replacement, as well as clinical assessment, can prevent this from occurring.

Summary box 25.5

Refeeding syndrome

Patient is considered to be at risk of developing refeeding syndrome with
EITHER

One or more of the following:

- BMI <16 kg/m^2
- Unintentional weight loss >15% within the last 3–6 months
- Little or no nutritional intake for more than 10 days
- Low potassium, phosphate or magnesium levels prior to feeding

OR

Two of more of the following:

- BMI <18.5 kg/m^2
- Unintentional weight loss >10% within the last 3–6 months
- Little or no nutritional intake for more than 5 days
- History of alcohol abuse or on medication, including insulin, chemotherapy, antacids or diuretics

NUTRITION SUPPORT TEAMS

Multidisciplinary nutrition support teams are essential to ensure that all essential aspects relating to the appropriateness of nutritional support, initiation and maintenance are addressed safely. The team should include doctors, dieticians, specialist nutrition support nurses and pharmacists and may also include other allied healthcare professionals such as speech and language therapists. Specialist nutrition support nurses, in conjunction with ward nurses and dieticians, should aim to minimise complications related to enteral or parenteral feeding, develop and implement protocols for training of ward nurses in administration of enteral and parenteral nutrition,

and support transition of feeding into the community setting around the time of discharge from hospital.

SUMMARY

Appropriate and safe assessment and administration of fluid therapy and nutritional support is of key importance in good surgical practice. It is imperative that the preoperative nutritional state of the patient and the impact of any surgical intervention are taken into account when considering nutritional requirements and the mode of nutrient delivery. Appreciation and avoidance of complications of both enteral and parenteral nutrition such as refeeding syndrome are also essential. Nutrient support teams play an important role in ensuring the safe administration and weaning of supplemental nutrition in a challenging area of practice.

CHAPTER 26

Introduction to trauma

Learning objectives

- Become familiar with the timeline concept in trauma management
- Understand how to assess a trauma problem
- Appreciate the importance of observing trends for identification of evolving conditions
- Recognise that specific criteria exist for implementation of different treatment strategies

DEFINITION OF TRAUMA

Trauma can be defined as an injury to any part of the human body as the result of energy transfer from an inflicting source. The forces that can lead to injury include chemical, thermal, ionising radiation and mechanical. The extent and severity of the trauma sustained depends upon the magnitude, nature and duration of the inflicting cause.

Major trauma denotes injuries to more than one body region or organ system. In Part 4, trauma will be examined from a variety of viewpoints, interconnected to different specialties. In this chapter we will examine the facets that bind the whole topic together.

THE MAGNITUDE OF THE PROBLEM

In western industrialised countries, trauma accounts for the largest number of deaths and disability in children and young adults. According to the World Health Organization, there are an estimated 5 million injury fatalities worldwide, representing about 9% of global deaths. This rate is 1.7 times higher than deaths caused by malaria, tuberculosis and human immunodeficiency virus (HIV)/acquired immunodeficiency syndrome (AIDS).

Road traffic accidents (RTAs), falls and intentional violence continue to be the most prevalent causes of trauma fatalities, with a combined rate of 64%. Of note, the major burden of injury is increasing in low- and middle-income countries secondary to industrialisation and increasing motorised transportation. Interestingly, the annual incidence and trends over time show that there is variation from country to country. Information is usually obtained from national statistics organisations that use the International Classification of Diseases, a system that can be limited in providing accurate descriptions of injury severity. In contrast, the Abbreviated Injury Scale dictionary consists of a greater level of detail (including more than 2000 injury codes) and assigns to every injury a severity score between 1 (mild) and 6 (maximum). This can be summated into the so-called injury severity score (ISS), which provides an indication of the anatomical severity of injury suffered by the individual patient. Major trauma is defined as an ISS greater than 15. The majority of patients admitted to hospital with injury have low ISS values, ranging between 4 and 9, with injuries such as an isolated limb fracture and/or isolated mild head injury. Overall, major trauma affects approximately 15% of all injured patients.

According to the UK Department of Transport, in 2019, the overall number of casualties following an RTA reported to the police, including all severities, was 153 158, of whom 25 945 had sustained severe injuries. Overall, 1752 individuals died as a result of their injuries. Across Europe, according to the data presented by the European Transport Safety Council's Performance Index (PIN) report, it appears that the overall number of fatalities was reduced by 3% compared with 2018, and was estimated to be 22 660. In 16 countries, the death rate decreased whereas in 12 it increased, with the four remaining countries registering no change.

As countries do not use the same definition of serious injury, international comparisons are based on road deaths per million inhabitants. In the 27 Member States of the European Union (EU27), the overall level of road mortality was 42 deaths per million inhabitants in 2020 compared with 67 per million in 2010 (***Figure 26.1***). The EU road mortality rate was 51 per million in 2019; the unprecedented drop in mortality between 2019 and 2020 was mainly due to the traffic restrictions to contain the pandemic.

Norway remains the leader among PIN countries with 17 road deaths per million inhabitants, followed by Sweden with 20 deaths per million inhabitants in 2020. In Malta, the UK, Switzerland and Denmark, road mortality is below 27 per million. The highest road mortality is in Romania and Latvia, with 85 and 73 road deaths per million inhabitants, respectively.

A large proportion of severely injured survivors experience long-term or permanent disability as a result of their injuries. Approximately one-third of severely injured survivors sustained life-changing injuries and were unable to return to

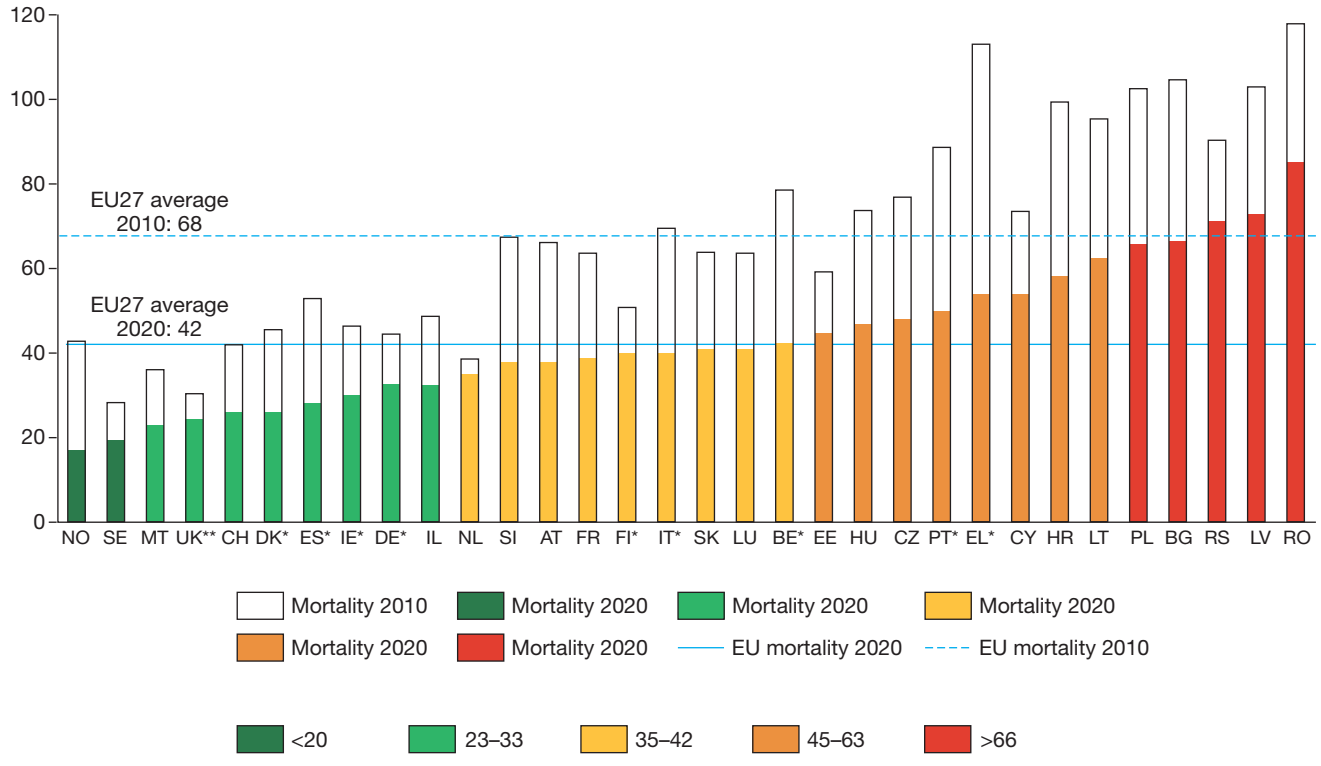

Figure 26.1 Mortality (road deaths per million inhabitants) in 2020 (coloured bars) with mortality in 2010 for comparison (white bars) (courtesy of the European Transport Council). *National provisional estimates used for 2020. The annual number of deaths in LU and MT are particularly small and, therefore, subject to substantial annual fluctuations. **UK data for 2020 are the provisional total for Great Britain for the year ending June 2020 combined with the total for Northern Ireland for the calendar year 2020.

their previous level of function and occupation, undergoing profound lifestyle changes including long-term pain and suffering. It should be emphasised that an injury affects not only the injured person but also everyone who is involved in the injured person's life. The impact of the modern epidemic of RTAs on the universal epidemic of violent injury cannot be overstated. The annual direct medical cost of injuries treated in hospitals and additional care facilities is estimated to be somewhere between £3.5 billion and £4 billion. Moreover, additional indirect costs, due to loss of earnings, loss of productivity and a reduced quality of life, increase the total sum significantly.

Multiple injuries are often thought to occur primarily in younger patients who are involved in incidents with a high energy transfer. Lately, multiple injuries are also seen in the older population as patients live longer, are more active and we have better diagnostics. The last point is particularly important as older adult patients were often underinvestigated, so the full extent of injury was not appreciated.

Recent data published by the UK's National Institute for Health and Care Excellence (NICE) revealed that there are an estimated 500 000 new patients with fragility fractures per year in the UK; approximately 70 000 of these are admitted with proximal femoral fractures, among whom 6.7% of those aged >65 years will die within 30 days of the incident, as reported by the National Hip Fracture Database. Most of the remaining patients with proximal femoral fractures will have diminished independence and functional capacity. It is therefore unsurprising that this particular cohort of patients, the number of whom will increase in coming years owing to the anticipated increase in life expectancy, is thought to represent a huge burden on healthcare services and society in general.

In summary, the overwhelming majority of trauma is not life- or limb-threatening and full recovery with return to preinjury status is usually expected. However, it remains of paramount importance that injuries are detected early in order to properly intervene and therefore achieve a favourable outcome. For instance, one must be vigilant not to miss paediatric non-accidental injury (NAI) (see ***Chapter 44***) or injuries secondary to a chronic underlying disease process rather than the injury itself, for example pathological fractures in older age groups. Of note, it has been shown that, in 66% of cases when children die as a result of abuse, there has been some previous interaction with a health professional or with social services, but the seriousness of the situation was not fully appreciated.

Summary box 26.1

Trauma: the magnitude of the problem

- The vast majority of trauma is not life- or limb-threatening
- Severe trauma continues to be a major cause of death in young patients
- Older adult patients with fragility fractures are a special group posing a further burden to a healthcare system
- Promptly identifying important features of injuries could influence the outcome

THE MANAGEMENT OF TRAUMA

As soon as a severe injury occurs, every second counts, and all aspects of decision making and management are critical for a patient's long-term quality of life and even their survival. The concepts of initial assessment and management have specific goals that are based on practice over a long period of time. In the modern era, new protocols have been formulated that are centred on a profound understanding of the physiology of the host response to an acute threat to homeostasis; these protocols allow clinicians to use standardised measures and to speak a common language. They also reduce delays and expedite patient care, especially when clinicians are under pressure to make a critical decision. However, an understanding of the reasoning behind them remains crucial.

As in other acute conditions, the patient is particularly reliant upon the clinician when trauma occurs. A patient with a chronic condition is familiar with the nature of their problem and the way in which it is progressing. The surgeon may offer a remedy and the patient may consider the potential benefits and choose appropriately whether to accept the remedy. The injured patient does not know what will happen without treatment and so relies on the surgeon to inform them of both the natural history and the potential benefits of any intervention. The implication is that, as surgeons, we have a duty to be aware of both.

The significance of time in the outcome

Injuries can happen at lightning speed. Time point 0 (time 0) is defined as literally the seconds prior to the event, when the patient is at their normal baseline. All subsequent events, including the acute physiological response to injury, the body's internal mechanisms to maintain homeostasis (to compensate for the sequelae of trauma), the healing processes and the actions instigated by health professionals, are associated with a 'timeline'. This 'timeline principle' is crucial to a deeper understanding of how to prioritise assessment, investigation and treatment in what may be a rapidly evolving situation following injury. There is an optimal time window during which an intervention can have a radically positive effect on treatment outcome. Based on this timeline, interventions may be grossly categorised as emergent (life-saving), acute (restoring and maintaining physiological and physical stability) and delayed or semielective (focusing on the treatment of post-fracture fixation complications [non-union, infection and malunion from the orthopaedic trauma point of view]).

In the immediate aftermath of a major trauma, the physiological crisis continues to evolve, the risk of death is increased and less appropriate and prompt interventions are carried out. Potentially rapidly evolving situations, such as airway obstruction, tension haemothorax and haemopericardium, if left untreated, will inevitably have catastrophic consequences and therefore should be given priority in terms of the initial medical response to an injured patient. Thus, the seriousness and the immediate impact of a specific clinical condition should dictate its prioritisation, leading to a systematic approach ('what kills first should be managed first') (***Figure 26.2***).

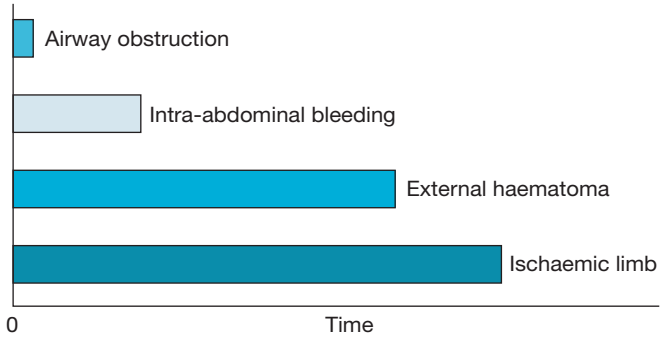

Figure 26.2 Estimated time from incident to death or irretrievable damage for various conditions.

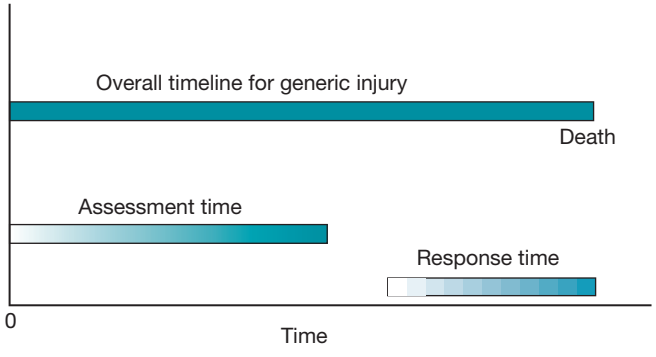

Figure 26.3 Diagrammatic representation of the relationship between assessment and response times. In this example, there is time to assess and respond effectively before death.

The Advanced Trauma Life Support (ATLS) system delineates an order of priorities defined by ABCD; that is, airway, breathing, circulation and disability (neurology). This hierarchy of priorities is based on the 'time dependence' principle. In other words, the time taken to manage an individual problem is the sum of the time taken to identify it and to execute effective treatment (***Figure 26.3***). In such settings, time is critical, so the normal history and physical investigations are not performed during the ATLS primary survey, but the primary focus is on detecting and identifying individual problems, ranking them in order of priority and dealing with them effectively and efficiently in their appropriate timeframes.

The clinician should take into consideration the mechanism of injury and initial clinical findings then promptly request and carry out specific investigations, for example computed tomography (CT) scans. This is to allow rapid and precise identification of injuries that may benefit from early therapeutic intervention and that otherwise might be clinically challenging as the initial signs may be subtle or non-specific. This proactive approach is critical, as the evaluation and diagnosis of an important injury may be difficult before the full-blown and potentially life-threatening presentation of that injury.

A typical example would be an RTA victim with a scalp laceration and a reduced Glasgow Coma Scale (GCS) score of 13/15; such a drop in the GCS could be explained by head

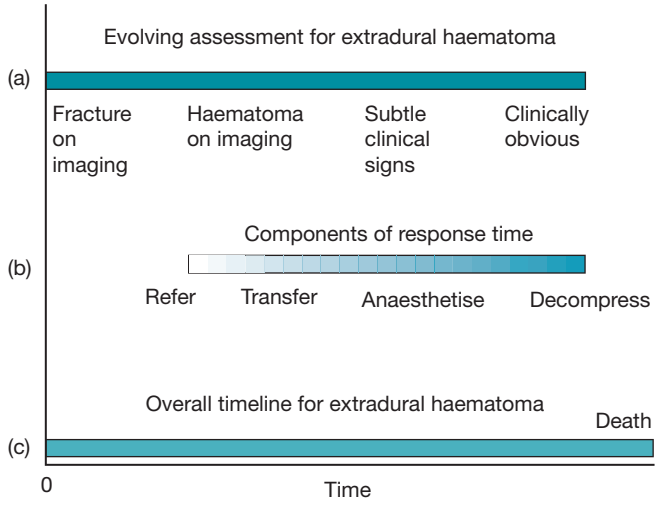

Figure 26.4 Diagrammatic representation of the relationship between assessment and response times for extradural haematoma: **(a)** the stages of assessment, **(b)** the components of the response and **(c)** the overall time from incident to death. It can be seen that relying on obvious clinical signs gives insufficient time to respond effectively.

injury or by the presence of shock and hypoxia. Waiting for the development of overt clinical signs could be dangerous. Should there be any injury such as an extradural haematoma this can be diagnosed with a head CT prior to the presentation of clinical signs. Prompt surgical decompression will result in a reduced risk of morbidity and mortality. In this situation, if the time taken to make the diagnosis were prolonged, such that the clinical signs presented prior to treatment intervention, it may be too late to prevent the death of the patient (***Figure 26.4***). This frequently encountered clinical case scenario demonstrates the principle that we need to introduce a management response even before we have made the definitive diagnosis if we want to save the patient's life. It is clear, therefore, that the 'timeline concept' is critical in the safe management of trauma patients.

Reducing the diagnosis time and response time of our interventions is dependent not only on clinical staff but also on the availability of resources. For the example above, a dedicated trauma team and a CT scanner should be available 24/7. Recently, this 24/7 availability of the trauma team and the designation of regional hospitals to operate as Level I Trauma Centres, with the availability of all disciplines and appropriate equipment on site, has provided the necessary foundation for the development of a unified trauma care system in England. Indeed, the first reports published on its effectiveness in saving lives have been very positive.

The 'timeline concept' that has been discussed in the management of patients with multiple trauma can be applied to patients with isolated injuries. Again, the key issue – irrespective of the number of injuries – is to minimise delays in making the diagnosis and promptly initiate treatment. Such a global approach would save lives, reduce morbidity and make the healthcare system more efficient in terms of resource utilisation, as well as cost-effectiveness.

Summary box 26.2

The importance of time

- A thorough understanding of the 'timeline concept' in trauma is critical
- Assessment should be completed within a set time
- The time to respond is limited
- The goal is for both assessment and response to take place in the time window prior to irreversible damage or death

Most importantly, dealing with a patient in an acute setting is a dynamic situation, which may fluctuate unpredictably along the timeline. Therefore, any observation and analysis may evolve rapidly to an extent that interventions need to be modified accordingly. Thus, ongoing patient evaluation is essential in order to identify and respond to every fluctuation noted in a timely fashion. The initial primary survey, applied according to the ATLS protocol in trauma patients, should be followed by secondary and tertiary clinical assessment, even after the acute phase of treatment has been completed successfully. Ongoing monitoring of vital organ activity, ordering of the necessary biochemical and radiological investigations and recording of all the findings in a single place can allow easier evaluation and identification of trends over time to facilitate prompt intervention. Such a strategy may reduce the risk of having undiagnosed injuries and delays in a patient's treatment. Several studies have been published that report on missed injuries and make some recommendations on how to avoid these.

The timeline following an injury is continuous, and the accumulated documentation may become voluminous, complex and confusing. It is helpful periodically to make the effort to stand back and summarise the situation. In its recent trauma guidelines, NICE refers to this and advises that a plain language summary of the situation directed at the patient's family doctor, but intelligible and available to the patient or carers, should be produced within 24 hours.

ASSESSMENT AND RESPONSE

The assessment of trauma

Traditionally, and especially when learning the theory of the various component parts of the assessment of the injured patient, this is done in a sequential linear fashion. However, when dealing with a severely injured patient in practice, time is of the essence and when resources allow several things may be happening simultaneously – this is so-called horizontal management; while there may be a number of practical activities occurring simultaneously, the coordination, assessment and control of the situation remains as a mental exercise for the 'hands-off' team leader. In particular, acquiring very early definitive diagnoses with CT is increasingly important. To provide such a level of care generally needs a systematic approach to concentrating resources and to preferably bringing the severely injured patient to that resource – a major trauma system.

The objective of assessment of a trauma patient is to form the best understanding possible of the injuries sustained and their consequences. Forming that whole picture is a challenging process. The clinician must make the best use of what they know of the mechanism of injury, pre-existing patient factors and the injuries already found. Synthesising the associations of these three factors will help direct attention to finding other less obvious problems. Sometimes, the pieces of the puzzle do not 'add up'; at that point, the clinician should attempt to think 'outside of the box' as there may be something unexpected, such as an unknown underlying pathology leading to a pathological fracture, or deliberately concealed, such as in NAI.

For instance, a 50-year-old male restrained passenger in a car involved in a head-on collision with another vehicle may sustain rib fractures, a sternal fracture and a thoracic spine fracture but there may also be cardiac contusion and abdominal injuries. Very early CT and echocardiography may decrease the need for clinical acumen, but in many centres it is not available. The clinician then needs to use their knowledge of the mechanism of injury and the obvious rib and sternal fractures to direct their attention to excluding the less obvious but potentially life-threatening abdominal or cardiac injuries. Similarly, when sophisticated investigations and techniques are available, the clinician should not be over-reliant on them and neglect the important logical thought processes required to piece together the information that is available. It remains of value to consider how a clinician can make best use of the available information for the benefit of the patient.

Summary box 26.3

The assessment of trauma

- Appreciate the factors in the relationship: mechanism + patient factors = injuries sustained
- Use this to allow obvious features to lead to the discovery of less obvious injuries
- When the features do not appear to 'add up' this should be an alert for the clinician to think 'outside the box' and connect the dots

Mechanisms

Mechanisms may be broadly classified as blunt, penetrating or even of a combined nature. ***Table 26.1*** shows examples of how knowledge of the mechanism may help detect more covert injuries. Early definitive imaging may be thought to reduce the need for such considerations, but the clinician can help the radiologist by directing their attention to potential diagnoses. The adage that 'unless you are very fortunate you only find what you look for' is apt. The most common mechanism involves blunt trauma, which may be either direct or indirect. In a direct mechanism, the damage is localised to the initial site of that mechanism. In contrast, in an indirect mechanism the damage occurs at a distant site after transmission of the force exerted. For example, a direct kick to the medial aspect of the mid-shaft of the tibia in a footballer by an opponent may induce an isolated transverse tibial fracture. There will be localised bruising and ecchymosis where the force was applied.

Figure 26.5 The injury force in a car accident can be transmitted from the dashboard to the knee and then to the hip, which is the site of injury.

On the other hand, a fall from a height of 1 metre with a twisting moment as the foot hits the ground can lead to a spiral fracture of the distal tibia. In this situation the force is transmitted through the body's tissues to a location some distance away from its original point of application. In this case, other injuries may have occurred along that line of transmission and should also be sought, such as a remote fibular fracture. Similarly, a motor vehicle crash associated with a point of impact of the knee joint of the driver on the dashboard of the car could induce a fracture dislocation of the acetabulum and hip joint (transmission of force from the knee joint to the hip socket – an indirect blunt mechanism) (***Figure 26.5***).

TABLE 26.1 Examples of patterns of injury.

Mechanism	Obvious features	Covert injuries
Left-sided impact from road traffic accident	• Lateral compression of the pelvis • Left-sided pneumothorax	• Splenic rupture • Extradural haematoma
Flexion distraction (lap belt)	• Chance fracture of the lumbar spine • Dislocated knee • Head injury	• Duodenal rupture • Popliteal artery disruption • Cervical spine fracture
Electrocution	Burn on hand and collapse	Posterior dislocation of the shoulder
Dashboard impact	Knee wound	Posterior dislocation of the hip

The 'timeline concept' previously discussed should not be taken to imply that every injury needs urgent treatment or that every injury of a similar type is of equal urgency. For instance, a tibial fracture that a footballer has sustained may be treated satisfactorily for some time after the moment of injury but, in

contrast, a fracture of the acetabulum with a hip dislocation (as described above) represents an emergency owing to the potential development of neurovascular complications (damage to the sciatic nerve; avascular necrosis of the femoral head). Therefore, the clinician's decision-making process should be informed by the peculiarities of the type of injury sustained and the anatomical location involved.

Moreover, it should be appreciated that the conduction of energy in an indirect mechanism, which is transferred via the soft tissues or fluid, can be difficult both to understand and to diagnose (accurately and promptly). For example, the rise in pressure secondary to a lower abdominal force could be passed to the vascular tree (aorta), leading to unexpected haemorrhage and death. Therefore, one can argue that the effects of direct mechanisms are easier to comprehend than those of indirect ones.

Penetrating injuries are caused either by sharp objects or by firearms (see ***Chapter 34***). When dealing with sharp objects, it is necessary to take into account their length, surface area and the size of the entry point. For example, a pair of scissors will cause damage to the underlying tissues that they contact (skin, subcutaneous fat, fascia, etc.). Local examination will confirm the extent of the injury and the need for wound exploration. It is critical to be familiar with the relevant anatomy of the area involved to accurately assess peripheral nerve function and tendon and muscle integrity. Here again the 'timeline concept' of prompt assessment and response (treatment) can be crucial in cases where there is vascular injury, a compartment syndrome due to internal bleeding or even joint penetration that could lead to septic arthritis. Knowledge of the anatomical structures at risk is essential to making the right decision in a timely fashion. This is particularly critical for penetrating wounds over the torso (see ***Chapter 29***) because it is not always easy to establish the track that the sharp object has followed. In this context, it should not be forgotten that the abdominal structures extend higher than anticipated, and as high as the level of the fifth rib in expiration.

Summary box 26.4

Sharp object injuries

- Length of the sharp object involved is important
- Familiarity with local anatomy is essential
- Crucial point: abdominal structures at risk of injury extend high into the chest

Penetrating injuries caused by firearms are more difficult to understand than incisional injuries caused by sharp objects. A low-velocity projectile may cause similar injuries to a knife, whereas a high-velocity projectile (bullet) causes extensive damage to the tissues as it travels, inducing lateral acceleration far from the point of impact and producing either a permanent or a temporary cavity (see ***Chapter 34***). The importance of the temporary cavity is that it lasts for only milliseconds and is usually not evident during the clinical examination. It is important to be aware that this temporary cavity usually extends far from the boundaries of the apparent injury and there may be ingress of foreign material. Awareness of this phenomenon will ensure that the surgeon carries out sufficient exploration and wound excision.

Summary box 26.5

Firearm injuries

- Passage of high-velocity bullets induces permanent and temporary cavitation
- Temporary cavitation can contain foreign material, but disappears after a few seconds and is less evident to the clinician
- Low-velocity bullets induce similar damage to knives

Patient factors

Every patient is different: each possesses a unique profile and medical history and so will respond differently to a given traumatic incident. Of note, age plays an important role in this regard. Children and adults of different ages will sustain different injuries as a result of the same mechanism. For instance, a car hitting a pedestrian will induce different injuries in an adult from those in a child (***Figure 26.6***). It is important to consider the other aspects of the patient's history: past medical history, medication and allergy risk will direct not only the clinical assessment but also the treatment.

Obvious injuries

Some injuries are very obvious and can be identified before details of the mechanism or patient are known. One can take advantage of this, as the presence of an obvious injury can inform and lead to the identification of another that is less obvious. Obvious injuries are usually visible externally. It is therefore unsurprising that at the end of the ABCD protocol there is also an E, referring to exposure and the need to look for other signs of injury. Bruising to the scrotum of a motorcyclist following a collision with a car suggests a pelvic fracture. Contusion over the greater trochanter of the proximal femur in an older patient experiencing difficulty with straight leg raise points to a fracture of the neck of the femur. Finger-shaped bruises on a child's arms or thighs suggest NAI. The presence of a seat belt mark on the lower abdomen of a patient involved in a car crash and who has substantial abdominal pain points to damage inside the abdomen. Thus, exposure of the trauma patient should be routine practice in order to avoid missing the 'obvious'.

Hidden factors

Mechanisms

Sometimes, the formula 'mechanism + patient = injury' does not seem to 'add up'. If this is the case, the clinician should look further as hidden information may be contained in the mechanism. Occasionally, there is a deliberate attempt to misinform. While the majority of alert and orientated patients tell the truth, other patients, in order to protect themselves or others, may fabricate a mechanism. This may mislead the clinician and guide them to look for the wrong pattern of injuries. For instance, a patient in their twenties with a calcaneal fracture

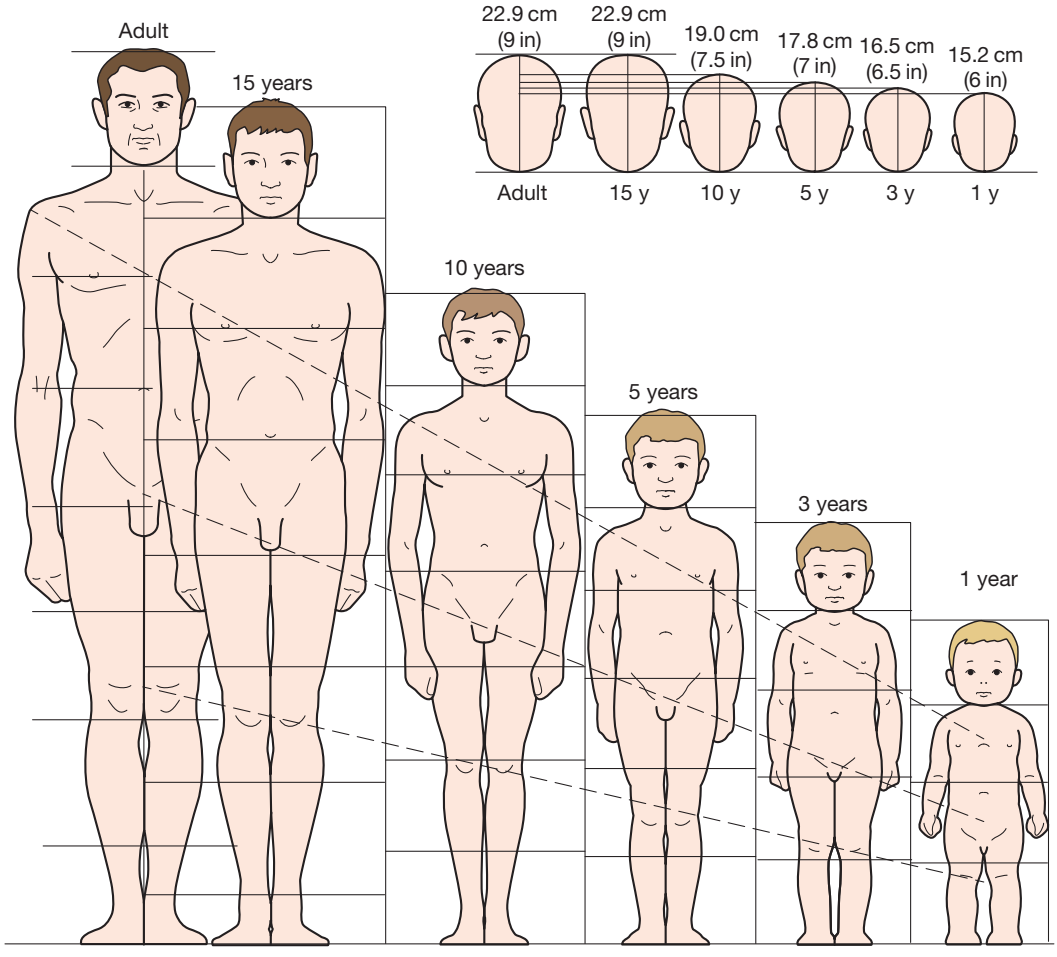

Figure 26.6 Body proportions at various ages and the anatomical location of injuries when hit by a car.

may report that this was the result of a fall into a pothole in the road, when in fact it had occurred during a burglary following a fall from a height of 10 metres. This can delay the accurate diagnosis of the specific injury and may prevent the diagnosis of other important injuries, such as a lumbar spine fracture. Although the patient should be given the chance to tell their story, it should not always be believed, particularly if there are inconsistencies.

A similar situation may arise when a patient is unable to give their history of events, for instance patients who are unconscious. In this scenario, the mechanism of injury is missing. The physically and mentally vulnerable include older patients, perhaps with dementia, and very young children. The difficulty or inability to report the injury is compounded by the fact that it might relate to criminal activity (e.g. NAI). Parameters that should alert the clinician and raise suspicion of NAI include:

- external signs of injuries not consistent with the mechanism reported;
- long bone fractures in a preambulatory child;
- inconsistent or changing history;
- aggressive or unusual behaviour of carers at interview;
- posterior rib injuries.

Summary box 26.6

Hidden mechanisms

- The vast majority of conscious patients will tell the truth
- Patients involved in criminal activity may not tell the truth
- Fear of abuse may prevent vulnerable patients from telling the truth
- Clinicians have the responsibility to take action when NAI is suspected

It is absolutely paramount to make a rapid diagnosis and treat the injuries, but most importantly to protect the patient from further harm, particularly vulnerable individuals (children and older adults). An early sign of abuse that is neglected may lead to further episodes and the potential of serious harm. For these reasons, procedures are usually in place and can be followed by passing on the problem to the appropriate team and professionals (see ***Chapter 44***).

Another important issue is the fact that any obvious injuries may provide important evidence regarding the mechanism, which may be important to a criminal investigation. The clinician must endeavour, without compromising treatment, not

to affect such evidence by their medical actions and bear in mind that forensic evidence may be needed for a conviction at a later stage. Furthermore, the importance of this is made more apparent if we consider that the victim of an attack may subsequently be a murder victim.

Patients

Apart from the deliberate circumstances outlined above, where the injury and mechanism are inconsistent, the clinician should consider the possibility that the patient may have an unknown pre-existing condition. For example, when a fracture occurs following what seems to have been an insufficient mechanism, the clinician should suspect that the bone was already susceptible to fracture. Such pathological fractures may be secondary to underlying problems such as metastatic or primary tumour, osteoporosis or congenital disease. One example is the preambulatory child with multiple fractures secondary to osteogenesis imperfecta, which may mimic NAI. Failure to identify a pathological fracture through a primary tumour will lead to inappropriate initial management compromising appropriate cancer treatment. An initial osteoporotic or herald fracture should signal the need for appropriate investigation and, potentially, treatment to prevent further or secondary fractures. Similarly, fractures may be secondary to an undiagnosed or poorly controlled medical condition. For example, a patient presenting with a scalp laceration and a wrist fracture may have fallen as a result of a transient ischaemic attack (a hidden patient factor). In this situation, it is essential to include a medical secondary survey to identify the real cause of the injuries sustained and prevent further trauma.

Injuries

When analysis of the formula 'mechanism + patient = injury' has failed to identify hidden injury, there are two other approaches:

1. the look everywhere approach;
2. the focused exclusion approach.

Look everywhere approach. This represents the secondary and tertiary elements of the ATLS system and involves a detailed secondary survey, from top to bottom and at different time points: soon after the initial treatment phase when measures relating to saving the patient's life have been completed, the day after injury, e.g. during a ward round, or several days after injury, e.g. when the patient first wakes up in the intensive care unit (ICU). The implementation of whole-body CT (WBCT) (scanning the whole body) in all major trauma centres has allowed the clinical team to pick up injuries early. Such injuries would have been missed in the past when reliance was placed on the initial radiographs of the chest, pelvis and cervical spine. The threshold for using more WBCT has been lowered substantially. There is no doubt that WBCT scan algorithms have been shown to accelerate diagnostic work-up, but their effect on survival is controversial. Moreover, concerns have been voiced about the overexposure of patients to radiation with the increasing and often uncritical use of this type of scan. The effective radiation dose to all organs from a single full-body CT is 12–16 millisieverts (mSv). Survivors of the atomic bomb whose radiation dose was in the range 5–100 mSv had a statistically significant increase in the risk of solid cancers. Overall, the risks associated with one scan are relatively modest, approximately 1 in 1250 or 0.08%. However, it has been reported that widespread liberal use of CT is responsible for 1.5–2.0% of all cancers in the USA. Of interest, WBCT equates to 76 chest radiographs or 6 months of background radiation. It has been suggested that it should be requested wisely and that developing a triaging protocol can minimise the criticism of its overuse.

Focused exclusion approach. This is based on the knowledge that some specific injuries are missed on a remarkably regular basis. Such injury patterns include metatarsal and metacarpal fractures, scaphoid fractures, perilunate dislocations and posterior shoulder dislocations. When such injuries are suspected, a detailed focused history, clinical examination and appropriate investigations should be carried out to either confirm or exclude them. A high level of alertness and a high index of suspicion are always required to think beyond the obvious.

Summary box 26.7

Trauma assessment

- Knowledge of timelines for important diagnoses is essential
- Initial assessment should focus on what kills first
- Screen high-risk patients before clinical signs become apparent, as it may be too late to intervene once signs develop

THE RESPONSE TO TRAUMA

Completion of the initial patient evaluation according to the formula (patient + mechanism = injury) should provide the necessary information to formulate and implement a 'response' (treatment). During this stage of management, the response to injury will continue to evolve and decompensation may occur unexpectedly. Vigilance is required throughout treatment to identify the potential exhaustion of biological reserve mechanisms.

The patient's response to injury

Immediately after the traumatic event, physiological reactions are initiated as part of the body's homeostasis mechanisms to preserve vital organ functions and to maintain survival. Initial responses represented by the so-called acute-phase response may be altered as the insult of injury evolves and deterioration of the patient's condition may occur.

It is essential therefore that the timing and nature of interventions should be altered accordingly. Reversal of haemodynamic instability due to ongoing bleeding must be carried out promptly in order to avoid the development of coagulopathy and secondary damage to vital organs (i.e. the brain) due to hypoxia. It is important to monitor the patient's physiological state, including body temperature, degree of oxygenation and organ perfusion. Low body temperature is commonly present

as a result of exposure, blood loss and dormancy. Covering the patient with appropriate blankets during transportation, resuscitation and surgery will reduce the risk of hypothermia, coagulation disturbances and ongoing bleeding. Administration of inspired oxygen or ventilation, if required, will improve the patient's degree of oxygenation.

Ongoing blood loss is associated with low blood pressure, reduced perfusion of the extremities (skin discoloration), tachycardia and an altered level of consciousness. Normally, vasoconstriction and endogenous clotting factors are activated to stop the bleeding in order to maintain adequate circulatory volume. A further consideration is that traumatised lung parenchyma cannot tolerate surplus fluid. Therefore, the latest resuscitation guidelines advocate a reduction in crystalloid administration and the early transfusion of blood products. Furthermore, there is a need to quickly identify the source of bleeding and stop loss of blood.

Another important part of the response to injury is activation of the immune–inflammatory system. Acute-phase mediators are released systemically, stimulating polymorphonuclear leukocytes to interact with the endothelium via the expression of surface receptors (integrins). If certain conditions are met extravasation of leukocytes may take place, particularly into the lung parenchyma, causing autodestruction. Clinical decisions should aim to minimise the risk of an exaggerated immune–inflammatory reaction. Surgical procedures, which can act as a second insult, where injury is considered the first, should be carefully timed and selected.

The medical response to injury

Initial management

After initial assessment of the patient's condition at the scene of an accident, paramedics communicate with the nearest hospital, triggering activation of 'the trauma team on call' and allowing personnel to expect the patient's arrival in the resuscitation room. The team leader, according to the ATLS protocol, will assign trained nurses and doctors to specific duties. Protective clothing, such as gloves and lead aprons, is required to protect the personnel from fluids and radiation exposure. Optimum coordination of the trauma team throughout the resuscitation process is essential to avoid careless delays, which may compromise the response time and the patient's condition. Timely involvement of different disciplines in assessing and planning treatment of injuries in different body areas is crucial and may lead to issues around priority in terms of planning and interventions. This situation could lead to confusion and uncertainty: 'Who should go first?' or 'What investigation should be next?' It is the role of the team leader to ensure that this is avoided and that decisions which may be critical for the patient's well-being are executed smoothly.

In situations where the system operates according to locally developed protocols, someone should have the responsibility of overruling the protocol if this is in the best interests of the patient, in order to keep the process moving along.

Following common pathways to manage patients can save time and reduce errors. In this respect the development of the NICE guidelines for the initial assessment and treatment of patients with major trauma can be useful. In addition, short standards documents, such as BOAST (British Orthopaedic Association Standards for Trauma), can be downloaded and printed for display in hospitals and so can support planning and decision making.

The development of local protocols, NICE guidelines and BOAST documents has contributed to the establishment of specific treatment pathways and to improved patient care and outcomes. Nonetheless, caution should prevail as, once a diagnosis (label) has been made, the pathway is set and it may not be in the patient's best interests if the diagnosis is misleading and troublesome. For instance, an older male patient fell in his garden and sustained a wrist fracture. He was given the label of 'accidental fall and wrist fracture', placed in a plaster of Paris back slab and arrangements were made for him to be admitted for fracture stabilisation. However, this patient had a number of medical comorbidities (heart failure, epilepsy, previous myocardial infarction and high blood pressure). Consequently, the label given as 'accidental fall and wrist fracture' may be associated with more severe underlying pathology and injuries. The wrong label may disguise the seriousness of the injuries sustained and the patient's condition may rapidly deteriorate, putting their life at risk. Thus, the first clinician in the diagnostic chain has disproportionate responsibility. Early inappropriate assessment and incorrect labelling could place the patient on the wrong treatment care pathway. This can be avoided by conducting appropriate physiological triage with senior input.

Beyond the first hour

The objective of the first (golden) hour is to reach the end points of resuscitation and completion of the diagnostic procedures identifying the injuries sustained. However, in polytraumatised patients, further interventions are necessary. For example, a spleen laceration, a lung contusion, a vertical shear pelvic fracture, an open right tibial fracture, a left femoral fracture or a distal humerus fracture are injuries necessitating treatment. The spleen laceration may be managed non-operatively or with embolisation, depending on its severity. The timing and priority of fixation of the other skeletal injuries and the type of fixation have been points of much discussion during the past decade.

Two treatment strategies have prevailed: early total care (ETC) and damage control orthopaedic (DCO) surgery. Since the late 1990s the ETC approach (fix all fractures early within 24 hours) revolutionised the management of patients with multiple injuries. This practice became the gold standard of treatment for polytrauma patients. Nonetheless, in specific groups of patients, for example those with severe chest and/or head injuries or those in an extreme physiological state (with ongoing bleeding from different sources such as the abdomen, pelvis and chest), it was observed that the ETC concept led to early complications and mortality.

With the advances made in the fields of molecular medicine, biology, intensive care and immunology the physiological response to injury was better understood. It was appreciated that the trauma sustained at the scene of an accident (first hit) induces an immune–inflammatory reaction that evolves with time and can prime the patient to reach an uncontrolled physiological state. Subsequently, surgical interventions can

induce an additional physiological stress (second hit) response, exhausting the biological reserve of the patient and leading to the development of adult respiratory distress syndrome (ARDS), multiple organ dysfunction syndrome (MODS) and mortality. These observations led to the acceptance of the so-called DCO philosophy, which is also called damage control surgery (DCS) in more generalised settings (see later chapters). The stages of DCO are:

- resuscitation;
- haemorrhage control;
- decompression;
- decontamination;
- fracture splintage.

Application of the DCO concept includes temporary stabilisation of long bone fractures and pelvis with external fixators. This approach allows rapid procedures to stabilise the affected bones as part of the resuscitation process. Definitive fixation of the fractures (conversion of the external fixators to intramedullary nailing for the femur and plating of the pelvis) would usually take place 4 days later, when the physiological state of the patient has been normalised, or even later if necessary. The two strategies of fracture fixation – the ETC and DCS – are currently practised on the basis of some specific criteria. The vast majority of polytrauma patients are suitable for ETC (80–90%). Specific criteria are shown in ***Table 26.2***.

TABLE 26.2 Criteria for damage control surgery (DCS) and early total care (ETC).

Criteria for DCS	Criteria for ETC
Hypothermia: <34°C	Stable haemodynamics
Acidosis: pH <7.2	No need for vasoactive/ inotropic stimulation
Serum lactate >5 mmol/L	No hypoxaemia, no hypercapnia
Coagulopathy	Serum lactate <2 mmol/L
Blood pressure <70 mmHg	Normal coagulation
Transfusion approaching 15 units	Normothermia
Injury severity score >36	Urinary output >1 mL/kg/h

Lately, other fixation strategies that have been proposed include the Early Appropriate Care, Safe Definitive Surgery and Prompt Individualised Safe Management (PRISM) concepts. The PRISM concept accepts that the decision-making process should be based on the principles of doing no 'further harm to the patient', intervening promptly and utilising the idea of individualised/personalised medicine. It is based on the understanding that every patient responds differently to the same degree of trauma, every individual has a different genetic profile and the fact that each trauma centre may have different resources and staff available to deal successfully with every trauma eventuality.

Irrespective of the treatment strategy selected, it is imperative to be aware that the patient's condition can change and deteriorate quickly. In particular, patients with a high ISS are at risk of decompensating rapidly. Therefore, ongoing evaluation of a patient's physiology is essential, with senior input involvement in order to deal successfully with the unexpected.

Overall, a plan should always be made available to the trauma team to inform them about the details of treatment, particularly in the operating theatre environment. The plan can be recorded on a whiteboard with clear guidance on the alternative pathway to be implemented should the patient's condition deteriorate. Ongoing monitoring of such parameters as core temperature, lactate, base excess and coagulation will provide knowledge of the patient's condition at any time point during care. Appropriate decisions can then be taken to ensure that the safety of the patient has not been compromised. For instance, if the ETC concept has been applied and a polytrauma patient with a head injury and chest trauma is on the operating table waiting to have a femoral fracture stabilised with intramedullary nailing and their condition deteriorates, the ETC plan can be changed to DCO (an external fixator can be applied quickly to stabilise the femoral fracture temporarily). This allows prompt transfer of the patient to the ICU, where resuscitation can continue within a safe environment with ongoing monitoring of vital organ function (lungs and brain).

When injuries involve the input of different disciplines in terms of surgical intervention, for instance a general surgeon for a liver laceration, a neurosurgeon for an intracranial haematoma, an orthopaedic surgeon for a pelvic and femoral fracture and a maxillofacial surgeon for a depressed orbital fracture, the most important intervention should go first. Clearly, communication and prioritisation among the team members is essential. As each procedure nears completion, communication with the anaesthetist will allow a decision as to whether it is safe to go on to the next procedure. Not infrequently, and assuming that it is technically possible, two teams can work simultaneously to significantly shorten the time the patient will spend in the operating theatre and allow subsequent prompt transfer to the ICU for optimisation and ongoing monitoring.

LOCAL PROTOCOLS AND GUIDELINES

While the ATLS protocol has become the standard of care for the initial management of patients with multiple injuries, other protocols and guidelines have also been developed to facilitate the treatment of patients in a more standardised way. Nowadays it is common practice for trauma centres to develop their own local protocols and guidelines, although national guidelines may also exist. However, regional developed guidelines may refer to smaller areas of clinical practice, such as antibiotic prophylaxis for open fractures, mass transfusion, pharmacotherapy for coagulation disturbances, steroids for spinal cord injuries, clearance of the cervical spine and angiographic embolisation of pelvic fractures or abdominal injuries. These protocols can facilitate swifter decision making, eliminating delays and benefiting the patient. They also protect the clinician and care provider with regard to medicolegal issues. An example relating to angiographic embolisation of pelvic fractures is shown in ***Figure 26.7***.

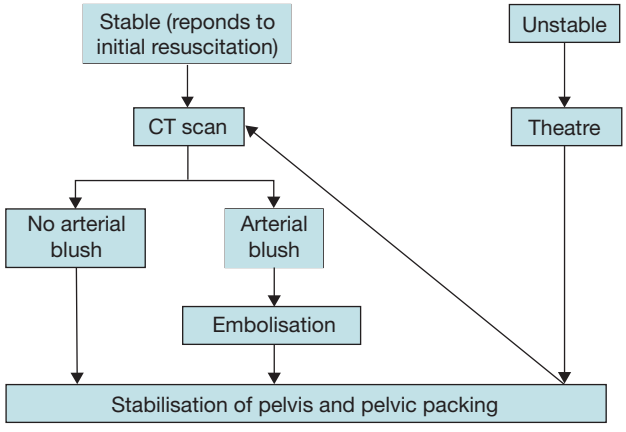

Figure 26.7 Pelvic fracture: angiography protocol. CT, computed tomography.

Local policies focusing on the creation of single charts facilitating daily input of a patient's vital signs and biochemical results are also useful in allowing sequential observation of the results, which can demonstrate important trends. These trends can be useful in identifying, at an early stage, a clinical condition that can be treated within the timeline concept and prior to irreversible damage to the affected organ, at which point any form of intervention will be meaningless. For instance, the clinical evolution of respiratory insufficiency in an individual without pre-existing lung disease secondary to pulmonary embolism is easier to identify by evaluating the trend in the oxygen saturation of inspired oxygen.

Planning an individual operation

Operative procedures in a multiply injured patient in a critical physiological state can be essential for their survival. It is vital to make the right decision the first time. This can be successfully done by studying in detail the history, the patient's condition and any interventions made, followed by appropriate planning and execution of treatment. For example, analysing the biochemical markers, overall physiological state and fracture pattern and deciding factors such as patient positioning, the surgical approach to be used to gain adequate access to a bone for reduction, the type of implant to be used, the correct positioning of the implant, soft-tissue handling and the type of rehabilitation are just some of the parameters for consideration.

Summary box 26.8

The response to trauma

- Rationalise patient management with the development of protocols and guidelines
- Avoid unnecessary delays
- Observe trends and promptly identify evolving conditions

The surgeon should ask themselves (and ensure that they have answered) questions such as: Is it the optimum time to carry out the procedure? Am I the most appropriate person to carry out the procedure? Have I made a contingency plan should the procedure become difficult to complete? What is my plan A, B and C so I am able to successfully finish the procedure? Recording all the important issues on a piece of paper, or suitable alternative, will ensure that no parameter of importance is left out of the planning. In order that the procedure runs smoothly in theatre, the plan can be documented on the whiteboard. Such a practice will allow every member of the surgical team to be aware of the potential issues to be addressed and the plan of action that has been decided. The appropriate surgical equipment for plans A, B and C can be clearly identified and kept in close proximity to the operating theatre. The above strategy will eliminate unnecessary detail and ensure that there will be no surprises, for instance essential equipment being unavailable.

The response to the mechanism of injury (injury prevention)

Not infrequently, two or more patients are seen who have been injured in the same geographical area by the same mechanism. A possible scenario is that, over a period of a few weeks, several patients are noted to present with a fall of 2–3 metres in the same location, for example from a particular bridge. Further investigation might establish that the bridge is easy to access, perhaps because of damage to safety measures. With appropriate steps the damage can be rectified and access to the bridge limited, preventing further harm. In this example, the surgeon is involved in both the treatment and the prevention of injury. Therefore, when a mechanism of injury becomes more frequent and is associated with serious life-threatening trauma, it is essential to take steps either to eliminate the mechanism or to lessen the consequences.

Summary box 26.9

Planning an individual operation

- Adequate preoperative planning is essential to eliminate unnecessary delays
- Document the plan to ensure no important parameter is left out
- A whiteboard can be used to demonstrate the order of plan execution and to act as a means of communication among staff

The issue of injury prevention is an important consideration not only for clinicians but also for other stakeholders, for example politicians (developing appropriate legislation relevant to road safety), manufacturers (optimising the safety of cars) and the construction industry. This accounts for the improvements in safety that can be achieved.

The response to patient factors

Injuries presenting with increased frequency in an individual patient require special attention. Older patients, perhaps with multiple medical problems, can represent such a vulnerable group. The reduced bone mineral density making their

Summary box 26.10

Response to the mechanism of injury

- Be alert to identifying frequent patterns of injury
- Many stakeholders, including clinicians, should engage in injury prevention
- Legislation and education are essential

skeletons 'fragile' is associated with an increased risk of fracture. Hip fractures, wrist fractures, spinal fractures and pelvic fractures are just some of the many results following minimal trauma. The risk of fracture is increased with the presence of comorbidities such as visual impairment, Parkinsonism or transient ischaemic heart attacks. Consequently, knowing the parameters associated with a particular group of patients, attempts can be made to reduce the number of patients requiring treatment. For instance, prescription of bone protection therapy and addressing medical comorbidities early (e.g. cataract surgery) may help to reduce the number and severity of injuries sustained. Development of specific guidelines and protocols can facilitate the much-needed implementation of unified measures allowing easy patient access and treatment.

Summary box 26.11

Response to patient factors

- Older patients may be vulnerable to injury, owing to poor bone stock and other comorbidities
- Bone protection treatment is essential
- Development of local and national guidelines to respond to patient factors is desirable

CONCLUSION

Trauma can affect all patient age groups. The severity of injury depends on the type and nature of the mechanical force applied. The formula 'patient + mechanism = injury' should be kept in mind when dealing with trauma patients. There is a connection among the three components of the formula, all of which should fit together in a coherent way. When no relationship can be made, examine for pre-existing pathology and hidden injuries or consider whether the history given by the patient is at fault (including deliberate attempts to mislead).

Be aware of the timeline concept because there is a minimum response time to initiate and complete treatment in order to deal with a specific condition successfully.

In patients with multiple injuries early assessment and management is performed using the ATLS protocol and other guidelines developed either locally or at a national level. In the early clinical pathway of the patient the objective is to restore haemodynamic stability (save life – prevent uncontrollable bleeding and death) and minimise the risk of developing subsequent complications. Surgical interventions should be short and part of the resuscitation process, executed in a timely manner. Afterwards, treatment for definitive stabilisation can be personalised for optimum outcomes. Existing specific criteria can aid the clinician to make the right decision for the right patient at the right time. Different groups of patients, such as older patients and children, have different demands and should be managed accordingly. While clinicians are focused on treating the injury sustained, they have other responsibilities, including active involvement in preventive measures. Preventive measures should be commissioned when particular mechanisms can be identified as being common or important causes of injury.

Summary box 26.12

Conclusion

- Look for hidden injuries
- Remember the timeline concept
- Different treatment strategies exist, complementing each other
- Specific criteria will decide the fixation strategy: ETC or DCO

PART 4 | Trauma

CHAPTER 27

Early assessment and management of severe trauma

Learning objectives

- How to identify and assess the severely injured patient
- Early treatment goals for multiply injured patients
- Understand the role of permissive hypotension, tranexamic acid and massive transfusion protocols
- Understand the principles of damage control surgery (DCS) versus early total care (ETC)

IDENTIFICATION OF SEVERE TRAUMA

The severely injured patient, with multiple injuries to different body systems, poses unique diagnostic and treatment challenges. The early assessment and management of severe trauma begins in the prehospital environment. Many of these patients will be easily identified at the scene of injury. Forewarning the receiving hospital allows the activation of the trauma team to prepare for the patient's arrival. Key information in the pre-alert includes basic demographic information (age and gender), mechanism of injury, injuries identified and vital signs, including respiratory rate, pulse, blood pressure and Glasgow Coma Scale (GCS).

Patients who are identified before reaching hospital as having sustained, or are at high risk of sustaining, severe multisystem trauma should generate trauma team activation in the receiving hospital. It should be noted that not all patients with severe multisystem trauma are immediately obvious. An older adult patient falling down a few steps can easily sustain a hip fracture, multiple rib fractures and a small subdural haemorrhage. At first glance the patient can appear well, but their injury severity score (ISS) and potential mortality could easily exceed those of a younger patient with multiple open long bone fractures. Both patients are critically injured and should be managed with the same principles in mind.

ROLE OF THE TRAUMA TEAM

All hospitals managing severe trauma should have a dedicated trauma team that is available immediately to attend and manage patients presenting with severe trauma. The composition of the team will depend on local policies but it will invariably involve doctors from the emergency department, anaesthetics and/or critical care, trauma and orthopaedics and general surgery. Increasingly, radiology and haematology doctors are contributing to the trauma team, as part of the patient's initial assessment and management. Hospitals managing large volumes of cases of severe multisystem trauma are recognising the need for an enhanced trauma team activation for the most severely injured patients – the so-called 'code red trauma call'. Patients identified before reaching hospital as being haemodynamically unstable or having acute airway compromise may initiate 'code red', triggering the automatic attendance of the most senior clinicians from each discipline prior to the patient's arrival and prehospital activation of massive transfusion protocols.

The role of the trauma team is to apply the principles of Advanced Trauma Life Support (ATLS) to rapidly identify and treat life-threatening injuries during the primary survey. The principal advantage of a trauma team is that this activity can occur concurrently instead of sequentially; while the anaesthetist is assessing and managing the patient's airway, another team member can be assessing and managing the patient's breathing, etc. The importance of the trauma team leader cannot be overemphasised: they brief and prepare the team, coordinate these sequential activities, manage time, interpret findings and plan the next move. Increasing recognition of the importance of this role has led to the development of postgraduate training courses designed to teach both the technical and non-technical skills required. Generally, the trauma team leader and most senior clinicians should be standing back from the patient, looking at the bigger picture, in order to anticipate the next key decisions.

Summary box 27.1

The role of the trauma team

- Allows the simultaneous and efficient application of ATLS principles to rapidly identify and treat life-threatening pathologies
- Should be led by the most senior clinician
- The most senior clinicians from each specialty should attend 'code red trauma calls'
- The team leader should be constantly trying to anticipate the next move

PRIMARY SURVEY

The primary survey aims to identify and manage the most immediately life-threatening pathologies first and follows cABCDE.

c: Exsanguinating external haemorrhage

Experience from war zones over the past 20 years has shown that exsanguinating external haemorrhage from massive arterial bleeding needs to be controlled even before the airway is managed (see ***Chapter 34***). Most of these injuries are due to gunshot wounds or blasts and are mainly seen in military practice. However, they are also encountered in civilian practice. Bleeding must be controlled immediately by the application of packs and pressure directly onto the bleeding wound and proximal artery. Haemostatic dressings that contain agents that augment local coagulation are now available. Failure to control bleeding in the limb by direct pressure with surgical dressings should be followed by the application of a tourniquet proximal to the wound. In the field, simple tourniquets can be improvised if pneumatic tourniquets are not available. It is vital to appreciate that once a tourniquet is applied the limb becomes ischaemic; therefore, the length of time for which the tourniquet is applied must be recorded on the patient and the patient requires urgent surgical control of the bleeding in order to reperfuse the limb.

A: Airway with cervical spine control

All trauma patients should have their cervical spine immobilised and protected throughout. An immediate assessment of the patient's airway is made. A compromised airway requires a stepwise progression, first clearing the airway by suctioning secretions or blood, followed by simple airway manoeuvres such as a jaw thrust, chin lift and insertion of an oropharyngeal or nasopharyngeal airway. Advanced airway manoeuvres necessitate the insertion of a cuffed endotracheal tube. This may require an anaesthetic with rapid sequence induction or a surgical airway. Emergency intubation of the severely injured trauma patient is a difficult and demanding skill – standardised and rehearsed procedures should be in place for failure to intubate (***Figure 27.1***). Equipment and expertise for achieving a surgical airway must be readily available.

B: Breathing and ventilation

All patients should receive high-flow oxygen. Life-threatening chest pathology such as tension pneumothorax, massive haemothorax and flail segment should be diagnosed and managed immediately. Equipment and expertise for rapid insertion of intercostal chest drains should be available.

C: Circulation and haemorrhage control

All patients require adequate intravenous (IV) access with at least two large-bore IV cannulae. Equipment and expertise for insertion of central or intraosseous venous access should be available where peripheral access is not easily obtainable. Blood should be taken for cross-match and laboratory assessment, including haemoglobin and venous lactate. An assessment of the haemodynamic status should be made to identify shocked patients: the skin may be cool and sweaty, the pulse rate raised to over 100 per minute and the blood pressure low. A pelvic binder should be applied to all haemodynamically unstable patients following blunt trauma and not removed until after a pelvic fracture has been excluded. Hypotensive trauma patients are treated as hypovolaemic until proven otherwise. The priority is simultaneous fluid resuscitation and identification of the source of the haemorrhage.

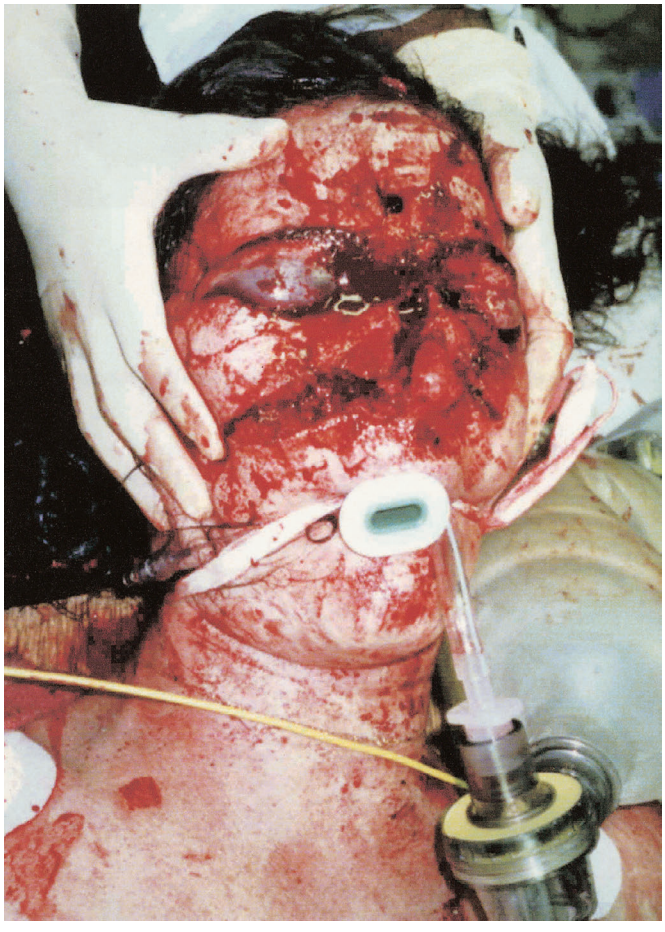

Figure 27.1 Unrestrained driver with severe craniofacial injury (courtesy of Johannesburg Hospital Trauma Unit).

Permissive hypotension, massive transfusion protocols and tranexamic acid

The initial aim of resuscitation is to maintain the blood supply to the vital organs: the brain, heart and kidneys. For a short time, this can be achieved with a target systolic blood pressure of 70–90 mmHg, although a higher pressure of >90 mmHg should be the target if a head injury is suspected. Small boluses of IV fluids (e.g. 250 mL of O negative blood, or normal saline if blood is not immediately available) should be administered to achieve this target, which should result in a palpable radial pulse. Excessive IV crystalloid or colloid solutions should be

avoided because they cause haemodilution, increase coagulopathy and increase the risk of adult respiratory distress syndrome. However, the key to this approach of permissive hypotension is that it is time limited. The primary source of haemorrhage must be identified and controlled as soon as possible.

Severely injured hypovolaemic patients should be resuscitated with blood and blood products, not crystalloid/colloid fluids. These must be warmed. All hospitals managing severe trauma should have a massive transfusion protocol that aims to provide blood and blood products in a ratio of 1 packed red cells : 1 fresh-frozen plasma : 1 platelets.

Tranexamic acid

Tranexamic acid is an antifibrinolytic drug that reduces the risk of mortality from bleeding in both blunt and penetrating trauma. One gram is given intravenously over 10 minutes, followed by a further 1-g dose over 8 hours. Tranexamic acid should be given to all trauma patients suspected to have significant haemorrhage, including those with a systolic blood pressure of <110 mmHg or a pulse of over 110 per minute. It needs to be administered as early as possible and ideally within the first hour from injury; the first dose should not be administered more than 3 hours from injury. In the UK it is normally given by paramedics in the prehospital environment.

Summary box 27.2

Severe hypovolaemia

- Tranexamic acid reduces mortality after trauma
- All traumatised patients suspected of bleeding should receive tranexamic acid as soon as possible after injury
- All trauma centres should have an established massive transfusion protocol
- Severely hypovolaemic trauma patients should be resuscitated using blood and blood products
- The only role for crystalloids in the initial management of severely hypovolaemic patients is for the administration of small quantities to maintain blood pressure while waiting for blood products to become available

Identification and management of haemorrhage

The sites of major haemorrhage in trauma patients are the chest, abdomen, pelvis and long bones, and external haemorrhage (***Figure 27.2***). Blunt trauma patients frequently have multiple sources of haemorrhage. Clinical examination and investigations should aim to rapidly confirm or exclude significant bleeding from each of these sites. Computed tomography (CT) from the head to pelvis with IV contrast, the so-called 'whole-body CT' (WBCT), is the gold standard investigation in patients with signs or symptoms of multiple injury or deranged physiology, but note that WBCT should not be performed on the basis of the mechanism of injury alone (see ***Further reading***). There is no role for scanning selective body systems in the severely injured trauma patient. Wherever possible, WBCT should be performed as soon as possible during the patient's resuscitation. A provisional 'hot report' can be issued within minutes to identify immediate life-threatening pathology to the trauma team. A more detailed definitive report should be available within 30–60 minutes.

Traditionally, chest and pelvis radiographs have been obtained early in the assessment of patients with polytrauma but these investigations are increasingly omitted in favour of obtaining a rapid CT scan, as described above. Most trauma centres now have rapid access to CT scanners located within, or immediately adjacent to, the resuscitation area. This has allowed haemodynamically unstable patients to have a WBCT with resuscitation by the trauma team continuing simultaneously during CT. Identifying which patients are too haemodynamically unstable to scan safely is a difficult decision for the trauma team leader and will be influenced by local factors and facilities.

Some patients will be so haemodynamically unstable on arrival that they need immediate surgical control of their haemorrhage before a CT scan. The most likely sources are abdominal or pelvic bleeding. An immediate chest radiograph will exclude catastrophic intrathoracic haemorrhage. An immediate pelvic radiograph is essential but should not delay transfer to the operating theatre. A focused abdominal sonography for trauma (FAST) scan (if immediately available) may also be useful in this scenario to locate the major source of haemorrhage. All patients undergoing immediate laparotomy in the operating theatre should have a pelvic binder applied and not removed. A correctly positioned pelvic binder at the level of the greater trochanters does not obstruct trauma laparotomy. These patients will invariably require a WBCT scan after surgical control of haemorrhage has been achieved.

Summary box 27.3

Whole-body CT (WBCT)

- WBCT from the head to pelvis with IV contrast is the gold standard investigation of the severely injured adult blunt trauma patient
- There is no role for selective scanning of body systems in these patients
- WBCT scan is a time-critical investigation and should be obtained as early as possible in resuscitation of the severely injured patient
- Any patient undergoing immediate trauma laparotomy after blunt trauma without a WBCT scan should have a pelvic binder applied and not removed until a pelvic fracture is excluded. Such patients should have an immediate pelvic radiograph either in the emergency department or as they arrive in the operating theatre

D: Disability and E: Exposure

On admission, the GCS score should be calculated (***Table 27.1***), the pupils assessed for size and reaction to light and the patient observed to determine whether they are moving all four limbs. The core temperature must be recorded. Patients are managed with cervical spine protection (cervical collar and blocks) and protection of the thoracolumbar spine using standard log roll techniques until a spinal injury has been excluded. Early WBCT scan will rapidly identify the majority of intracranial and spinal pathology.

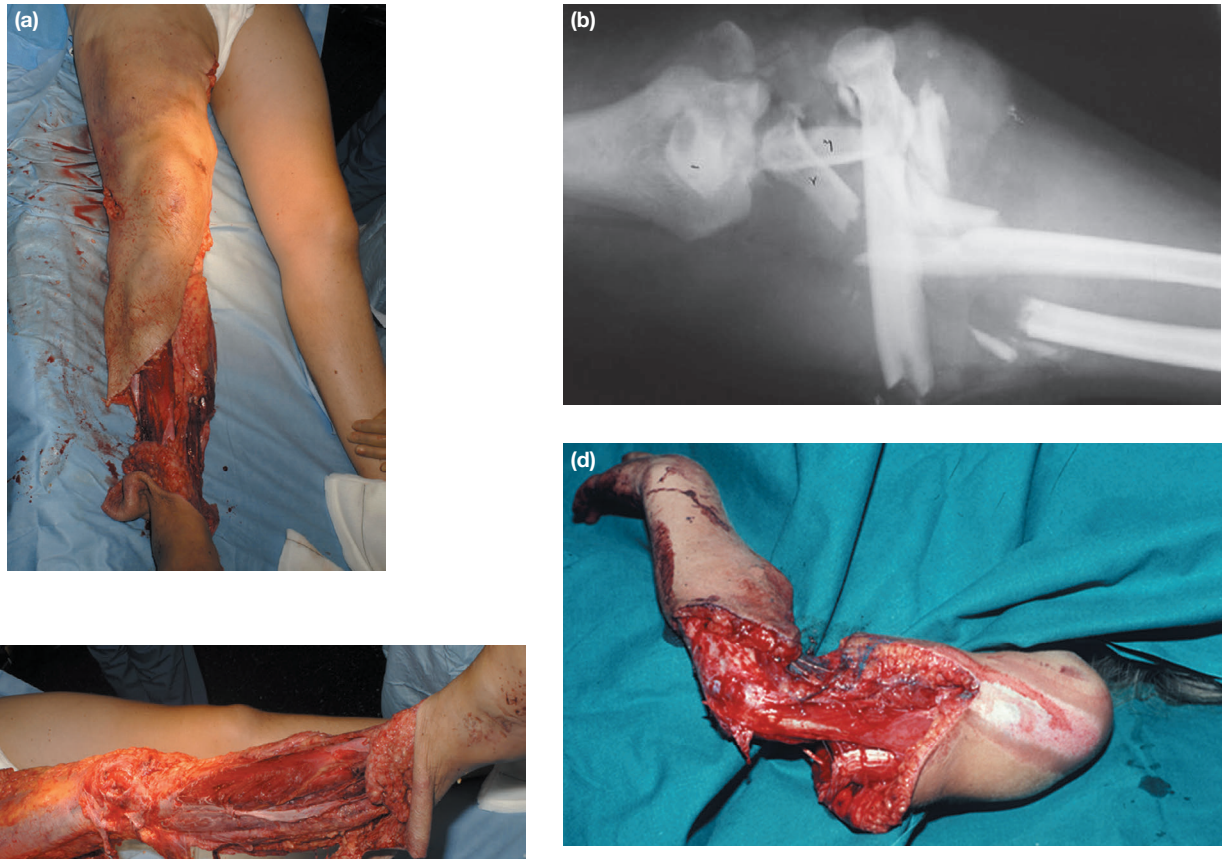

Figure 27.2 (a–d) Severe degloving injuries to the upper and lower limbs following a high-speed road traffic accident. The initial appearance and severity of the injury should not detract from following the important Advanced Trauma Life Support (ATLS) sequence in evaluating and treating immediate life-threatening injuries. Bleeding and severe injuries within the chest, abdomen and pelvis must be actively excluded.

The patient must be adequately exposed to allow a thorough and systematic clinical examination during the secondary survey but they must be kept warm. Trauma patients are frequently hypothermic and this will further increase coagulopathy. Every effort should be made to maintain normal temperature by minimising unnecessary exposure of the patient and by using warmed blankets and trolleys and warmed fluids during resuscitation.

Log-rolling patients with severe pelvic fractures may harm the patient by disturbing established blood clots. Log-rolling should not occur until a pelvic fracture has been radiographically excluded. If patients need to be moved during their primary survey, such as when moving onto the CT scanning gantry, a 20° roll with inline spinal stabilisation should be used. Modern 'scoop stretchers' mean that there is no requirement to roll any patient more than 20° until a pelvic fracture has been excluded.

Formal log-rolling of the blunt trauma patient to examine the back during the primary survey adds minimal useful clinical information, delays the WBCT scan and may cause harm to a patient with a pelvic fracture. It should be deferred until after the primary survey, with the exception of patients

TABLE 27.1 Glasgow Coma Scale.

Best eye response (E)	Best verbal response (V)	Best motor response (M)
4 Eyes opening spontaneously	5 Oriented	6 Obeys commands
3 Eye opening to speech	4 Confused	5 Localises to pain
2 Eye opening in response to pain	3 Inappropriate words	4 Withdraws from pain
1 No eye opening	2 Incomprehensible sounds	3 Flexion in response to pain
	1 None	2 Extension to pain
		1 No motor response

with penetrating trauma, where it is important to identify the presence of a posterior torso wound.

Mechanical testing of the pelvis in the emergency room ('springing the pelvis') adds no useful clinical examination and will disrupt any blood clot that has formed around a pelvic fracture. It should never be performed – a pelvic fracture should always be diagnosed radiographically.

Summary box 27.4

The cABCDE of trauma care

- c – Control of massive external haemorrhage
- A – Airway with cervical spine protection
- B – Breathing and ventilation
- C – Circulation and haemorrhage control: apply a pelvic binder and do not remove until a pelvic fracture is excluded
- D – Disability (neurological status)
- E – Exposure (assess for other injuries)

SECONDARY SURVEY

All severely injured patients require a detailed top-to-toe examination after life-threatening injuries have been identified and managed during the primary survey. Patients may be intubated and unresponsive at this point, limiting the accuracy of clinical examination. Such patients should have a 'tertiary survey' when extubated and alert to identify any missed 'minor' injuries, such as a scaphoid fracture in the wrist or a rotator cuff tear in the shoulder. These injuries have the potential to cause significant long-term disability. It is essential that the findings of the primary, secondary and tertiary surveys are clearly recorded in the patient's case notes.

DAMAGE CONTROL SURGERY VERSUS EARLY TOTAL CARE

As discussed in ***Chapter 26***, the concept of damage control surgery (DCS) was developed because severely traumatised patients with impaired physiology have poor outcomes after lengthy and complex surgical reconstructive procedures performed shortly after their trauma. Prolonged procedures result in additional trauma and further immune and physiological derangement; the 'triad of death' – a cycle of acidosis, coagulopathy and hypothermia – may develop and result in multiorgan failure and death.

Consequently, surgical interventions in the trauma patient with physiological abnormality are limited to rapid life- and limb-saving procedures: control of haemorrhage, decompression of cavities (e.g. craniotomy, fasciotomy), revascularisation of ischaemic organs and limbs and removal of contamination. This damage control approach aims to rapidly achieve these objectives and then move the patient to a critical care environment and continue with resuscitation.

Subsequent definitive reconstructive procedures are deferred until the patient is adequately resuscitated and physiologically optimised. DCS in the abdomen is limited to packing and control of haemorrhage, debridement and resection of devitalised tissue and removal of contamination by foreign bodies or faeces. Damage control orthopaedic surgery is limited to debridement of severe open fractures, rapid temporary splintage or stabilisation of long bone fractures and decompression of limb compartment syndrome where required.

Revascularisation of a limb following arterial injury may be appropriate for isolated injuries but in the patient with severe multiple system trauma it may increase the threat to life and therefore amputation may be the better option. Such patients are then transferred to critical care for further resuscitation and physiological stabilisation before definitive surgical procedures can be planned.

The majority of trauma patients respond well to resuscitation, are not physiologically compromised after appropriate resuscitation and are therefore suitable for early total care (ETC). A number of physiological indices are used to evaluate the response to resuscitation, including a pulse rate less than 100 per minute, normal blood pressure and respiratory rate, as well as urine output >30 mL/h. The patient should not have hypothermia (temperature <35°C) nor evidence of acidosis on arterial blood gases and should have a normal coagulation screen.

Lactate levels are also a good indicator of tissue perfusion and should rapidly return to normal. In this situation, it is usually safe for the surgeon to proceed with definitive repair or reconstruction of injured organs.

For musculoskeletal injuries, ETC allows definitive fixation of all unstable long bone, spinal and pelvic fractures within 36 hours of injury. This facilitates nursing care, allows early mobilisation of the patient and reduces pulmonary complications and length of stay on intensive care.

If a sequence of fracture fixations is required, at the conclusion of each procedure the surgeon and anaesthetist should determine whether the patient's physiological status has been maintained sufficiently to allow the next procedure, or whether the patient should return to critical care for a further period of resuscitation.

Summary box 27.5

ETC versus DCS

- ETC describes the definitive management of a patient's injuries within 36 hours of injury after a period of initial resuscitation
- DCS describes simultaneous resuscitation with early rapid life- and limb-saving surgery. Time-consuming definitive surgery is deferred until the patient's physiological status allows
- An ETC approach can be changed to a damage control approach if the patient's physiology deteriorates during definitive surgery

Venous lactate

Venous lactate is a useful marker of resuscitation and physiological state. A normal lactate (<2 mmol/L) is a sign that the patient is probably resuscitated and suitable for ETC. An elevated lactate (>3 mmol/L) suggests the patient is under-resuscitated and should either have a period of further resuscitation or DCS if surgery is urgent. If a patient's lactate

is 2–3 mmol/L then the trend (upwards or downwards) should be noted and the other physiological markers considered to determine whether the patient is suitable for definitive surgical procedures.

The identification of patients suitable for ETC versus DCS should be made by senior surgeons and anaesthetists/critical care doctors. This may be an easy decision, for example the haemodynamically unstable patient with intra-abdominal bleeding will always undergo rapid damage control laparotomy. In other cases a careful review of the patient's physiology and coagulation state will be required.

Summary box 27.6

Venous lactate is an essential marker of resuscitation

- <2 mmol/L – ETC
- 2–3 mmol/L – look at the trend (increasing or decreasing)
- >3 mmol/L – may be under-resuscitated; should either have further resuscitation or DCS if surgery is urgent
- >5 mmol/L – DCS (see ***Chapters 26 and 29***)

SUMMARY

The early assessment and management of trauma patients should follow established ATLS principles.

A WBCT scan, from the head to the pelvis, with IV contrast is the gold standard investigation for major trauma patients and should be performed early and whenever possible.

Warmed blood and blood products in a 1:1:1 ratio of blood : plasma : platelets should be used with tranexamic acid in the early resuscitation of haemodynamically unstable trauma patients.

Trauma patients requiring surgery should have an early decision made whether a damage control or ETC approach is required. Surgical procedures in physiologically compromised patients should be limited to those required to save the life and/or limb of the patient, while simultaneous resuscitation is continued.

PART 4 | Trauma

CHAPTER 28

Traumatic brain injury

Learning objectives†

To be familiar with:

- The physiology of cerebral blood flow and the pathophysiology of raised intracranial pressure
- The resuscitation, assessment, investigation and continuing care of head-injured patients
- The prevention and detection of secondary intracranial and systemic insults

INTRODUCTION

Head injury accounts for 3–4% of emergency department attendances, with around 1500 cases per 100 000 population per year in the UK. Annual mortality attributable to head injury is estimated at 9 per 100 000, and it remains the leading cause of death and disability from childhood to early middle age, with an estimated 2% of the US population suffering long-term disability as a result of head injury. Road traffic accidents are the leading cause of head injury, responsible for up to 50% of cases. Other common mechanisms of injury include falls and assault. There is significant geographical variation, for example firearms are the third leading cause in the USA.

Traumatic brain injury (TBI) can be considered as the combination of primary injury sustained on impact, and hence not medically modifiable, and secondary injury developing in the following hours and days. Understanding the importance of intracranial pressure (ICP) and related parameters is key to minimising secondary injury and improving outcomes.

INTRACRANIAL PRESSURE

Intracranial pressure and cerebral blood flow

The brain depends on continuous perfusion for oxygen and glucose delivery, and hence survival. Normal cerebral blood flow (CBF) is about 55 mL/min for every 100 g of brain tissue. Ischaemia results when this rate drops below 20 mL/min, and even lower levels will result in infarction unless promptly corrected.

Flow depends on cerebral perfusion pressure (CPP), which is the difference between the mean arterial pressure (MAP) and the intracranial pressure (ICP):

CPP (75–105 mmHg) =
MAP (90–110 mmHg) – **ICP** (5–15 mmHg)

Typical normal values are given in parentheses. In fact, in the normal brain, variations in vascular tone maintain a constant CBF across a range of MAP between 50 and 150 mmHg (or higher in the setting of chronic hypertension) and a corresponding range of CPP – the process of **cerebral autoregulation**. Autoregulation can be impaired in the context of trauma, so that MAP and ICP must be actively regulated in these patients to maintain proper perfusion.

The Monro-Kellie doctrine and herniation syndromes

Alexander Monro observed in 1783 that the cranium is a 'rigid box' containing a 'nearly incompressible brain'. Any expansion in the contents, especially haematoma and brain swelling, may be initially accommodated by exclusion of fluid components, venous blood and cerebrospinal fluid (CSF). Further expansion is associated with an exponential rise in ICP (***Figure 28.1***).

Uncontrolled increases in ICP result in cerebral herniation (***Figure 28.2***). Typically, herniation of the uncus of the temporal lobe over the tentorium results in pupil abnormalities (see ***Pupils***), usually occurring first on the side of any expanding haematoma. Cerebellar tonsillar herniation through the foramen magnum compresses medullary vasomotor and

†The learning objectives of this chapter are aligned with the Intercollegiate Surgical Curriculum Programme (ISCP) ST3 Neurosurgery Knowledge Requirements in Cranial Trauma and comprise:

- the resuscitation, assessment, investigation and continuing care of head-injured patients
- the prevention and detection of secondary intracranial and systemic insults.

Alexander Monro (secundus), 1733–1817, Scottish anatomist, physician and medical educator.
George Kellie, 1770–1829, Scottish surgeon and pupil of Alexander Monro (secundus).

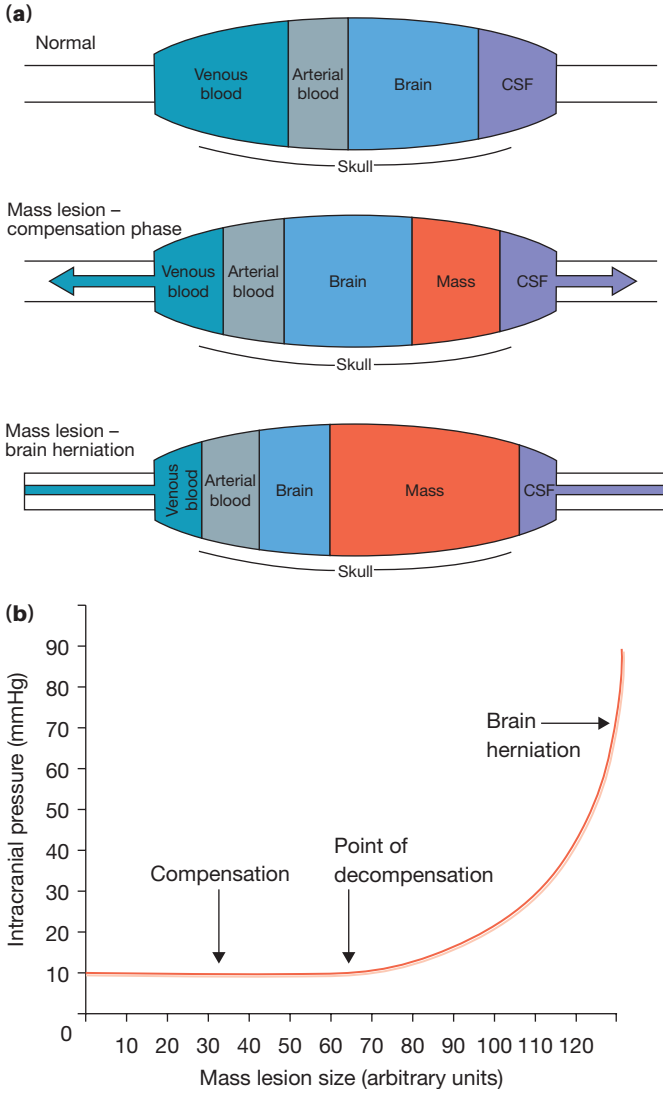

Figure 28.1 The Monro–Kellie doctrine accounts for the ability of the intracranial compartment to accommodate expanding mass lesions, primarily by excluding venous blood and cerebrospinal fluid (CSF), and the rapid rise in pressure associated with exhaustion of this compensation.

respiratory centres, classically producing **Cushing's triad**: hypertension, bradycardia and irregular respiration. The patient is then said to be '**coning**', and brainstem death will result without immediate intervention.

Summary box 28.1

Intracranial pressure

- A continuous supply of oxygenated blood is essential for brain survival
- Raised ICP can compromise cerebral perfusion, resulting in a cycle of secondary brain injury and swelling

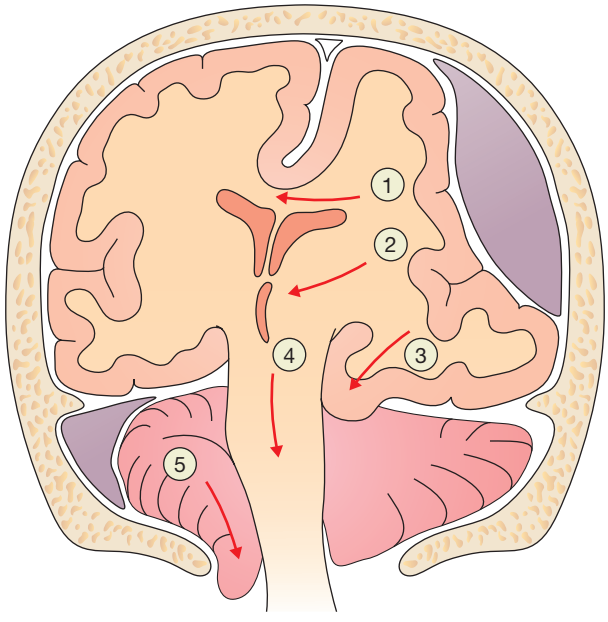

Figure 28.2 Brain herniation. (1) Subfalcine herniation – the cingulate gyrus is herniating under the falx cerebri. (2) Midline shift is evident. (3) Uncal herniation – the temporal lobe is herniating over the tentorium cerebelli, where it can compress the third nerve. (4) Central herniation and (5) tonsillar herniation result in brainstem compromise, manifesting as Cushing's triad.

CLASSIFICATION OF HEAD INJURY

The severity of head injury is classified according to the post-resuscitation Glasgow Coma Scale (GCS) score (***Table 28.1***), as it is the GCS score – and in particular the motor score – that is the best predictor of neurological outcome. In broad terms, significantly obtunded patients have moderate injuries and comatose patients have severe injuries; alcohol and drug effects often complicate the classification.

TABLE 28.1 Head injury severity: clinical classification.

Minor head injury	GCS 15 with no LOC
Mild head injury	GCS 14 or 15 with LOC
Moderate head injury	GCS 9–13
Severe head injury	GCS 3–8

GCS, Glasgow Coma Scale; LOC, loss of consciousness.

MINOR AND MILD HEAD INJURY

After exclusion of associated cervical spine injury, it is important to consider the possibility of a 'lucid interval' that may precede delayed deterioration due to an expanding intracranial haematoma. In general, patients with isolated head injuries and without ongoing deficits can be safely discharged from the emergency department, provided they meet suitable criteria,

Harvey Williams Cushing, 1869–1939, Professor of Surgery, Harvard University Medical School, Boston, MA, USA, considered the founding father of modern neurosurgery.

for instance those provided by the UK National Institute for Health and Care Excellence (NICE) (*Table 28.2*).

TABLE 28.2 UK National Institute for Health and Care Excellence discharge criteria in minor and mild head injury.

- GCS 15/15 with no focal deficits
- Normal CT brain if indicated (see *Table 28.3*)
- Patient not under the influence of alcohol or drugs
- Patient accompanied by a responsible adult
- Verbal and written head injury advice: seek medical attention if:
  - Persistent/worsening headache despite analgesia
  - Persistent vomiting
  - Drowsiness
  - Visual disturbance
  - Limb weakness or numbness

CT, computed tomography; GCS, Glasgow Coma Scale score.

Patients who do not meet all the discharge criteria will need admission for a further period of observation and/or brain imaging. Early computed tomography (CT) imaging is desirable in patients with a persistent reduced conscious level, focal deficits, suspected fractures or risk factors for intracranial bleed (*Table 28.3*). Significant clinical or radiological abnormalities should be discussed with the neurosurgical service. Many of these patients will struggle with features of concussion for a period after their injury, with headaches and somnolence typical. Follow-up by a head injury specialist nurse or equivalent is therefore desirable.

TABLE 28.3 UK National Institute for Health and Care Excellence (NICE) guidelines for computed tomography (CT) in head injury.

Indications for CT imaging in head injury within 1 hour
• GCS <13 at any point
• GCS <15 at 2 hours
• Focal neurological deficit
• Suspected open, depressed or basal skull fracture
• More than one episode of vomiting
• Post-traumatic seizure
Indications for CT imaging within 8 hours
• Age >65
• Coagulopathy (e.g. aspirin, warfarin or rivaroxaban use)
• Dangerous mechanism of injury (e.g. fall from a height, RTA)
• Retrograde amnesia >30 minutes

GCS, Glasgow Coma Scale score; RTA, road traffic accident.

Non-accidental injury

Head injury in children and vulnerable adults may be due to abuse. Significant findings include delayed presentation, injuries of disparate age, retinal haemorrhages, bilateral chronic subdural haematomas, multiple skull fractures and neurological injury without external signs of trauma.

Concussion, second impact syndrome and postconcussive syndrome

Concussion is defined as the alteration of consciousness as a result of closed head injury but is generally used to describe mild head injury without imaging abnormalities: loss of consciousness at the time of injury is not a prerequisite. Key features include confusion and amnesia. The patient may be lethargic, easily distractable, forgetful, slow to interact or emotionally labile. Gait disturbance and incoordination may be seen. While symptomatic following a head injury, patients may exhibit disordered cerebral autoregulation, making them especially vulnerable to repeat impacts. Second impact syndrome following an apparently trivial repeat injury comprises malignant brain swelling that can quickly progress to coma and death. Although the existence of the syndrome is disputed, and it is certainly rare, it should be considered in advice to individuals engaged in sports or activities carrying a risk of further injury: symptomatic players should not return to play.

Postconcussive syndrome is a loosely defined constellation of symptoms persisting for a prolonged period after injury. Patients may report somatic features such as headache, dizziness and disorders of hearing and vision. They may also suffer a variety of neurocognitive and neuropsychological disturbances, including difficulty with concentration and recall, insomnia, emotional lability, fatigue, depression and personality change. Some patients may exaggerate symptoms, seeking secondary gain (compensation).

Summary box 28.2

Minor and mild head injury

- Decisions on imaging and discharge are best made guided by published criteria
- In preverbal children and other vulnerable groups, non-accidental injury must be considered
- Amnesia, confusion, headaches and somnolence are typical features of concussion

MODERATE AND SEVERE TRAUMATIC BRAIN INJURY

Resuscitation and evaluation

Resuscitation is performed according to Advanced Trauma Life Support (ATLS) guidelines, beginning with management of the airway with cervical spine control and proceeding to assess and manage breathing and circulation. The history obtained in parallel is key to shaping ongoing management.

History

Mechanism

In moderate and severe TBI, a history must be obtained from witnesses and paramedics. High-energy mechanisms of injury, including a fall from a height or a high-speed road accident, will require careful clinical and radiological exclusion of associated multisystem and spinal injury (see *Chapters 27 and 30*). In the case of road traffic accidents in particular, extraction time and evidence of hypoxia or haemodynamic instability at the scene is important information to obtain from the paramedics. Falls

and crashes are often caused by a primary medical problem such as myocardial infarction, hypoglycaemia or subarachnoid haemorrhage, with crucial implications for management.

Neurological progression

A specific check should be made for any loss of consciousness at the time of injury and its duration. The GCS score and pupil responses should be recorded at the scene, during transfer, at admission and regularly thereafter. A deterioration in the GCS score is an important index of developing a potentially reversible secondary injury. It is also useful to assess the extent of amnesia, retrograde (events prior to the injury) and anterograde (events afterwards). If the patient was intubated at the scene of the accident, it is valuable to know whether the patient was moving all four limbs before this.

Past medical history

Obtain details of the patient's medical background, including allergies and normal medications. Of particular note here are antiplatelet agents, potentially requiring platelet transfusion especially if surgery is required, and anticoagulants, which may need reversal.

Summary box 28.3

History

- Bystanders and paramedics may give vital information on the:
  - Preinjury state (fits, alcohol, chest pain)
  - Mechanism and energy involved in the injury (speed of vehicles, height fallen)
  - Conscious state and haemodynamic stability of the patient after the accident
  - Length of time taken for extrication
- Check the medication history, especially anticoagulants and antiplatelet agents

Examination: primary survey

ATLS guidelines address a fundamental priority: ensuring uninterrupted perfusion of the brain with oxygenated blood. This is especially important after a head injury, given the disturbance to intracranial autoregulation and the sensitivity of the primary injured brain tissue to further insult. Bleeding from scalp lacerations may require management as part of the primary survey as the blood loss can be substantial and ongoing. Check the responsiveness of the pupils and conscious level and check for any gross focal neurological deficits. The blood glucose level should also be measured as early as possible as hypoglycaemia is very dangerous and easily reversible.

Pupils

The pupil size should be recorded in millimetres and the reactivity documented as present, sluggish or absent. Uncal herniation (*Figure 28.2*) can compress the third nerve, compromising the parasympathetic supply to the pupil. Unopposed sympathetic activity produces a sluggish enlarged pupil, progressing to fixed and dilated under continued compression. Established pupil changes may reflect pathology anywhere in the eye or the reflex loop made up by the optic nerve, the oculomotor nerve and the brainstem. Direct ocular trauma or nerve injury in association with a skull base fracture can cause mydriasis (dilated pupil) to be present from the time of injury. Pre-existing discrepancy in the pupil size (anisocoria), as a result of Holmes–Adie pupil or cataracts for example, may also complicate assessment.

Glasgow Coma Scale score

The GCS score is the sum of scores on three components, as detailed in *Table 28.4*. The breakdown of the GCS score into eye opening, verbal and motor components should always be recorded and used when communicating the status to other doctors. Remember that the score represents the best performance elicited, so a patient flexing in response to a painful stimulus on the left and localising on the right scores 'M5'. A sternal or supraorbital rub or trapezius squeeze represents an appropriate painful stimulus.

Neurological deficit

Gross focal neurological deficits, such as paraplegia, may be evident at the primary survey, and an assessment to exclude such a deficit should be carried out, especially if the patient is to be intubated so that subsequent examination will be impossible. Detailed neurological examination is included in the secondary survey.

TABLE 28.4 Glasgow Coma Scale score for head injury.

Eyes open	Spontaneously	4
	To verbal command	3
	To painful stimulus	2
	Do not open	1
Verbal	Normal	5
	Confused	4
	Inappropriate/words only	3
	Sounds only	2
	No sounds	1
	Intubated patient	T
Motor	Obeys commands	6
	Localises to pain	5
	Withdrawal/flexion	4
	Abnormal flexion	3
	Extension	2
	No motor response	1

Sir Gordon Morgon Holmes, 1876–1965, physician, National Hospital for Nervous Diseases, London, UK.
William John Adie, 1886–1935, physician, National Hospital for Nervous Diseases, London, UK.

Summary box 28.4

Primary survey

- Ensure adequate oxygenation and circulation
- Exclude hypoglycaemia
- Check pupil size and response and GCS score as soon as possible
- Check for focal neurological deficits before intubation if possible

Examination: secondary survey

A full secondary survey will be required. Particular attention must be paid to the head, neck and spine.

Head

Examination of the head should include inspection and palpation of the scalp for evidence of subgaleal haematoma and scalp lacerations, which may bleed profusely and potentially overlie fractures. Examine the face for evidence of fractures, especially to the orbital rim, zygoma and maxilla. Clinical evidence of a skull base fracture may include Battle's sign (*Figure 28.3*) and 'racoon' or 'panda' eyes (bilateral periorbital bruising). Haemotympanum, or overt bleeding from the ear if the tympanic membrane has ruptured, and CSF rhinorrhoea or otorrhoea are also highly suggestive of a fracture of the base of the skull.

A complete examination of the cranial nerves will reveal, for example, facial or vestibulocochlear nerve damage associated with skull base fracture. Midbrain or brainstem dysfunction may produce gaze paresis (inability of the eye to look across beyond the midline), dysconjugate gaze (inability of the eyes to work together) or roving eye movements. Inspect the conjunctiva and cornea of the eyes, and the retina using an ophthalmoscope, looking for hyphaema (blood in the anterior chamber of the eye), papilloedema or retinal detachment. Blood in the mouth may be due to tongue-biting at seizure. The GCS score and pupil status, assessed as part of the primary survey, require re-evaluation at the secondary survey and regularly thereafter.

Figure 28.3 Battle's sign. A skull base fracture may be associated with bruising over the mastoid process.

Neck and spine

Studies have demonstrated an incidence of cervical fracture of up to 10% in association with moderate and severe TBI. Cervical spine injury must be presumed in the context of head injury until actively excluded. In a high-energy mechanism such as a road traffic accident or fall from a height, thoracic and lumbar spine injuries must also be excluded. Plain radiographs are of limited value in excluding significant cervical spine injury. Even CT imaging does not exclude the possibility of significant ligamentous injury. Therefore, whenever feasible, these patients should be managed in a hard collar until the neck can be cleared clinically.

A peripheral nerve examination with documentation of limb tone, power, reflexes and sensation needs to be performed early to identify spinal pathology. This is especially important in patients who may subsequently be intubated and ventilated when this assessment will no longer be possible. Obtunded patients should move all four limbs in response to an appropriate painful stimulus.

The patient will need to be log-rolled to palpate for thoracic or lumbar deformity, and any cervical collar should be removed at this stage to allow palpation of the cervical spine before it is then replaced again. If there is associated spinal injury, a thoracic sensory level is much more easily established by sensory examination on the back. A per rectum examination is also performed at log-roll, assessing for anal tone, sensation in the awake patient and anal wink (sphincter seen to contract in response to a pinprick stimulus). Priapism is a strong predictor of severe cord injury even in intubated patients.

Summary box 28.5

Secondary survey

- Battle's sign, periorbital bruising and blood in the ears/nose/mouth may point to a base of skull fracture
- Cervical spine fractures are common and must be actively excluded
- Log-roll to check the whole spine for steps and tenderness and for a per rectum examination

Surgical pathology

Fractures: skull vault

Closed linear fractures of the skull vault are managed conservatively. Open or comminuted fractures should be considered for

William Henry Battle, 1855–1936, surgeon, St Thomas's Hospital, London, UK.

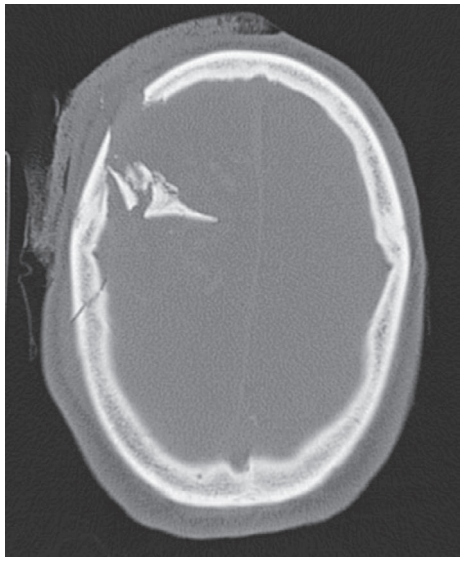

Figure 28.4 A right frontal comminuted depressed skull fracture, with a linear undisplaced fracture of the right parietal bone visible posteriorly.

debridement and prophylactic antibiotic therapy. Depressed skull fractures involve inward displacement of a bone fragment by at least the thickness of the skull (***Figures 28.4 and 28.5***). They occur when small objects hit the skull at high velocity. They are usually compound (open) fractures, and are associated with a high incidence of infection, neurological deficit and late-onset epilepsy. These fractures require exploration and elevation, especially where intracranial air is present, pointing to a breach in the dura mater. Fractures that involve the air sinuses should generally be managed as open fractures, using broad-spectrum antibiotics with or without exploration.

Fractures: skull base

Clinical signs of skull base fracture include bleeding or CSF leak from the ears (otorrhoea) or nose (rhinorrhoea) and bruising behind the ear (***Figure 28.3***) or around the eyes. Skull base fractures may be complicated by pituitary dysfunction, arterial dissection or cranial nerve deficits, with anosmia, facial palsy or hearing loss typical. CSF leak will generally resolve spontaneously but persistent leak can result in meningitis so repair may be required. Blind nasogastric tube placement is contraindicated in these patients.

Extradural haematoma

Extradural haematoma (***Figure 28.6***) is a neurosurgical emergency. It results from rupture of an artery, vein or venous sinus, in association with a skull fracture. The classical injury is a fracture to the thin squamous temporal bone, with associated damage to the middle meningeal artery. Transient loss of consciousness is typical, and the patient may then present in the subsequent lucid interval with headache but without any neurological deficit. As the haematoma expands, compensation is exhausted (see ***The Monro–Kellie doctrine and herniation syndromes***) with rapid deterioration. There is contralateral hemiparesis, a reduced conscious level and ipsilateral pupillary

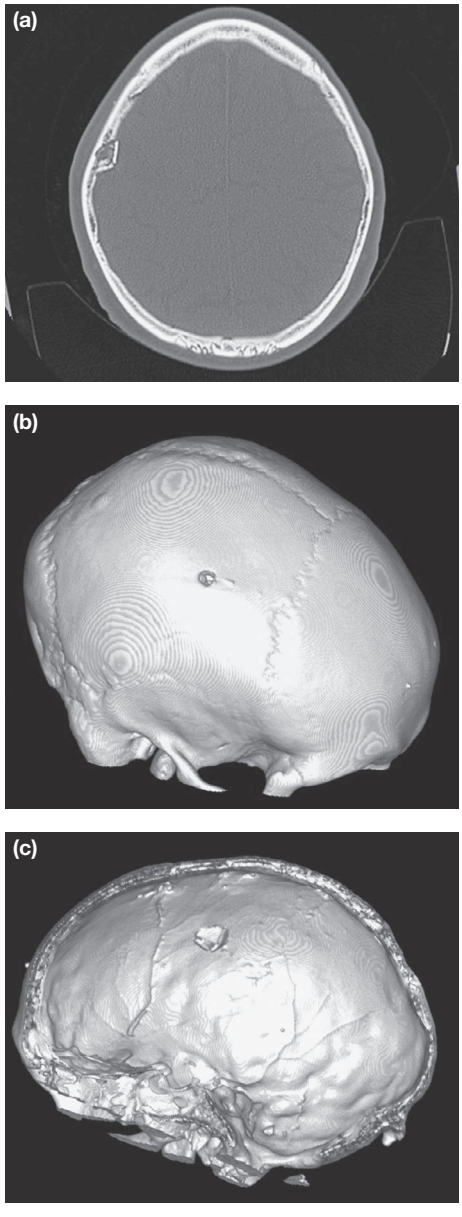

Figure 28.5 (a–c) A small depressed skull fracture of the parietal bone visible on an axial bone window **(a)**, visualised on bone vault reconstructions **(b)** with an underlying breach of the dura **(c)**.

dilatation, the cardinal signs of brain compression and herniation. Although this '**talk and die**' pattern of deterioration occurs in only one-third of cases, it is critically important to recognise the potential for rapid avoidable secondary brain injury in patients who present neurologically intact.

On CT, extradural haematomas appear as a lentiform (lens-shaped or biconvex) hyperdense lesion between the skull and the brain, constrained by the adherence of the dura to the skull. A mass effect may be evident, with compression of the surrounding brain and midline shift. Areas of mixed density suggest active bleeding. A skull fracture will usually be evident. Significant extradural haematoma mandates urgent transfer to the most accessible neurosurgical facility for immediate evacuation in deteriorating or comatose patients or those with large bleeds and for close observation with serial imaging in

other cases. The prognosis for promptly evacuated extradural haematoma, without associated primary brain injury, is excellent.

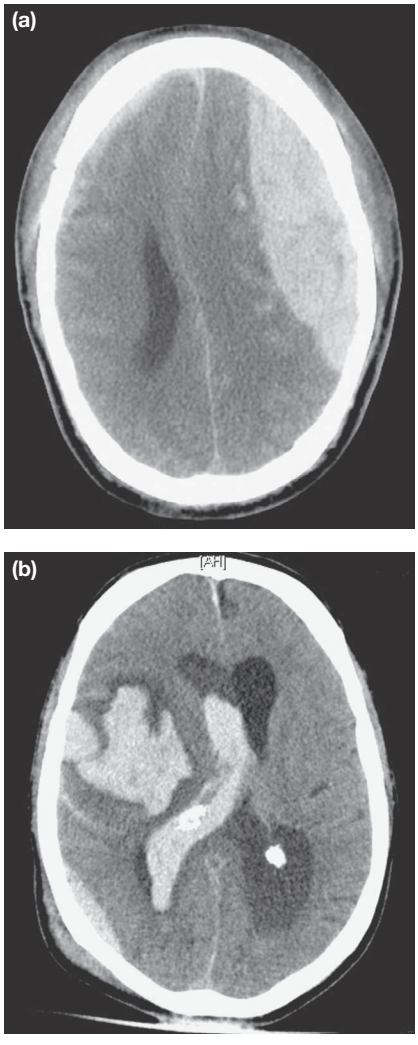

Figure 28.6 (a) A large left extradural haematoma (note the biconvex shape) exerts a mass effect; a smaller right acute subdural haematoma is also evident. **(b)** Right frontal intracerebral haematoma extending into the lateral ventricle is evident. There is a small right posterior extradural haematoma and traumatic subarachnoid bleeding in the sulci of the right hemisphere. **(c)** A surgical temporal bone exposure showing a linear skull fracture with underlying extradural haematoma visible through a burr hole.

Summary box 28.6

Extradural haemorrhage

- Can follow relatively minor trauma with brief loss of consciousness
- Followed by a lucid interval and then sudden deterioration
- Lentiform lesion on CT
- Require immediate transfer to a neurosurgical unit for decision on evacuation

Acute subdural haematoma

Acute subdural haematoma (***Figure 28.7***) is encountered in two broadly distinct contexts. First, high-energy injury mechanisms can result in the rupture of cortical surface vessels with significant associated primary brain injury. This results in an expanding haematoma with rapid deterioration and

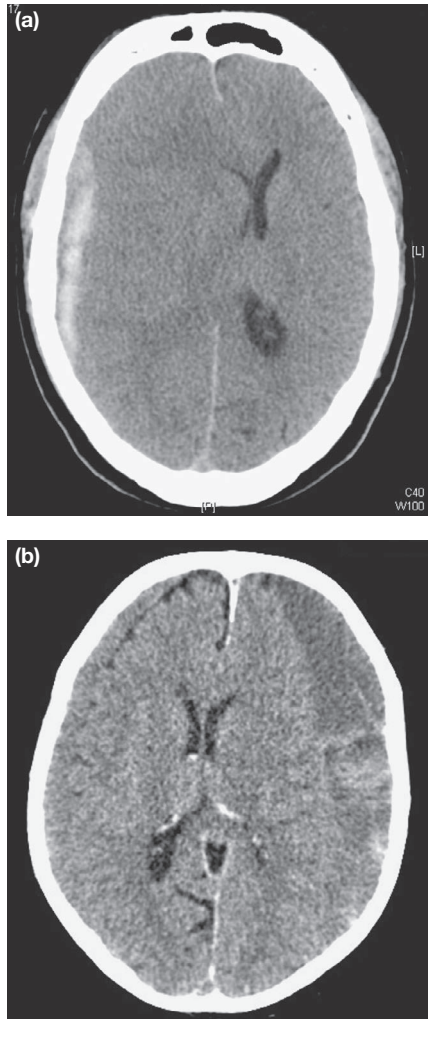

Figure 28.7 (a) Right-sided acute subdural haematoma (hyperdense). The substantial midline shift reflects brain swelling as well as bleeding – this is a high-energy injury. **(b)** Bilateral subdural haematomas: the left is mixed density, the hypodense material representing old blood and the higher density indicating more recent bleeding, probably loculated so requiring a craniotomy to evacuate. The bleed on the right is isodense, indicating intermediate age.

development of signs of raised ICP reminiscent of extradural haematoma, without the lucid interval. These collections require prompt evacuation, typically by craniotomy or craniectomy.

In a second group of patients, older and often anticoagulated, a lower energy injury leads to venous bleeding around the brain. Depending on the total volume of bleeding, the resulting haematoma may present early as acute subdural haematoma, after delay and osmotic expansion as chronic subdural haematoma or may even remain clinically silent. This last group may present much later with a further 'acute-on-chronic' subdural haematoma. On diagnosis, clotting function should be corrected wherever possible. Bleeds of significant size, with significant associated midline shift or with deteriorating neurology, require urgent evacuation. Smaller bleeds in neurologically stable patients may be managed conservatively, at least initially: liquefaction of the clot over 7–10 days after the bleed may allow for a much less invasive evacuation through burr holes.

Since the dura is not as adherent to the brain as it is to the skull, subdural blood is free to expand across the brain surface, giving a diffuse concave appearance.

Summary box 28.7

Acute subdural haemorrhage

- High-energy injuries, or elderly/anticoagulated
- Generally require urgent evacuation by craniotomy/craniectomy

Chronic subdural haematoma

Chronic subdural haematoma (***Figure 28.7***) is a common cause of acute neurological deterioration in older adults. Cerebral atrophy in this age group results in stretching of the cortical–dural bridging veins, which are then vulnerable to rupture. The resulting haematoma can expand over days or weeks by osmosis, ultimately producing symptoms of raised ICP or focal deficits. There is usually a history of recent injury, but, especially in the context of antiplatelet or anticoagulant medication, even apparently trivial impacts may be responsible.

On presentation it is important to exclude coexisting electrolyte disturbance and infections, which may contribute to clinical impairment. Imaging reveals diffuse hypodensity overlying the brain surface. Recent bleeding may be isodense or hyperdense, and mixed density can indicate an acute-on-chronic subdural haematoma.

Anticoagulation should be reversed, either by administration of vitamin K or urgently by transfusion of recombinant clotting factors in patients who have deteriorated acutely. Conservative management, sometimes with administration of corticosteroids, can be considered for small bleeds without symptoms or with headache alone. For the majority drainage is performed using burr holes. Urgency is dictated by the clinical condition of the patient and imaging evidence of mass effect. If clinically stable, a delay of 7–10 days to allow platelet function to normalise after withdrawal of aspirin/clopidogrel may be considered.

Summary box 28.8

Chronic subdural haemorrhage

- Common in the elderly, especially those on anticoagulants
- Clinical deficits result from osmotic expansion of a degrading clot over days/weeks
- Diffuse hypodense lesion on CT
- Burr hole drainage is usually preferred

Traumatic subarachnoid haemorrhage

Trauma is the commonest cause of subarachnoid haemorrhage (***Figures 28.6b and 28.8***), and this is managed conservatively. It is not usually associated with significant vasospasm, which characterises aneurysmal subarachnoid haemorrhage. The possibility of spontaneous subarachnoid haemorrhage actually leading to collapse and so causing a head injury needs to be borne in mind, and formal or CT angiography may be required to exclude this.

Cerebral contusions

Contusions are common and are found predominantly where the brain is in contact with the irregularly ridged inside of the skull, i.e. at the inferior frontal lobes and temporal poles. '**Coup contre-coup**' contusions refer to brain injury both at the site of impact and distant to this, where the brain impacts on the inside of the skull as the skull and brain accelerate and then decelerate out of synchrony with each other. Contusions appear heterogeneous on CT, reflecting their composition of injured brain matter interspersed with acute blood (***Figure 28.8***). Contusions rarely require surgical intervention but may warrant delayed evacuation to reduce a mass effect.

Figure 28.8 A large right extradural haematoma is evident. There are widespread cerebral contusions most prominent in the left frontal lobe. There is traumatic subarachnoid blood in the third and lateral ventricles.

Diffuse axonal injury

This is a form of primary brain injury seen in high-energy accidents that usually renders the patient comatose; it is associated with poor outcomes. It is strictly a pathological diagnosis made at postmortem, but haemorrhagic foci in the corpus callosum and dorsolateral rostral brainstem on CT may be suggestive. Magnetic resonance imaging is more sensitive and is employed to evaluate for diffuse axonal injury in patients who fail to improve neurologically.

Arterial dissection

Cerebral arterial dissection occurs spontaneously or in the context of trauma. In the hours after significant trauma, dissection of the carotid extracranially, or at the skull base in association with fractures, is most common. It presents with headache, neck pain and focal ischaemic deficits due to occlusion by mural haematoma, thrombus and thromboembolism. Intracranial dissection often affects the vertebral artery and may result in subarachnoid bleeding.

Summary box 28.9

Specific injuries

- Traumatic versus primary subarachnoid haemorrhage is an important distinction
- Cerebral contusions arise adjacent to rough bone surfaces
- Diffuse axonal injury results from extreme accelerations of the skull contents
- Arterial dissection is associated with fractures of the skull base

Medical management

From initial resuscitation, through surgical intervention and into the subsequent phase of ICU management, medical management strategies aim to minimise secondary brain injury through avoidance of hypoxia and hypotension and control of ICP. Unchecked, secondary injury leads to a further cycle of deterioration (***Figures 28.2 and 28.9***).

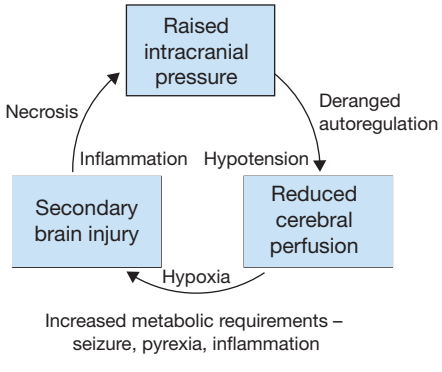

Figure 28.9 Brain swelling and mass lesions contribute to raised intracranial pressure, which compromises perfusion, leading to secondary brain injury and further swelling.

The role of neurosurgical centres

Early discussion of patients and imaging with the regional neurosurgical service is advisable. UK trauma audit and research network data show higher mortality in patients with severe TBI managed in non-neurosurgical centres, and this is reflected in NICE guidelines, which recommend early transfer irrespective of the need for surgery.

Control of intracranial pressure

Intubation and ventilation are required early in the management of severe brain injury for airway control. They are often required in moderate brain injury to facilitate the safe management and transfer of unstable and frequently agitated patients and in order to control ICP. A bolus of mannitol or hypertonic saline may be administered to temporise ICP, for example while scanning and transferring the patient.

Management of the intubated patient, following evacuation of any focal haematomas, is guided by ICP monitoring using a bolt ICP monitor or else an external ventricular drain inserted into the lateral ventricle, which can also contribute to ICP control by permitting CSF drainage. A sustained elevated ICP exceeding 20–25 mmHg is associated with a poor outcome, and maintenance of a CPP of at least 60 mmHg is important in preventing secondary injury.

ICP can be controlled by simple measures, including raising the head of the bed and loosening the collar to improve venous drainage. Seizures and pyrexia should be actively controlled. Medical management titrated to ICP includes escalating doses of sedatives, analgesics and ultimately muscle relaxants. Target ventilatory and circulatory parameters are set out in ***Table 28.5***.

TABLE 28.5 Key parameters to maintain in head-injured patients in neurointensive care.

- $PaCO_2$ = 4.5–5.0 kPa
- PaO_2 >11 kPa
- MAP = 80–90 mmHg
- ICP <20 mmHg
- CPP >60 mmHg
- $[Na^+]$ >140 mmol/L
- $[K^+]$ >4 mmol/L

$[K^+]$, plasma potassium concentration; $[Na^+]$, plasma sodium concentration; CPP, cerebral perfusion pressure; ICP, intracranial pressure; MAP, mean arterial pressure; $PaCO_2$, partial pressure of carbon dioxide in arterial blood; PaO_2, partial pressure of oxygen in arterial blood.

Where these measures fail, neurointensivists may seek to control brain swelling using mannitol or hypertonic saline infusions. Where autoregulation is preserved, inducing high CPP may reduce ICP through vasoconstriction. A range of further interventions are effective in controlling ICP, but evidence for long-term outcome benefit is limited or absent. These interventions include induction of therapeutic hypothermia or thiopentone coma and surgical decompressive craniectomy.

Pituitary dysfunction

Electrolyte imbalance is common in TBI and contributes to brain swelling and to causing seizures. Diverse mechanisms

are involved. Cerebral salt wasting, a poorly understood form of excretory dysregulation in association with brain insult, leads to volume depletion and hyponatraemia. The syndrome of inappropriate antidiuretic hormone (SIADH) leads to water retention and hyponatraemia in the context of pituitary damage. This is of particular concern in head injury since low serum osmotic pressure can contribute to brain swelling, so hypotonic fluids are avoided in this setting. Conversely antidiuretic hormone secretion may be compromised in the context of trauma, producing diabetes insipidus, resulting in hypernatraemia.

All aspects of pituitary function may be compromised in the setting of TBI. Routine screening of pituitary hormone levels and liaison with endocrinology are important aspects of optimal medical management. Note that routine, rather than directed, administration of corticosteroids in severe head injury is associated with increased mortality and is not recommended.

Seizures

Seizures may occur early (within 7 days) or late. The cumulative probability is between 2% (mild TBI) and 60% (severe TBI with exacerbating features). Risk factors include injury severity, especially the presence of intracerebral haemorrhage, depressed skull fractures and tears of the dura. Antiepileptics, typically phenytoin, are administered prophylactically to patients at high risk of seizures.

Nutrition

Enteral nutrition is preferred to intravenous parenteral nutrition on the grounds of cost and associated complications, and should be commenced within 72 hours of injury. Prokinetics (e.g. metoclopramide, erythromycin) can be administered to promote absorption.

Outcomes and sequelae

The long-term sequelae of moderate and severe TBI include headache and memory and cognitive impairments, contributing to the postconcussive syndrome described above. Rehabilitation represents a complex and prolonged multidisciplinary challenge. The Glasgow Outcome Scale score is used to quantify the degree of recovery achieved after head injury, especially for research purposes, and is detailed in ***Table 28.6***. Good recovery implies independence and potential to return to work rather than a full return to previous capacity.

TABLE 28.6 Glasgow Outcome Scale.

Good recovery	5
Moderate disability	4
Severe disability	3
Persistent vegetative state	2
Dead	1

Summary box 28.10

Medical management of head injury

- First line ICP control involves optimising sedation, ventilation and serum sodium levels
- Paralysis and external ventricular CSF drainage are important adjuncts
- There is little evidence for benefit with therapeutic hypothermia, barbiturate coma or decompressive craniectomy
- Check pituitary function, consider seizure prophylaxis, commence enteral nutrition within 72 hours

TRAUMATIC BRAIN INJURY IN THE CHILD

Head injury in children is common and presents specific challenges relating to physiology, assessment, management and safeguarding. Children have large heads compared with the rest of their bodies, predisposing to both head and neck injury. In the case of minor head injury, good assessment depends on winning the trust of child and parent, while identifying risk factors requiring further admission for observation or CT scan (***Table 28.7***). Non-accidental injury should always be considered; for example, it is key to ensure that the reported mechanism of injury is in keeping with the child's developmental stage and to examine for injuries outside the normal distribution for childhood accidents. The Paediatric Glasgow Coma Scale is applied in the under-twos (***Table 28.8***).

Moderate and severe head injury should be managed by a trauma team in a resuscitation room, using paediatric ATLS protocols directed at optimising physiology to prevent secondary brain injury, and with intensive care unit (ICU) involvement for airway management as appropriate. Children with open sutures can lose substantial blood volumes into the head. Palpating the fontanelle allows direct assessment of ICP, and in all cases head and neck CT imaging are key to guiding definitive management.

TABLE 28.7 UK National Institute for Health and Care Excellence criteria for computed tomography scan in children following head injury.

- Suspicion of NAI
- First seizure
- GCS <14 or <15 in under-ones
- GCS <15 2 hours post injury
- Signs of fracture of the base of skull
- Focal neurological deficit

CHAPTER
29 Torso and pelvic trauma

Learning objectives

To understand:

- The importance of physiology over anatomy in the management of trauma
- The gross surgical anatomy of the chest and abdomen
- The pathophysiology of torso injury
- The clinical assessment in the injured patient
- The use of special investigations and their limitations
- The operative approaches to the thoracic cavity
- The special features of an emergency department thoracotomy for haemorrhage control
- The indications for, and techniques of, the trauma laparotomy
- The philosophy of damage control resuscitation
- The management of trauma to the pelvis

INTRODUCTION

Injury seldom respects anatomical boundaries, hence the division of the body into the abdomen and the thorax is artificial. Therefore, injury to the torso with its associated physiological consequences is more appropriate. The torso is generally regarded as the focal point of the human body, consisting of the chest, abdomen and pelvis and not including the head, neck, arms and legs. About 42% of all deaths are the result of brain injury, but some 39% of all trauma deaths are caused by major haemorrhage, usually from torso injury (***Figure 29.1***).

Historically, injury was treated on an anatomical basis; however, it has become clear that physiology should be the over-riding consideration. The driver of successful resuscitation is therefore the preservation of normal physiology. Techniques such as damage control resuscitation and its key component damage control surgery have dramatically improved survival through an understanding of the best techniques required to restore physiological stability (see ***Chapters 1, 26 and 27***).

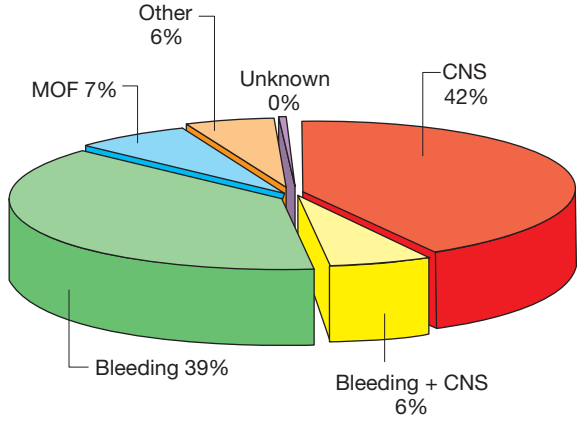

Figure 29.1 Causes of death in trauma. CNS, central nervous system; MOF, multiple organ failure.

INJURY MECHANISMS ASSOCIATED WITH TORSO TRAUMA

Injury consistently traverses different anatomical zones of the body, affecting structures on both sides of traditional anatomical zones. These zones are known as junctional zones.

Junctional zones

The key junctional zones are:

- between the neck and the thorax;
- between the thorax and the upper limbs;
- between the thorax and the abdomen;
- between the abdominopelvic structures and the groin.

These zones represent surgical challenges in terms of both diagnosis of the area of injury and the required surgical approach. Such factors have to be balanced against the physiological stability of the patient.

Root of the neck

Most injuries affecting the base of the neck may also affect the upper mediastinum and thoracic inlet. Choice of access is determined by the need for surgical control of the vascular structures contained within.

The mediastinum

The mediastinum, with its major vessels and the heart, is also an extremely high-risk area for penetrating wounds. Any wound in this region should immediately raise the suspicion of a major vascular or an associated cardiac injury, even in the absence of initial gross physical signs.

Diaphragm

The thorax and abdomen are separated by the diaphragm, which is mainly responsible for breathing, allowing movement

during breathing between the fourth and eighth intercostal space. Any penetrating injury below the nipples on the chest may therefore have penetrated the diaphragm and entered the abdomen. Injuries in this junctional zone, therefore, should be investigated as if both cavities had been penetrated (*Figure 29.2*). In blunt trauma, rupture of the diaphragm can result in migration of abdominal viscera into the chest, with left-sided hemidiaphragm rupture being more common.

Pelvic structures

The pelvis contains a large plexus of vessels, both venous and arterial. Should injury occur, control of haemorrhage can prove to be exceptionally difficult and may require control of both arterial inflow and venous outflow. Angioembolisation can be a very useful adjunct to treatment, especially with deep pelvic injuries.

Summary box 29.1

Junctional zones

- Between neck and the thorax
- Between thorax and upper limbs
- Between thorax and the abdomen
- Between the abdominopelvic structures and the groin

CRITICAL PHYSIOLOGY

Resuscitation of all injuries to the chest and abdomen should follow the latest Advanced Trauma Life Support (ATLS) principles (*Table 29.1*; see *Chapters 26 and 27*).

TABLE 29.1 Advanced Trauma Life Support principles of resuscitation.

C	Catastrophic haemorrhage
A	Airway
B	Breathing
C	Circulation
D	Disability (neurology)
E	Environment and exposure

TABLE 29.2 Clinical indicators of potential ongoing bleeding in torso trauma.

Physiological	Increasing respiratory rate
	Increasing pulse rate
	Falling blood pressure
	Rising serum lactate
Anatomical	Visible bleeding
	Injury in close proximity to major vessels
	Penetrating injury with a retained missile

Haemorrhage is the major problem. This may be obvious at the time of evaluation; however, in the young physically fit individual, bleeding may produce no or only minimal changes in vital measures and, therefore, be difficult to assess (*Table 29.2*). Although obvious injury may be present, traditional indicators (such as pulse rate), in isolation, are unreliable.

Bleeding occurs from five major sites – '**one on the floor and four more**':

- external – 'floor';
- chest;
- abdomen (including the retroperitoneum);
- pelvis;
- extremities.

THORACIC INJURY

Thoracic injury accounts for 25% of all severe injuries. In a further 25%, it may be a significant contributor to the subsequent death of the patient. In most of these patients, the cause of death is haemorrhage. In excess of 80% of patients with chest injury can be managed non-operatively. The key to a good outcome is early physiological resuscitation followed by a correct diagnosis.

Investigation

Routine investigation in the emergency department of injury to the chest is based on clinical examination, supplemented by appropriate imaging.

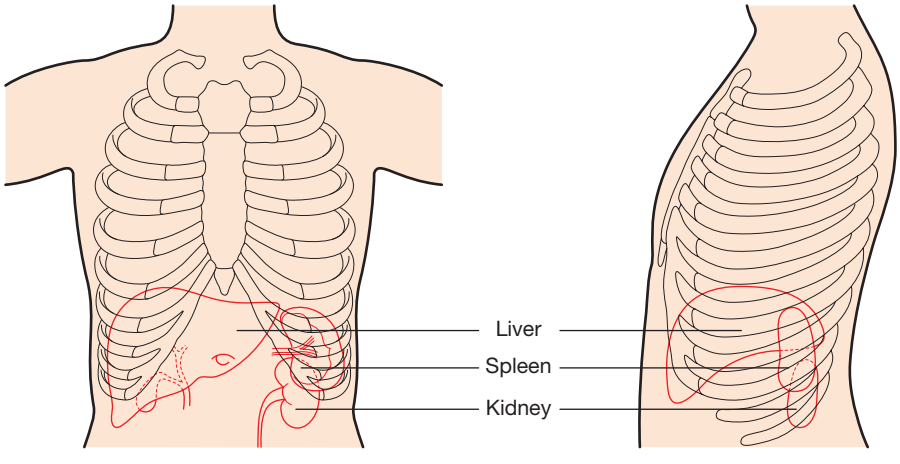

Figure 29.2 The anatomical extent of the abdomen.

Ultrasound – extended focused assessment with sonography for trauma (eFAST)

Ultrasound can be used to differentiate between contusion and the actual presence of blood. Extended focused assessment with sonography for trauma (eFAST) is becoming the most common investigation. The technique uses sonographic assessment in the chest, looking for a cardiac tamponade or free blood and air in the hemithoraces, and assessment for blood in the abdominal cavity, in the paracolic gutters, subdiaphragmatic spaces and pelvis.

Finger thoracostomy

In the physiologically grossly unstable patient, where physical examination is inconclusive and there is no time for radiological investigations, bilateral finger thoracostomy can be a diagnostic procedure as well as a therapeutic one, and the benefits of undertaking it often outweigh the risks. It is undertaken by making a 5-cm skin incision on the fifth rib just anterior to the mid-axillary line. The intercostal muscles are then separated just above the fifth rib and the pleural cavity entered. A finger is then inserted and a pleural sweep made to ensure the pleural cavity has been entered.

Chest radiograph

In those cases where the patient is physiologically non-compromised or the spine is at risk, an anteroposterior (AP) supine chest radiograph is usually the simplest initial investigation. It will provide good information regarding tracheal deviation, lung and mediastinal pathology as well as skeletal injury.

In penetrating injury, it may be more helpful for the radiograph to be performed with the patient positioned erect, as this will best reveal a small pneumothorax, fluid meniscus, air–fluid level or the presence of free gas under the diaphragm, indicating the presence of a hollow abdominal viscus perforation. Note that up to 300 mL of blood may pool behind the domes of the diaphragm, and may not be visible even in the erect view.

The presence of thoracic skeletal injury should alert the clinician to the possibility of adjacent thoracic or abdominal visceral injury. Rupture of the thoracic aorta can be related to fractures of the first and second rib, bilateral clavicular fracture and fracture of the sternum, thoracic spine or scapula. Fracture of the lower ribs can be related to injury of the liver or spleen. Fracture of the ribs, irrespective of site, can be related to injury to the lung parenchyma or thoracic wall vasculature, causing pneumothorax, haemothorax or lung contusion.

Computed tomography scan

The computed tomography (CT) scan with contrast allows for three-dimensional reconstruction of the chest and abdomen, as well as of the bony skeleton. It has become the principal and most reliable examination for major injury in trauma. In blunt chest trauma, the CT scan will allow the definition of fractures, as well as showing haematomas, pneumothoraces and pulmonary contusion. In penetrating trauma, the scan may show the track or presence of the missile and allow the proper planning of definitive surgery. However, although the presence of an isolated rupture of the diaphragm with migration of abdominal contents into the chest can be detected by CT scan, in injury without migration the diagnosis will not be obvious.

The pitfalls of investigation are:

- failure to assess tracheal shift immediately above the sternal notch clinically (deviation of the trachea occurs away from the affected side in tension pneumothorax and towards the affected side in lung collapse);
- failure to percuss and auscultate both front and back in a supine patient (an inflated lung will 'float' on a haemothorax, so auscultation from the front may sound normal);
- failure to pass a nasogastric tube if rupture of the diaphragm is suspected; a chest radiograph will show the nasogastric tube apparently within the chest cavity;
- a supine chest radiograph can show a haemothorax as a homogeneous increase in opacity of the hemithorax – this can cause confusion between the darker side and the lighter side as to which may be a haemothorax (less radiolucent) or a pneumothorax (more radiolucent); look carefully for lung markings and do not drain the wrong side;
- pursuing radiological investigation (radiography or CT scan) instead of resuscitation in the unstable patient.

Summary box 29.2

Investigation of chest injuries

- Directly or indirectly involved in >50% of trauma deaths
- More than 80% can be managed non-operatively
- A chest radiograph is the investigation of first choice
- Finger thoracostomy can be diagnostic and therapeutic
- A pan-CT scan provides rapid diagnosis

Management

In penetrating injury, most patients who have suffered injury to the chest can be managed with appropriate resuscitation and insertion of an intercostal drain.

If a sucking chest wound is present, this should not be fully closed but should be covered with a piece of plastic, closed on three sides to form a one-way valve, and thereafter an underwater chest drain should be inserted remote from the wound. No attempt should be made to close a sucking chest wound until controlled drainage has been achieved, in case a stable patient with an open pneumothorax is converted into an unstable patient with a tension pneumothorax.

In blunt injury, most bleeding occurs from the intercostal or internal mammary vessels and it is relatively rare for these to require surgery. If bleeding does not stop spontaneously, the vessels can be embolised, via an interventional radiological approach, or treated operatively, during which the vessels can be tied off or encircled. In blunt chest compressive injury, particularly in the presence of a flail chest, there can be an associated lung contusion.

The patient in extremis with exsanguinating chest haemorrhage is discussed in ***Emergency department thoracotomy or sternotomy***.

Life-threatening injuries can be remembered as the 'deadly dozen'. Six are immediately life-threatening and should be

Summary box 29.3

Closed management of chest injuries

- More than 80% of chest injuries can be managed with the insertion of an intercostal drain only
- Do not close a sucking chest wound until a drain is in place
- If bleeding persists, the chest will need to be opened and direct haemostatic control is obtained

sought and managed during the primary survey and six are potentially life-threatening and should be detected during the secondary survey (***Table 29.3***). A high index of suspicion must be maintained thereafter to diagnose the potential threats to life, as their symptoms and signs can be very subtle. Early consultation and referral to a trauma centre is advised in cases of doubt.

Immediate life-threatening injuries

Airway obstruction

Early intubation is very important, particularly in cases of neck haematoma or possible airway oedema. Airway distortion can be insidious and progressive and can make delayed intubation more difficult if not impossible.

Tension pneumothorax

A tension pneumothorax develops when a 'one-way valve' air leak occurs either from the lung or through the chest wall. Air is sucked into the thoracic cavity without any means of escape, completely collapsing and then compressing the affected lung. The mediastinum is displaced to the opposite side, decreasing venous return and compressing the opposite lung.

The most common causes are penetrating chest trauma, blunt chest trauma with a parenchymal lung injury and air leak that did not spontaneously close, iatrogenic lung injury (e.g. due to central venepuncture) and mechanical positive-pressure ventilation.

TABLE 29.3 The 'deadly dozen' threats to life from chest injury.

Immediately life-threatening	• Airway obstruction • Tension pneumothorax • Pericardial tamponade • Open pneumothorax • Massive haemothorax • Flail chest
Potentially life-threatening	• Aortic injuries • Tracheobronchial injuries • Myocardial contusion • Rupture of the diaphragm • Oesophageal injuries • Pulmonary contusion

The clinical presentation is dramatic. The patient is increasingly restless with tachypnoea, dyspnoea and distended neck veins (similar to pericardial tamponade). Clinical examination may reveal tracheal deviation; this is a late finding and is not

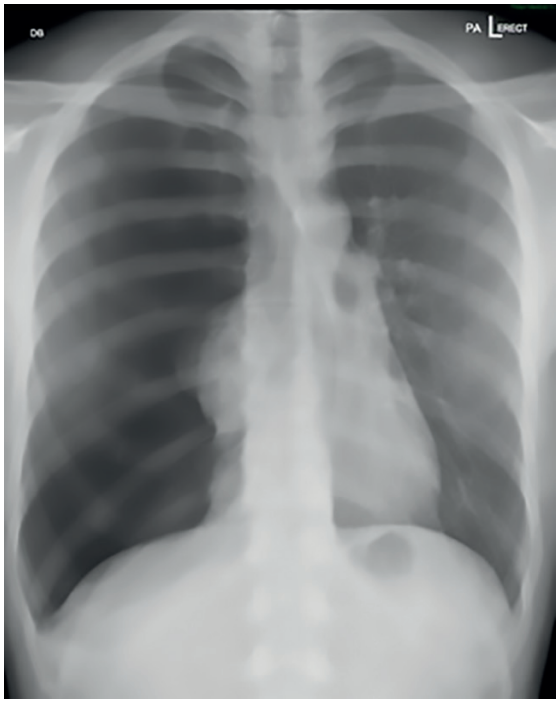

Figure 29.3 Radiological appearance of a tension pneumothorax (courtesy of Dr Elizabeth Dick, Consultant Radiologist, Imperial College Healthcare NHS Trust, London, UK).

necessary to clinically confirm diagnosis. There will also be hyper-resonance and decreased or absent breath sounds over the affected hemithorax. Tension pneumothorax is a clinical diagnosis and treatment should never be delayed by waiting for radiological confirmation. Always treat it with a high index of suspicion of being present (***Figure 29.3***).

Treatment consists of immediate decompression. This was historically taught by rapid insertion of a large-bore cannula into the second intercostal space in the mid-clavicular line of the affected side, followed by insertion of a chest tube through the fifth intercostal space in the anterior axillary line. However, current teaching advocates undertaking decompression in the safe triangle – defined posteriorly by latissimus dorsi, anteriorly by the lateral border of pectoralis major and inferiorly by a line perpendicular to the nipple going to the back, just anterior to the mid-axillary line – or, in extremis, a finger thoracostomy at the same location.

Pericardial tamponade

Pericardial tamponade needs to be differentiated from a tension pneumothorax in the shocked patient with distended neck veins. It is most commonly the result of penetrating trauma. Accumulation of a relatively small amount of blood (50 mL) into the non-distensible pericardial sac can produce compression of the heart and obstruction of the venous return, leading to decreased filling of the cardiac chambers during diastole. All patients with penetrating injury anywhere near the heart plus shock must be considered to have a cardiac injury until proven otherwise. Classically, the presentation consists of central venous pressure elevation, a decline in arterial pressure with tachycardia and muffled heart sounds. However, in cases

in which major bleeding from other sites has taken place, the neck veins may be flat. A high index of suspicion and further diagnostic investigations will be needed to make the diagnosis is those cases that are not clinically obvious. These include an eFAST showing fluid in the pericardial sac, which is the most expeditious and reliable diagnostic tool, or chest radiography, looking for an enlarged heart shadow.

In penetrating injury to the heart there is usually a substantial clot in the pericardium, which may prevent aspiration. **Pericardiocentesis has no role in the management of cardiac tamponade secondary to penetrating myocardial injury**. The correct immediate treatment of tamponade is operative, either via a subxiphoid window or by open surgery (sternotomy or left anterolateral thoracotomy), with repair of the heart in the operating theatre if time allows or otherwise in the emergency department.

Summary box 29.4

Pericardial tamponade

- The presentation is similar to a tension pneumothorax – deteriorating cyanosis, tachycardia and agitation
- eFAST is diagnostic and may also detect free fluid in the abdomen or pericardium
- There is no role for pericardiocentesis in traumatic cardiac tamponade. A left anterolateral thoracotomy or sternotomy should be performed with evacuation of the haematoma and repair of the myocardium

Open pneumothorax ('sucking chest wound')

This is due to a large open defect in the chest (>3 cm), leading to immediate equilibration between intrathoracic and atmospheric pressure. If the opening in the chest wall exceeds about two-thirds of the diameter of the trachea, then with each inspiratory cycle air will be preferentially drawn through the defect rather than through the trachea. Air accumulates in the hemithorax (rather than in the lung) with each inspiration, leading to profound hypoventilation on the affected side and hypoxia. If there is a valvular effect, increasing amounts of air in the pleura will result in a tension pneumothorax (see ***Tension pneumothorax***).

Initial management consists of promptly closing the defect with a sterile occlusive plastic dressing (e.g. OPSITE◊ or similar product), taped on three sides to act as a flutter-type valve. A chest tube is inserted as soon as possible in a site remote from the injury site.

Massive haemothorax

The most common cause of massive haemothorax in blunt injury is continuing bleeding from torn intercostal vessels or occasionally from the internal mammary artery secondary to fractures of the ribs. In penetrating injury, a variety of viscera, both thoracic and abdominal (with blood leaking through a hole in the diaphragm from the positive pressure abdomen into the negative pressure thorax), may be involved.

Accumulation of blood in a haemothorax can significantly compromise respiratory efforts, compressing the lung and preventing adequate ventilation. Presentation is with haemorrhagic shock, flat neck veins, unilateral absence of breath sounds and dullness to percussion. The initial treatment consists of correcting the hypovolaemic shock, insertion of an intercostal drain and, in some cases, intubation. Initial drainage of more than 1500 mL of blood or ongoing haemorrhage of more than 200 mL/h over 3–4 hours is generally considered an indication for urgent thoracotomy.

Blood in the pleural space should be removed as completely and rapidly as possible to prevent ongoing bleeding, an empyema or fibrothorax later. **There is no role for clamping a chest tube to tamponade a massive haemothorax**.

The following points are important in the management of an open pneumothorax/haemothorax:

- if the lung does not reinflate, the drain should be placed on low-pressure (5 cmH_2O) suction;
- clot occlusion of a chest drainage tube may result in 'no' drainage, even in the presence of ongoing bleeding;
- a second drain is sometimes necessary (but see ***Tracheobronchial injuries***);
- a chest radiograph or eFAST can help identify the presence of blood;
- physiotherapy and active mobilisation should begin as soon as possible.

Flail chest

This condition usually results from blunt trauma associated with multiple rib fractures, and is defined as three or more ribs fractured in two or more places. The blunt force typically also produces an underlying pulmonary contusion. The diagnosis is made clinically in patients who are not ventilated, not by radiography. To confirm the diagnosis the chest wall can be observed for paradoxical motion of a chest wall segment. On inspiration, the loose segment of the chest wall is displaced inwards and therefore less air moves into the lungs. On expiration, the segment moves outwards (paradoxical respiration). Voluntary splinting of the chest wall occurs as a result of pain, so mechanically impaired chest wall movement and the associated lung contusion all contribute to the hypoxia. There is a high risk of developing a pneumothorax or haemothorax. The CT scan remains the gold standard for diagnosis of this condition.

Traditionally, mechanical ventilation was used to 'internally splint' the chest but had a price in terms of intensive care unit (ICU) resources and ventilation-dependent morbidity. Currently, treatment consists of oxygen administration, adequate analgesia (including opiates) and physiotherapy. If a chest tube is in place, topical intrapleural local analgesia introduced via the tube can also be used. Ventilation is reserved for patients developing respiratory failure despite adequate analgesia and oxygen. Surgery to stabilise the flail segment using internal fixation of the ribs may be useful in a selected group of patients with isolated or severe chest injury and pulmonary contusion.

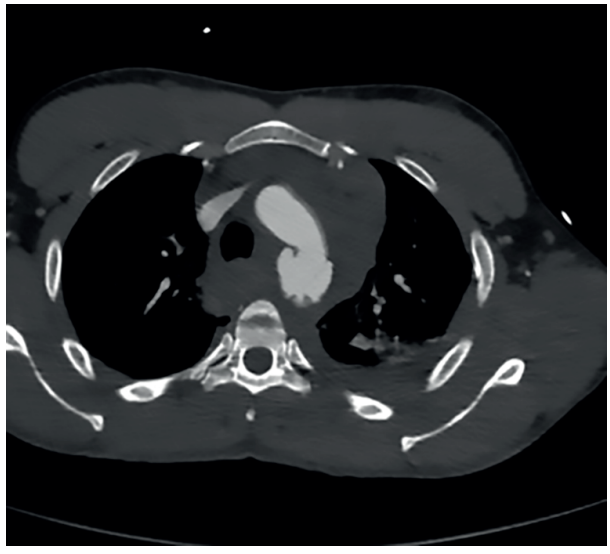

Figure 29.5 Computed tomography scan showing aortic disruption (courtesy of Dr Elizabeth Dick, Consultant Radiologist, Imperial College Healthcare NHS Trust, London, UK).

Potentially life-threatening injuries

Thoracic aortic disruption

Traumatic aortic rupture is a common cause of sudden death after a vehicle collision or fall from a great height. The vessel is relatively fixed distal to the ligamentum arteriosum, just distal to the origin of the left subclavian artery. The shear forces from a sudden impact disrupt the intima and media. If the adventitia is intact, the patient may remain physiologically non-compromised.

Thoracic aortic injury should be clinically suspected in patients with gross asymmetry in systolic blood pressure (between the two upper limbs, or between upper and lower limbs), widened pulse pressure and chest wall contusion. Erect chest radiography can also suggest thoracic aortic disruption, the most common radiological finding being a widened mediastinum (***Figure 29.4***). The diagnosis is confirmed by a CT scan of the mediastinum (***Figure 29.5***). In the hypotensive patient, widening of the mediastinum and aortic injury is not the cause of the hypotension. Invariably, these patients have other injuries causing hypotension as patients with complete aortic disruption rarely, if ever, survive to reach hospital.

In the presence of thoracic aortic injury, initial management consists of control of the systolic arterial blood pressure (to less than 120 mmHg). Thereafter, an endovascular intra-aortic stent (***Figure 29.6***) can be placed, or the tear can be operatively repaired by direct repair or by excision and grafting using a Dacron graft.

Tracheobronchial injuries

Severe subcutaneous emphysema with respiratory compromise can suggest tracheobronchial disruption. A chest drain placed on the affected side will reveal a large air leak and the collapsed lung may fail to re-expand. Bronchoscopy is diagnostic. Treatment involves intubation of the unaffected bronchus followed by operative repair. Referral to a trauma centre is advised.

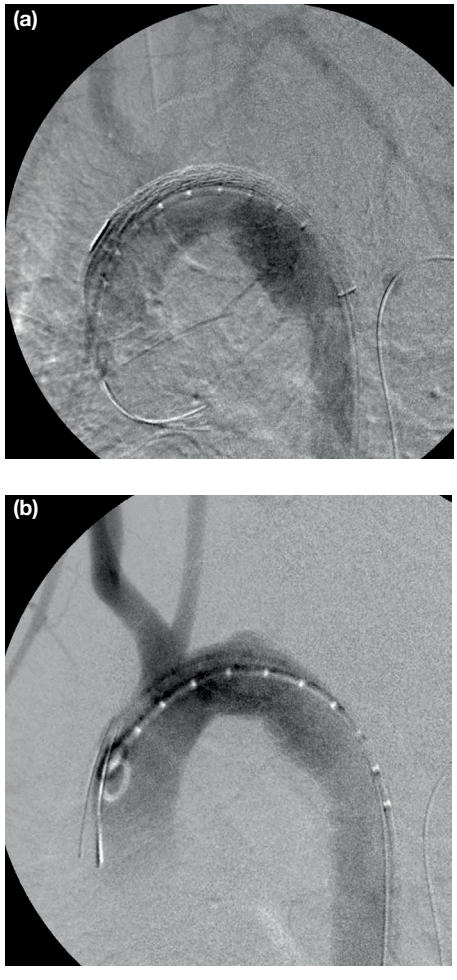

Figure 29.6 (a) Aortic tear showing the presence of a preinflation stent and test run. **(b)** Aortic tear post inflation of the stent and test run (courtesy of Dr Elizabeth Dick, Consultant Radiologist, Imperial College Healthcare NHS Trust, London, UK).

Blunt myocardial injury

Significant blunt cardiac injury that causes haemodynamic and physiological instability is rare. Blunt myocardial injury should be suspected in any patient sustaining blunt trauma who develops early electrocardiogram abnormalities.

Transthoracic echocardiography may show wall motion abnormalities. A transoesophageal echocardiogram may also be helpful. There is very little evidence that enzyme estimations have any place in diagnosis.

All patients with myocardial contusion diagnosed with conduction abnormalities are at risk of developing sudden dysrhythmias and should be closely monitored.

Diaphragmatic injuries

Any penetrating injury below the fifth intercostal space should raise suspicion of diaphragmatic penetration and, therefore, injury to abdominal contents.

Blunt injury to the diaphragm is usually caused by a compressive force applied to the torso. The diaphragmatic rupture is usually large, with herniation of the abdominal contents into the chest. Diagnosis of diaphragmatic rupture can easily be missed in the acute phase, and may only be discovered at operation or through the presentation of complications.

Most diaphragmatic injuries are silent and the presenting features are those of injury to the surrounding organs. There is no single standard investigation. Historically and in limited resource environments, chest radiography after placement of a nasogastric tube may be helpful (as this may show the stomach herniated into the chest). CT scan and ultrasound scan all lack positive or negative predictive value. The most accurate evaluation is by video-assisted thoracoscopy or laparoscopy, the latter offering the advantage of allowing the surgeon to proceed to a repair and additional evaluation of the abdominal organs.

The thorax is at negative pressure and the abdomen is at positive pressure. A complication of a breach of the diaphragm is herniation of abdominal contents into the chest. This may present much later, and strangulation of any of the contents can then occur, with a high mortality rate. Operative repair is recommended in all cases. All penetrating diaphragmatic injury must be repaired via the abdomen – and not the chest – to rule out penetrating hollow viscus injury.

Oesophageal injury

Most oesophageal injuries result from penetrating trauma; blunt injury is rare but should be suspected in patients exposed to barotrauma. A high index of suspicion is required. The patient can present with odynophagia (pain on swallowing saliva, foods or fluids), subcutaneous or mediastinal emphysema, pleural effusion, air in the perioesophageal space and unexplained fever. Mediastinal and deep cervical emphysema are evidence of an aerodigestive injury until proven otherwise.

The mortality rate rises exponentially if treatment is delayed. A combination of CT with oral contrast and oesophagoscopy confirms the diagnosis in the great majority of cases. The treatment is operative repair of any defect and drainage.

Pulmonary contusion

Pulmonary contusion occurs more frequently following blunt trauma, and is usually associated with a flail segment or fractured ribs. This is a very common, potentially lethal injury and the major cause of hypoxaemia after blunt trauma. Following gunshot wounds, there is an area of contusion from the shock wave of the bullet.

The natural progression of pulmonary contusion is worsening hypoxaemia for the first 24–48 hours. Chest radiographic findings may be typically delayed. Contrast CT scanning can be confirmatory. Haemoptysis or blood in the endotracheal tube is a sign of pulmonary contusion. In mild contusion, the treatment is oxygen administration, pulmonary toilet and adequate analgesia. In more severe cases mechanical ventilation is necessary. Normovolaemia is critical for adequate tissue perfusion and fluid restriction is not advised.

EMERGENCY THORACIC SURGERY

Emergency thoracic surgery is an essential part of the armamentarium of any surgeon dealing with major trauma. A timely surgical intervention for the correct indications can be the key step in saving an injured patient's life.

It is important to make a distinction between:

- immediate thoracotomy in the emergency department for the control of haemorrhage, cardiac tamponade or internal cardiac massage;
- emergency sternotomy for anterior mediastinal structures and the heart;
- planned thoracotomy for definitive correction of the problem – this usually takes place in the more controlled environment of the operating theatre.

The clinical decision as to whether a patient requires surgery in the emergency department or they can be transferred to the operating theatre can be complex. It is far better to perform a thoracotomy in the operating theatre, either through an anterolateral approach or a median sternotomy, with good light and assistance and the potential for autotransfusion or bypass, than it is to attempt heroic emergency surgery in the resuscitation area. However, if the patient is *in extremis* with a falling systolic blood pressure, there is no choice but to proceed immediately with a left anterolateral thoracotomy. In certain circumstances, when care is futile, it may not need to be performed at all. A resuscitation room thoracotomy following blunt trauma has limited indications and is rarely successful.

Emergency department thoracotomy or sternotomy

Emergency department thoracotomy (EDT) should be reserved for those patients with penetrating injury in whom signs of life are still present. Patients who have received cardiopulmonary resuscitation (CPR) in the prehospital phase of their care are unlikely to survive, and electrical activity must be present.

In certain situations, EDT is considered futile:

- CPR for more than 15 minutes (despite endotracheal intubation) in the presence of penetrating thoracic trauma;
- CPR for more than 10 minutes (despite endotracheal intubation) in the presence of blunt thoracic trauma;
- blunt trauma when there have been no signs of life at the scene.

The survival rates for EDT in patients with penetrating trauma in whom the blood pressure is falling despite adequate resuscitation are shown in *Table 29.4*.

TABLE 29.4 Survival rates for thoracotomy in patients with penetrating trauma.

Blood pressure despite resuscitation	Survival
>60 mmHg	60%
>40 mmHg	30%
<40 mmHg	3%

The aim of EDT is to perform:

- internal cardiac massage in the cardiovascularly 'full' patient (no role for internal massage in the 'empty' patient);
- control of haemorrhage from injury to the heart or lung;
- control of intrathoracic haemorrhage from other sources;
- control of massive air leak;
- clamping of the thoracic aorta to preserve the blood supply to the heart and brain, and cutting off the arterial supply distally, in a moribund patient with a major distal penetrating injury.

Planned emergency thoracotomy

Planned emergency thoracotomy implies an emergency thoracotomy performed as a planned procedure in the operating theatre, directed at the management of a specific injury. As such, the approach chosen is dependent on the indication for surgery and the organ injured (*Table 29.5*). Some organs are best approached through a median sternotomy. Otherwise the thoracotomy may be right or left sided, and these may be joined, producing the so-called 'clamshell incision'. This gives excellent exposure for any surgeon who is not routinely entering the chest.

Posterolateral thoracotomy is not used in the emergency situation because of the difficulties in positioning of the patient, except for specific access to certain posterior mediastinal organs.

TABLE 29.5 Different approaches to the contents of the chest cavity.

Approach	Best for
Left anterolateral thoracotomy	• Left lung and lung hilum • Thoracic aorta • Origin of left subclavian artery • Left side of heart • Lower oesophagus
Right anterolateral thoracotomy	• Right lung and lung hilum • Azygos veins • Superior vena cava • Infracardiac inferior vena cava • Upper oesophagus • Thoracic trachea
Median sternotomy	• Anterior aspect of heart • Anterior mediastinum • Ascending aorta and arch of aorta • Pulmonary arteries • Carina of the trachea

ABDOMINAL INJURY

Patients who have suffered abdominal trauma can generally be classified into the following categories based on their physiological condition after initial resuscitation:

- physiologically 'normal' – investigation can be completed before treatment is planned;
- physiologically 'non-compromised' – investigation is more limited; it is aimed at establishing whether the patient can be managed non-operatively, whether angioembolisation can be used or whether surgery is required;
- physiologically 'compromised' – investigations need to be suspended as immediate surgical correction of the bleeding is required.

A trauma laparotomy is the final step in the pathway to delineate intra-abdominal injury. Occasionally it is difficult to determine the source of bleeding in the shocked, multiple injured patient. If doubt still exists, especially in the presence of other injuries, a laparotomy may still be the safest option. The key is to make a decision, as indecision leads to delay in definitive control.

The patient's physiology must be assessed constantly; if there is an indication that the patient is still actively bleeding, the source must be identified unless the patient is unstable and requires immediate surgery. Blood loss into the abdomen can be subtle and there may be no clear clinical signs. Blood is not an irritant and does not initially cause any abdominal pain. Distension is subjective, and a drop in the blood pressure may be a very late sign in a young fit patient. Examination in compromised patients should take place either in the emergency department or in the operating theatre if the patient is deteriorating rapidly.

Investigation

Investigations are driven by the cardiovascular status of the patient. In torso trauma, the best and most sensitive modality is a CT scan with intravenous contrast; however, in the unstable patient, this is generally not possible.

In patients with penetrating injury, metal markers (e.g. bent paper clips) should be placed on all external wounds before plain films are taken, irrespective of the area being radiographed, as this allows an assessment of the trajectory and helps to correlate the number of holes and the number of missiles that can be seen within the patient. This will help determine whether two holes are indicative of one missile passing through the patient, or two missiles, both retained internally (*Figure 29.7*). A single hole implies that the projectile has been retained.

Focused abdominal sonography for trauma and extended FAST (FAST and eFAST)

Focused abdominal sonography for trauma (FAST) is a technique whereby ultrasound (sonography) imaging is used to assess the torso for the presence of free fluid in the abdominal cavity, and is extended into the thoracic cavities and pericardium (eFAST). There should be no attempt to determine the nature or extent of the specific injury. eFAST is usually a

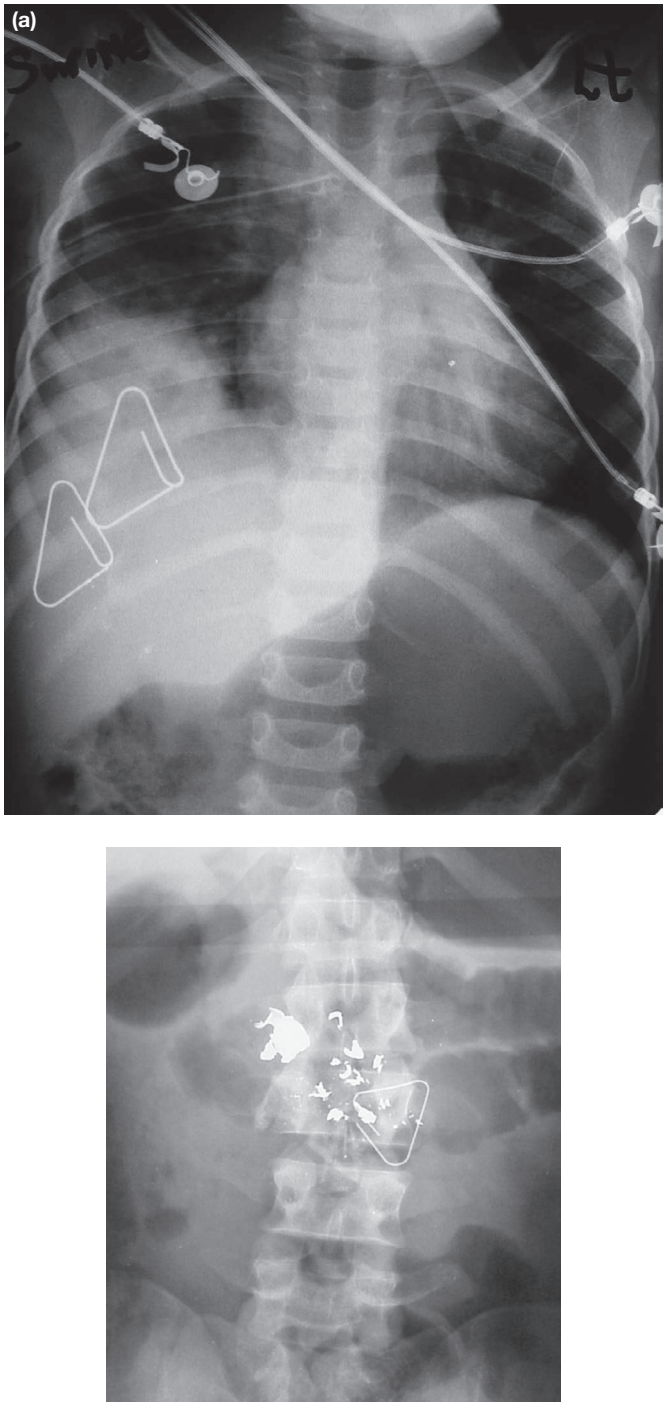

Figure 29.7 (a) Chest radiograph showing a gunshot wound with bullet markers. **(b)** Abdominal radiograph of a gunshot wound showing bullet markers.

rapid, reproducible, portable and non-invasive bedside test and can be performed at the same time as resuscitation. eFAST is accurate at detecting >100 mL of free blood; however, it is very operator dependent and, especially if the patient is very obese or the bowel is full of gas, it may be unreliable. Hollow viscus injury and solid organ injury are difficult to diagnose, even in experienced hands, as small amounts of gas or fluid are difficult to assess and eFAST has a low sensitivity (29–35%) for organ injury without haemoperitoneum. eFAST is also unreliable for excluding injury in penetrating trauma. If there is doubt, the eFAST examination can be repeated.

Summary box 29.5

Utilisation of eFAST

- Detects free fluid in the abdomen or pericardium
- Will not reliably detect less than 100 mL of free blood
- Does not directly identify injury to hollow viscus
- Cannot reliably exclude injury in penetrating trauma
- May need repeating or supplementing with other investigations
- Is unreliable for assessment of the retroperitoneum

Diagnostic peritoneal lavage

Diagnostic peritoneal lavage (DPL) is a test rarely used in modern-day practice but can be of value in resource-limited settings. It is a test used to assess the presence of blood or contaminants in the abdomen. A nasogastric tube is placed to empty the stomach and a urinary catheter is inserted to drain the bladder.

A cannula is inserted below the umbilicus, directed caudally and posteriorly. The cannula is aspirated for blood (>10 mL is deemed as positive) and, following this, 500 mL of warmed Ringer's lactate solution is allowed to run into the abdomen from a 1-litre bag. The bag, with 500 mL remaining, is placed on the floor and the intra-abdominal fluid is allowed to flow under the influence of gravity – this aids drainage. The presence of frank blood or similar contents to a nasogastric tube or urinary catheter denotes a positive DPL. If time allows and laboratory diagnosis is available, the presence of >100 000 red cells/μL or >500 white cells/μL is deemed positive (this is equivalent to 20 mL of free blood in the abdominal cavity), as is a raised amylase level. In the absence of laboratory facilities, a urine dipstick may be useful. Drainage of lavage fluid via a chest drain indicates penetration of the diaphragm.

Although DPL has largely been replaced by eFAST (see ***Focused abdominal sonography for trauma and extended FAST (FAST and eFAST)***), it remains the standard in many institutions where eFAST is not available or is unreliable.

Computed tomography scan

CT has become the 'gold standard' for the intra-abdominal diagnosis of injury in the stable patient. The scan can be performed using intravenous contrast. CT is sensitive for blood and individual organ injury as well as for retroperitoneal injury. An entirely normal abdominal CT is usually sufficient to exclude intraperitoneal injury.

The following points are important when performing CT:

- it remains an inappropriate investigation for physiologically compromised patients;

Sydney Ringer, 1835–1910, Professor of Clinical Medicine, University College Hospital, London, UK.

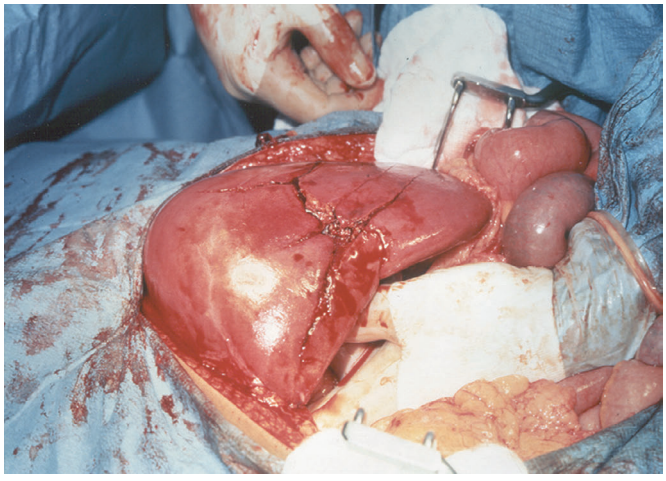

Figure 29.8 Compression injury to the liver, bursting the liver substance.

- if duodenal injury is suspected from the mechanism of injury, oral contrast may be helpful;
- if rectal and distal colonic injury is suspected in the absence of blood on rectal examination, air around the colon may indicate injury; in all cases clinical suspicion supersedes investigation results.

Laparoscopy

Laparoscopy or thoracoscopy may be a valuable screening investigation in physiologically non-compromised patients with penetrating trauma to detect or exclude peritoneal penetration and/or diaphragmatic injury.

Laparoscopy may be divided into:

- screening: used to exclude a penetrating injury with breach of the peritoneum;
- diagnostic: finding evidence of injury to viscera;
- therapeutic: used to repair the injury.

In most institutions, evidence of penetration requires a laparotomy to evaluate organ injury as it is difficult to exclude all intra-abdominal injuries laparoscopically. When used in this role laparoscopy reduces the non-therapeutic laparotomy rate. There is no place for laparoscopy in the unstable patient.

INDIVIDUAL ORGAN INJURY

Liver

Blunt liver trauma occurs as a result of direct injury. The liver is a solid organ and compressive forces can easily burst the liver substance (***Figure 29.8***). The liver is usually compressed between the impacting object and the ribcage or vertebral column. Most injuries are relatively minor and can be managed non-operatively.

Penetrating trauma to the liver is relatively common. Bullets have a shock wave and when they pass through a solid structure such as the liver they cause significant damage some distance from the actual track of the bullet. Not all penetrating wounds require operative management and may stop bleeding spontaneously.

In the physiologically non-compromised patient, CT is the investigation of choice. It provides information on the liver injury itself, as well as on injuries to the adjoining major vascular and biliary structures. Injury in which there is a suggestion of a vascular component should be reimaged, as there is a significant risk of the development of subsequent ischaemia, false aneurysms, arteriovenous fistulae or haemobiliary fistula. It is advised that all patients should be rescanned prior to discharge.

Liver injury can be graded and managed using the American Association for the Surgery of Trauma (AAST) Injury Scoring Scale (ISS) (https://www.aast.org/resources-detail/injury-scoring-scale).

Management

The operative management of liver injuries can be summarised as 'the four Ps':

- Pressure;
- Pringle;
- Plug;
- Pack.

At laparotomy the liver is reconstituted and bleeding is controlled by direct bimanual compression to achieve its normal architecture as best as possible (Pressure). The inflow from the portal triad is controlled by a Pringle's manoeuvre, with direct compression of the portal triad, either digitally or using a soft clamp (***Figure 29.9***). This has the effect of reducing arterial and portal venous inflow into the liver, although it does not control the backflow from the inferior vena cava and hepatic veins. Any holes due to penetrating injury can be plugged directly using silicone tubing or a Sengstaken–Blakemore tube; after controlling any arterial bleeding, the liver can then be packed (see ***Damage control surgery***).

Bleeding points should be controlled locally when possible, and such patients, if required, subsequently undergo angioembolisation. It is not usually necessary to suture penetrating injuries of the liver unless haemostasis cannot be controlled by other means. If there has been direct damage to the hepatic artery, it can be tied off. Damage to the portal vein must be repaired, as tying off the portal vein carries a greater than 50% mortality rate. If it is not technically feasible to repair the vein at the time of surgery, it should be shunted and the patient referred to a specialist centre. A drainage system must be left *in situ* following hepatic surgery. Finally, the liver can be definitively packed, restoring the anatomy as closely as possible. Placing omentum into cracks in the liver is not recommended.

James Hogarth Pringle, 1863–1941, Australian-born surgeon, The Royal Infirmary, Glasgow, UK.
Robert William Sengstaken, 1923–1978, surgeon, Garden City, NY, USA, and **Arthur Hendley Blakemore**, 1897–1970, Associate Professor of Surgery, The College of Physicians and Surgeons, Columbia University, New York, NY, USA, designed a tube with two in-built balloons for the treatment of oesophageal varices. The tube was passed and the distal balloon inflated. The tube was drawn backwards until the distal balloon was held at the oesophageal hiatus. The proximal balloon was inflated, allowing tamponade of any varices in the distal oesophagus.

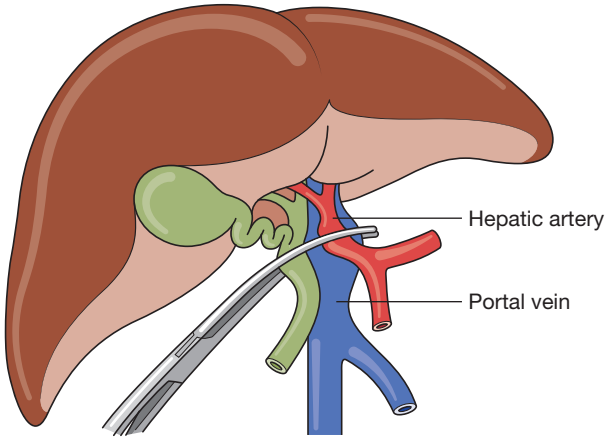

Figure 29.9 The Pringle manoeuvre.

Summary box 29.6

Liver trauma

- Blunt trauma occurs as the result of direct compression
- Penetrating trauma of the upper abdomen or lower thorax can damage the liver
- CT scanning is the investigation of choice in a stable patient
- Surgical management consists of: Pressure, Pringle, Plug and Pack
- The hepatic artery can be tied off but not the portal vein (which should be stented)
- Closed drainage should always be used

Biliary injuries

Isolated traumatic biliary injuries are rare and occur mainly from penetrating trauma, often in association with injuries to other structures that lie in close proximity. The common bile duct can be repaired over a T-tube or drained and referred to appropriate care as part of damage control, or even ligated.

Spleen

Splenic injury occurs from direct blunt trauma. Most isolated splenic injuries, especially in children, can be managed non-operatively. However, in adults, especially in the presence of other injury or physiological compromise, laparotomy should be considered. The spleen can be theoretically packed, repaired or placed in a mesh bag. However, in reality, splenectomy is the safer option, especially in the compromised patient with multiple potential sites of bleeding. In certain situations, selective angioembolisation of the spleen can play a role.

Following splenectomy there are significant, though transient, changes to blood physiology. The platelet and white count rise and may mimic sepsis. Inoculation against *Pneumococcus* is advisable within 2–3 weeks, by which time the patient's immune system has recovered.

Pancreas

Most pancreatic injury occurs as a result of blunt trauma. The major problem is that of diagnosis because the pancreas is a retroperitoneal organ. CT remains the mainstay of accurate diagnosis. Amylase or lipase estimation is insensitive. In penetrating trauma, injury may only be detected during laparotomy.

Classically the pancreas should be treated with conservative surgery and closed, low-suction drainage. Injuries are treated according to the ISS system of the AAST. Injuries to the pancreatic body to the left of the superior mesenteric vessels and to the tail are treated by closed drainage alone, with distal pancreatectomy if the duct is involved. Proximal injuries (to the right of the superior mesenteric artery) are treated as conservatively as possible, although partial pancreatectomy may be necessary. The role of pyloric exclusion remains controversial and remains surgeon dependent. A Whipple's procedure (pancreaticoduodenectomy) is rarely needed and should not be performed in the emergency situation because of the very high associated mortality rate. A damage control procedure with packing and drainage should be performed and the patient referred for definitive surgery once stabilised.

Stomach

Most stomach injuries are caused by penetrating trauma. Blood presence is diagnostic if found in the nasogastric tube, in the absence of bleeding from other sources. Surgical repair is required but great care must be taken to examine the stomach fully, as an injury to the front of the stomach can be expected to have an 'exit' wound elsewhere on the organ.

Duodenum

Duodenal injury is frequently associated with injuries to the adjoining pancreas. Like the pancreas, the duodenum lies retroperitoneally and so injuries are hidden, discovered late or at laparotomy performed for other reasons. CT is the diagnostic modality of choice. The only sign may be gas or a fluid collection in the periduodenal tissue, and leakage of oral contrast, administration of which may improve accuracy of diagnosis.

Smaller injuries can be repaired primarily. The first, third and fourth parts of the duodenum behave like small bowel and can be repaired in the same fashion. The second part of the duodenum is fixed to the head of the pancreas with a common blood supply and may have a poorer blood supply than the remainder. Major trauma, especially if the head of the pancreas is simultaneously injured, should be treated as part of a damage control procedure and be referred for definitive care.

Small bowel

The small bowel is frequently injured as a result of blunt trauma. The individual loops may be trapped, causing high-pressure rupture of a loop or tearing of the mesentery. Penetrating trauma is also a common cause of injury.

Allen Oldfather Whipple, 1881–1963, Valentine Mott Professor of Surgery, The College of Physicians and Surgeons, Columbia University, New York, NY, USA.

Small bowel injuries need urgent repair. Haemorrhage control takes priority and these wounds can be temporarily controlled with simple sutures. In blunt trauma with mesenteric vessel damage, the bowel ischaemia that results will dictate the extent of a resection. Resections should be carefully planned to limit the loss of viable small bowel, but should be weighed against an excessive number of repairs or anastomoses. Haematomas in the small bowel mesenteric border need to be explored to rule out perforation. With low-energy wounds, primary repair can be performed, whereas more destructive wounds associated with military-type weapons require resection and anastomosis. Damage control 'clip and drop' of damaged or resected bowel may be necessary.

Colon

Blunt injuries to the colon are relatively infrequent; penetrating injuries occur more often. If relatively little contamination is present and the viability is satisfactory, such wounds can be repaired primarily. If, however, there is extensive contamination, the patient is physiologically compromised or the bowel is of doubtful viability, then the bowel can be closed off ('clip and drop'). A defunctioning colostomy can be formed later or the bowel reanastomosed once the patient is stable.

Rectum

Approximately 5% of colon injuries involve the rectum. These are generally from a penetrating injury, although occasionally the rectum may be damaged following fracture of the pelvis. Digital rectal examination will reveal the presence of blood, which is evidence of intestinal or rectal injury. These injuries are often associated with bladder and proximal urethral injury.

With intraperitoneal injuries, the rectum is managed as for colonic injuries. Full-thickness extraperitoneal rectal injuries can be managed with primary repair and drainage depending on the type of injury, i.e. suitable for knife wounds but not ballistic trauma. Where there is extensive tissue loss, this should be managed with either a diverting end-colostomy and closure of the distal end (Hartmann's procedure) or a loop colostomy. Presacral drainage is no longer used.

Renal and urological tract injury

In physiologically non-compromised patients, CT scanning with contrast is the investigation of choice. For assessment of bladder injury a cystogram should be performed at the time of CT. A minimum of 300 mL of contrast is instilled into the bladder via a urethral catheter. The large volume is essential because a small volume may not distend the bladder enough to produce a leak from a small bladder injury, once the cystic muscle is contracted.

Generally, renal injury is managed non-operatively unless the patient is physiologically compromised. The kidney can be angioembolised if required.

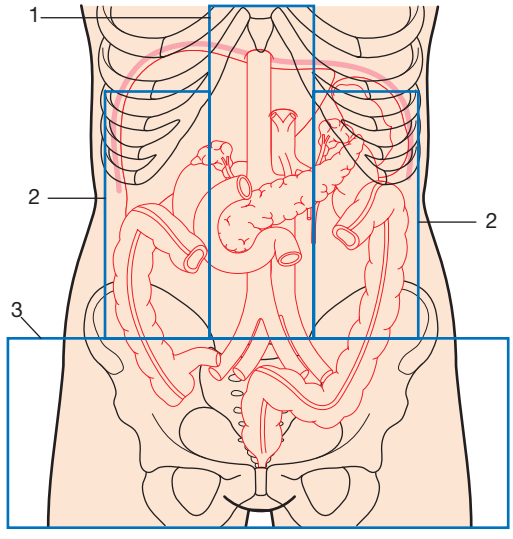

Figure 29.10 The zones of the retroperitoneum. Zone 1, central; zone 2, lateral; zone 3, pelvic.

Ureteric injury is rare and is generally due to penetrating trauma. Most ureters can be repaired or diverted if necessary, or may even be ligated as part of damage control procedures.

Intraperitoneal rupture of the bladder, usually from direct blunt injury, will require surgical repair. Extraperitoneal rupture is usually associated with a fracture of the pelvis and will heal with adequate urine drainage via the transurethral route. Suprapubic drainage is reserved for when this is not possible.

Summary box 29.7

Injuries to structures in the abdomen

- In children, splenic injury can be managed non-operatively in most cases, but not if physiologically compromised
- Duodenal injuries are often associated with pancreatic trauma
- Bowel injuries need urgent definitive repair, or isolation using resection or by stapling
- Rectal injuries are managed depending on whether intra- or extraperitoneal
- Kidney and urinary tract injuries are best diagnosed with contrast CT scanning
- Intraperitoneal bladder tears need formal repair and drainage

Retroperitoneum

Injury to the retroperitoneum is often difficult to diagnose, especially in the presence of other injury, when the signs may be masked. Diagnostic tests (such as ultrasound and DPL) may be negative. The best diagnostic modality is CT, but this requires a physiologically stable patient. The retroperitoneum is divided into three zones (*Figure 29.10*) for the purposes of intraoperative management in blunt trauma:

Henri Albert Charles Antoine Hartmann, 1860–1952, Professor of Clinical Surgery, Faculty of Medicine, University of Paris, Paris, France.

- Zone 1 (central): central haematomas should always be explored, once proximal and distal vascular control has been obtained.
- Zone 2 (lateral): lateral haematomas should only be explored if they are expanding or pulsatile or penetrating injury is present. They are usually renal in origin and can be managed non-operatively, although they may sometimes require angioembolisation.
- Zone 3 (pelvic): as with zone 2, these should only be explored if they are expanding or pulsatile or penetrating injury is present. Pelvic haematomas are exceptionally difficult to control and, whenever possible, should not be opened; they are best controlled with compression or extraperitoneal packing, or, if the bleeding is arterial in origin, with angioembolisation.

THE PELVIS

Although mortality following severe pelvic fractures has decreased dramatically with better methods of controlling haemorrhage, these patients still represent a significant challenge to every link of the treatment chain. Mortality rates exceeding 40% have recently been reported. Further, pelvic bleeding as one of the 'hidden bleeding sources' is still underestimated or missed, as retrospective chart analyses of potentially preventable deaths have revealed. Extreme force is required to disrupt the pelvic ring, and associated injuries and extrapelvic bleeding sources are common (up to 50% of cases). The haemodynamically unstable patient with severe pelvic fracture has a 90% risk of associated injuries and a 30% risk of intra-abdominal bleeding.

To save these patients, three questions need to be addressed:

- Is the patient at high risk of massive bleeding?
- Where is the source of the bleeding?
- How to stop the bleeding?

Anatomy

The surgical anatomy of the pelvis is key to the understanding of pelvic injuries.

- The pelvic inlet is circular. It is a structure that is immensely strong, but routinely gives way at more than one point should sufficient force be applied to it. Therefore, isolated fractures of the anterior or posterior pelvic ring are uncommon.
- The forces required to fracture the pelvic ring do not respect the surrounding organ systems.
- The pelvis has a rich collateral blood supply, especially across the sacrum and posterior part of the ileum. The cancellous bone of the pelvis also has an excellent blood supply. Most pelvic haemorrhage emanates from venous injury and fracture sites. However, in the haemodynamically unstable patient with severe pelvic injury, arterial bleeding is more frequent. Important for the treatment is that the surgeon has to deal with both arterial and venous bleeding.

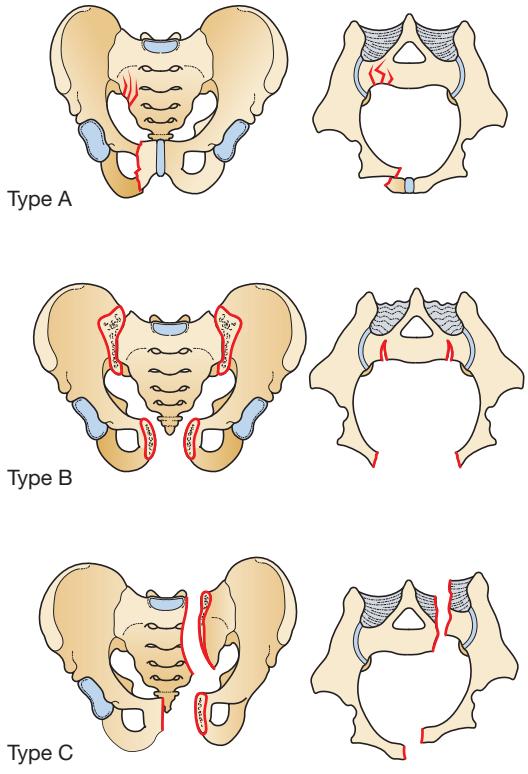

Figure 29.11 Tile classification of fractures of the pelvis.

- Postmortem examination has shown that the extrapelvic peritoneal space can accommodate more than 3000 mL. However, in the case of a severe pelvic fracture where the retroperitoneal compartment is disrupted and the external bony barrier is not stable, haematoma may extend upwards towards the mediastinum ('chimney effect') or downwards into the medial thigh in case of rupture of the pelvic floor.
- All iliac vessels, the sciatic nerve roots (including the lumbosacral nerve) and the ureters cross the sacroiliac joint; disruption of this joint may cause severe haemorrhage and sometimes cause arterial obstruction of the internal iliac artery and sciatic nerve palsy. Injuries to the ureters are rare.
- The pelvic viscera are suspended from the bony pelvis by condensations of the endopelvic fascia. Shear forces acting on the pelvis will transmit these to pelvic viscera, leading to avulsion and shearing injuries.
- The pelvis also includes the acetabulum, a major structure in weight transfer to the leg. Inappropriate treatment will lead to severe disability.

Classification

Pelvic ring fractures can be classified into three types, using the Tile classification (for subtypes and other classifications see ***Further reading***), based on the severity of the fracture (and reflecting the energy required to cause it) (***Figure 29.11***). However, no fracture pattern can exclude significant haemorrhage.

Marvin Tile, b. 1933, orthopaedic surgeon, Sunnybrook Medical Centre, Toronto, Canada.

Type A

Type A are the most common fractures and are completely stable. They result from lateral compression, which causes compression fractures of the pubic rami or compression fracture of the sacrum posteriorly.

Type B

These fractures are partially stable, and there is disruption of the anterior pelvis and partial disruption of the posterior pelvis. The pelvis can open and close 'like a book', but because the sacroiliac ligaments remain intact there is no vertical displacement. Internal or external stabilisation is required. Blood loss can be significant.

Type C

This fracture is completely unstable. Both the anterior pelvis and the entire posterior pelvic complexes are disrupted and the disrupted pelvic bones are free to displace horizontally and vertically. In both type B and type C pelvic injuries, there is a high risk of associated abdominal injuries (bowel perforation or mesenteric laceration) and rupture of the diaphragm.

Clinical examination

Pelvic fractures should be easily identified if ATLS guidelines are followed. There is no role of 'springing' the pelvis. If a binder has not been applied and an 'open book' fracture is suspected, a binder must be immediately applied as the presence of major pelvic fracture is associated with life-threatening blood loss and requires appropriate measures.

Inspection of the skin may reveal lacerations in the groin, perineum or sacral area, indicating an open pelvic fracture, the result of gross deformation. Evidence of perineal injury or haematuria mandates radiological evaluation of the urinary tract from below upwards (retrograde urethrogram followed by cystogram or CT cystogram and an excretory urogram, as appropriate) when the physiology allows. Inspection of the urethral meatus may reveal a drop of blood, indicating urethral damage.

Inspection of the anus may reveal lacerations to the sphincter mechanism. Rectal examination may reveal blood in the rectum and/or discontinuity of the rectal wall, indicating a rectal laceration. In male patients, the prostate is palpated; a high-riding prostate indicates a complete urethral avulsion. A full neurological examination is performed of the perineal area, sphincter mechanism and femoral and sciatic nerves.

Diagnosis

Radiograph

Examination of a plain radiograph of the pelvis requires an understanding of the mechanism of injury and a decision on the stability of the pelvic rim. It is important to note that the vast majority of patients with suspected pelvic fractures may have a pelvic binder in place and hence plain radiograph findings may be normal. FAST may be unreliable as it does not localise intra-abdominal bleeding in these patients. CT is the diagnostic modality of choice in the physiologically non-compromised patient, and CT angiography is particularly helpful in providing details of both the anatomy of the fracture and the origin of the bleeding (venous or arterial).

An open book-type mechanism causes one or both ilia to rotate externally (opening, like a book). A lateral compression mechanism causes the pelvis to collapse. An 'open book fracture' is seen as a widening of the pubic symphysis or widening at the site of a fracture in the pubic ramus. Not only is there disruption of the bony pelvis, but also tearing of the pelvic floor and thus the pelvic venous plexus is at risk. The more unstable the pelvis, the more likely the structures are to be damaged. When the pelvis collapses from a lateral compression injury, the pubic bones usually fracture. Displacement of the anterior pelvis by greater than 2 cm indicates at least partial instability. A vertical shear disruption of the sacroiliac joint with apparent shortening of the limb on the affected side implies significant energy of injury.

Management

The treatment for bleeding is to stop the bleeding!

The priorities for resuscitating patients with pelvic fractures are no different from the standard. These injuries can produce a real threat to the circulation, and management is geared towards controlling this threat. Initial management requires the use of a compression binder or a sheet, applied around the true pelvis at the level of the greater trochanters ('reduce the pelvic volume'), a potentially life-saving procedure that has to be done in the emergency department.

Eighty-five per cent of bleeding originating from the pelvis is of venous origin and can be controlled by non-operative means, including compression either by binding or external fixator or by extraperitoneal pelvic packing (i.e. packing the loose space between the bony wall of the pelvis and the peritoneum) to compress the pelvic veins. If other sources of bleeding have been ruled out, the extraperitoneal pelvic packing is done without entering the peritoneal cavity. This may be combined with external fixation.

If the bleeding is of arterial origin, interventional angioembolisation is the next choice for bleeding control. The techniques for bleeding control (compression, packing, fixation and angioembolisation) do not exclude each other but rather may complement each other. Persistent bleeding after packing may require angioembolisation and vice versa.

Severe pelvic injuries require a multidisciplinary team approach. If adequate orthopaedic experience is unavailable, consideration should be given towards early transfer of this patient to an institution with the necessary expertise.

If the source of the bleeding is in doubt or FAST/CT results are positive, showing a significant amount of blood in the peritoneal cavity, concurrent intra-abdominal injury cannot be excluded and it is wise to perform an exploratory laparotomy to treat or rule out intra-abdominal bleeding.

Summary

In summary, a haemodynamically normal patient can be safely transferred for stabilisation of unstable fractures within hours after injury and following control of the associated damage.

Summary box 29.8

Pelvic injury

- Associated injuries can only be managed once the patient is physiologically non-compromised
- Decision on the stability is of paramount importance
- Procedures for damage control may be the only available option
- External stabilisation of the pelvic ring is the basis of all treatment
- If necessary, further bleeding control can be achieved either by angioembolisation or by extraperitoneal packing

DAMAGE CONTROL

Following major injury, protracted surgery in the physiologically unstable patient can in itself prove fatal. Patients with the 'deadly triad' (hypothermia, acidosis and coagulopathy) are those at highest risk. Damage control or damage limitation surgery is a concept that originated from a naval shipbuilding strategy, whereby ships were designed so that the damage was kept 'local' and only minimal repairs were needed to prevent the ship from sinking while definitive repairs waited until it had reached port. The technique has been adopted following major trauma and includes initial care and resuscitation (damage control resuscitation) and the surgical correction of the injury (damage control surgery).

The minimum amount of surgery needed to stabilise the patient's condition may be the safest course until the physiological derangement can be corrected. Damage control surgery is restricted to only three goals:

- stopping any active surgical bleeding;
- controlling any contamination;
- restoring normal physiology.

Once the first two have been achieved then the operation is suspended and the abdomen temporarily closed to allow for restoration of physiology to occur. The patient's resuscitation then continues in the ICU, where other therapeutic interventions can take place. Once the physiology has been corrected, the patient warmed and the coagulopathy corrected, the patient is returned to the operating theatre for any definitive surgery.

Damage control resuscitation

The concept of damage control has been broadened to include the techniques used in resuscitation as well as in surgery. The time in the emergency department is minimised and the majority of resuscitation of the patient is carried out in the operating theatre and not in the resuscitation bay (***Table 29.6***). Resuscitation is individualised through repeated point-of-care testing of haemoglobin, acidosis (pH and lactate) and clotting, and is therefore directed towards the early delivery of biologically active colloids, clotting products and whole blood in order to buy time. The physiological disturbances that are associated with the downward spiral of acidosis, coagulopathy and hypothermia in these serious injuries are predicted and attempts are made to avoid them rather than react to them.

Damage control surgery

This is a key component of damage control resuscitation. The decision of whether damage control surgery is the appropriate course should be made early (***Table 29.7***) and allows the whole surgical and anaesthetic team to work together to limit the time in surgery and achieve the earliest possible admission of the patient to the ICU. Damage control is a staged process.

The initial focus is haemorrhage control, followed by control and limitation of contamination, which are achieved using a range of abbreviated techniques including simple ligation of bleeding vessels, shunting of major arteries and veins, drainage, temporary stapling of bowel and therapeutic packing.

Following the above, the abdomen is closed in a temporary fashion either by using commercially available products or by using a sheet of plastic (e.g. OPSITE◊ or similar product) over the bowel, an intermediate pack to allow suction and a further sheet of adherent plastic drape to the skin to form a watertight and airtight seal. Suction is applied to the intermediate pack area to collect abdominal fluid. This technique is known as the 'Vac-Pac' or 'OPSITE◊ sandwich' (***Figure 29.12***). As soon as control has been achieved the patient is transferred to the ICU, where resuscitation is continued.

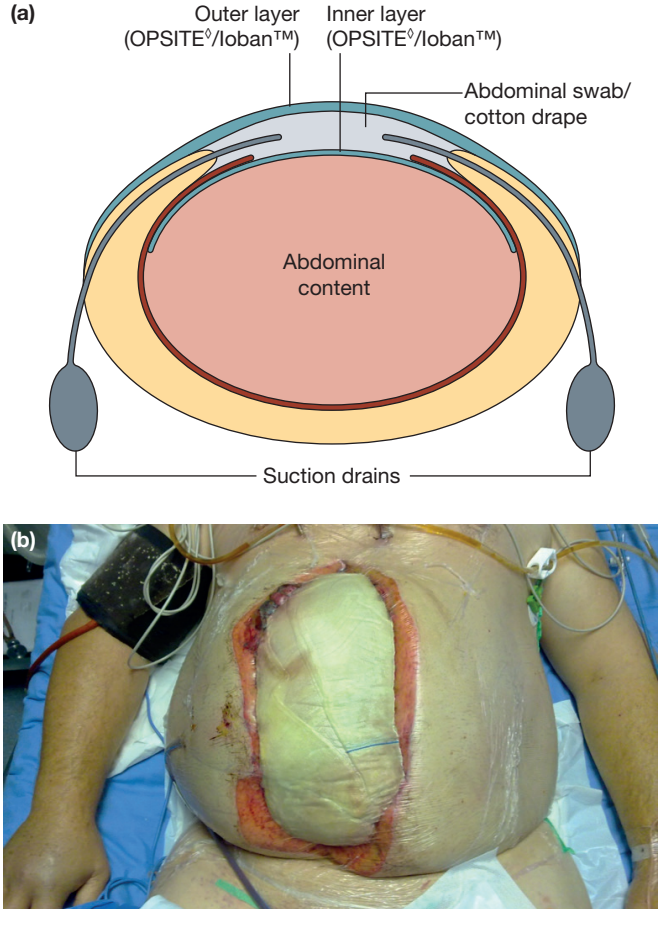

Figure 29.12 (a) Diagram showing temporary skin closure in damage control. **(b)** Abdominal closure following damage control surgery showing an OPSITE◊ closure.

TABLE 29.6 The stages of damage control surgery.

Stage	Intervention
I	Patient selection
II	Control of haemorrhage and control of contamination
III	Resuscitation continued in the intensive care unit
IV	Definitive surgery
V	Abdominal closure

The next stage following damage control surgery and physiological stabilisation is definitive surgery. The team should aim to perform definitive anastomoses, vascular reconstruction and closure of the body cavity within 24–72 hours of injury. However, this must be individualised to the patient, the response to critical care resuscitation and the progression of injury.

TABLE 29.7 Indications for damage control surgery.

Anatomical	• Inability to achieve haemostasis • Complex abdominal injury, e.g. liver and pancreas • Combined vascular, solid and hollow organ injury, e.g. aortic or caval injury • Inaccessible major venous injury, e.g. retrohepatic vena cava • Demand for non-operative control of other injuries, e.g. fractured pelvis • Anticipated need for a time-consuming procedure
Physiological (decline of physiological reserve)	• Temperature <34°C • pH <7.2 • Serum lactate >5 mmol/L (normal: <2.5 mmol/L) • Prothrombin time >16 s • Partial thromboplastin time >60 s • >10 units blood transfused • Systolic blood pressure <90 mmHg for >60 min
Environmental	• Operating time >60 min (core temperature loss is usually 2°C/h) • Inability to approximate the abdominal incision • Desire to reassess the intra-abdominal contents (directed relook)

The abdomen is closed as soon as possible, bearing in mind the risks of abdominal compartment syndrome (ACS). The closure is not without its own morbidity. Successful closure may require aggressive off-loading of fluid and even haemofiltration to achieve this if the patient will tolerate it. The best situation is closure of the abdominal fascia, or, if this cannot be achieved, then skin closure only. Occasionally, mesh closure can be used, with skin grafting over the mesh and subsequent abdominal wall reconstruction.

Thoracic damage control is conceptually based on the same philosophy. This is that haemorrhage control and focused surgical procedures minimise further surgical insult and lead to improved survival in the unstable trauma patient. The aim is to control bleeding and limit air leaks using the fastest procedures available, such as staplers, to minimise the operative time.

The indications and techniques for emergency thoracic surgery have already been described.

Damage control applies equally to the extremities. In this case, it is shunting of blood vessels, identifying and marking damaged structures such as nerves, fasciotomy and removal of contaminated tissue that are the main tasks. Subsequent definitive management can be carried out at a later stage.

Summary box 29.9

Damage control

- Resuscitation is carried out in the operating theatre using biologically active fluids (i.e. blood) – damage control resuscitation
- The surgery performed is the minimum needed to stabilise the patient
- The aims of surgery are to control haemorrhage and limit contamination
- Secondary surgery is aimed at definitive repair

ABDOMINAL COMPARTMENT SYNDROME AND THE OPEN ABDOMEN

Raised intra-abdominal pressure has far-reaching consequences for the patient; the syndrome that results is known as ACS. ACS is a major cause of morbidity and mortality in the critically ill patient and its early recognition is essential (*Table 29.8*).

In all cases of abdominal trauma in which the development of ACS in the immediate postoperative phase is considered a risk, the abdomen should be left open and managed as for damage control surgery.

TABLE 29.8 Effect of raised intra-abdominal pressure on individual organ function.

System	Effect
Renal	Increase in renal vascular resistance leading to a reduction in glomerular filtration rate and impaired renal function
Cardiovascular	Decrease in venous return resulting in decreased cardiac output because of both a reduction in preload and an increase in afterload
Respiratory	Increased ventilation pressures because of splinting of the diaphragm, decreased lung compliance and increased airway pressures
Visceral effects	Reduction in visceral perfusion
Intracranial effects	Severe rises in intracranial pressures

INTERVENTIONAL RADIOLOGY

Interventional radiology can be useful in the management of torso trauma as both an investigative and a therapeutic tool for patients with vascular injury. Angioembolisation following demonstration of ongoing bleeding in splenic and renal injury is a valuable technique.

NON-OPERATIVE MANAGEMENT

Non-operative management is generally preferred for the management of solid organ injury in physiologically non-compromised children. Non-operative management of solid abdominal organ injury has rapidly gained acceptance in the management of adults as well. A stable patient and accurate CT imaging are prerequisites for this approach. Failure of non-operative management is uncommon and typically occurs within the first 12 hours after injury. Therefore, if correctly selected, the vast majority of these patients will avoid surgery, require less blood transfusion and sustain fewer complications than operated patients.

ANTIBIOTICS IN TORSO TRAUMA

There is no level 1 evidence to recommend the use of antibiotics for the insertion of chest drains. However, prophylactic antibiotics prior to surgery should be used in all cases of penetrating abdominal trauma. Unless there is major contamination, a single dose is sufficient.

CHAPTER
30 The neck and spine

Learning objectives

To be familiar with:

- The accurate assessment of spinal trauma
- The basic management of spinal trauma and the major pitfalls
- The pathophysiology and types of spinal cord injury
- The prognosis of spinal cord injury, factors affecting functional outcome and common associated complications

ANATOMY OF THE SPINE AND SPINAL CORD

Spinal column anatomy

The vertebral column is composed of a series of motion segments (***Figure 30.1***). A motion segment consists of two adjacent vertebrae, their intervertebral disc and ligamentous restraints (***Figure 30.2***).

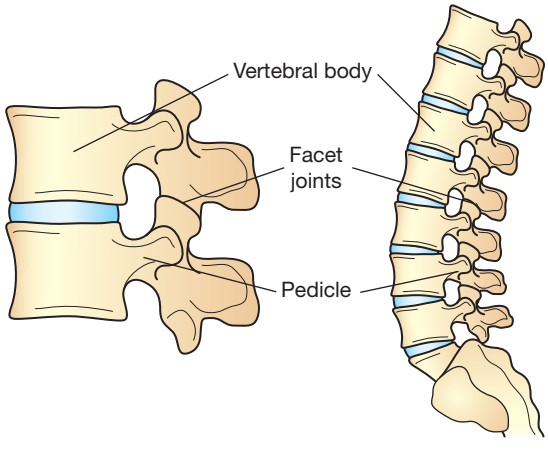

Figure 30.1 The spinal motion segment.

Regional variations

Upper cervical spine anatomy is designed to facilitate motion (***Figure 30.3***), and stability here is dependent on ligamentous restraints (***Figure 30.4***). Vertebral anatomy from C3 to C7 is similar. The cervicothoracic (***Figure 30.5***) and thoracolumbar (***Figure 30.6***) junctions are transitional zones where the spine changes from a mobile section (cervical and lumbar) to a more fixed one (thoracic). These two areas are common sites of injury.

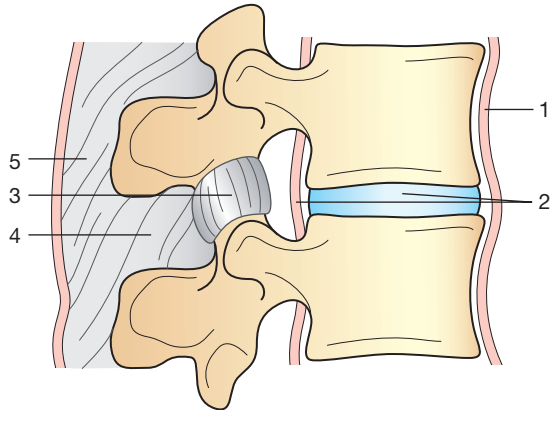

Figure 30.2 Ligamentous spinal restraints. (1) Anterior longitudinal ligament, (2) intervertebral disc and posterior longitudinal ligament, (3) facet joint capsule, (4) interspinous ligament, (5) supraspinous ligament.

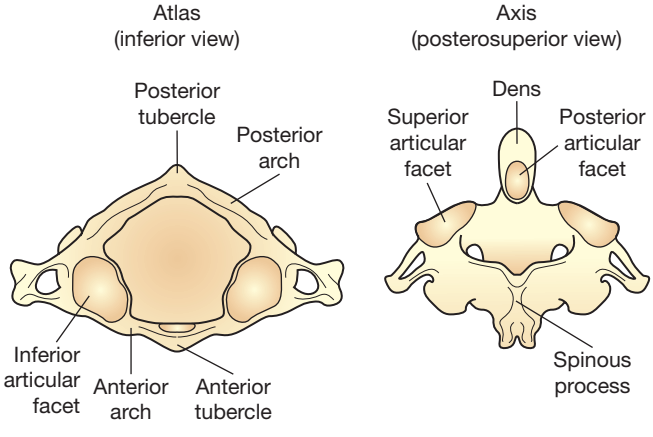

Figure 30.3 Atlantoaxial bony anatomy.

Figure 30.5 Cervicothoracic facet subluxation (arrow) (easily missed with inadequate radiographs).

Figure 30.6 Coronal T2-weighted magnetic resonance image demonstrating a fracture dislocation at the thoracolumbar junction.

Spinal stability

Spinal stability is the ability of the spine to withstand physiological loads with acceptable pain, avoiding progressive deformity or neurological deficit. The spine can be divided into three columns: anterior, middle and posterior (***Figure 30.7***). If two or more columns of the spine are injured, it is considered unstable. The AO classifications (Magerl and AO Spine Subaxial Classification System) are based on the mechanism of injury and are used to assess spinal stability.

Summary box 30.1

Spinal column anatomy

- Upper cervical spine stability is dependent on ligamentous restraints
- The cervicothoracic and thoracolumbar junctions are common sites of injury

Spinal neuroanatomy

The spinal cord extends from the foramen magnum to the L1/L2 level, where it ends as the conus medullaris in adults (lower in children) (***Figure 30.8***). Below this level lies the cauda equina. ***Figure 30.9*** illustrates a cross-section of the spinal cord.

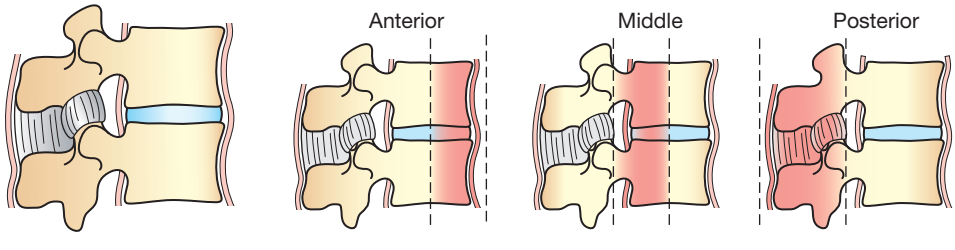

Figure 30.7 The three-column model of spinal stability.

Friedrich Paul Magerl, 1931–2020, Austrian surgeon and pioneer of spinal surgery.
AO, Arbeitsgemeinschaft für Osteosynthesefragen, may be translated from the German as 'Working Party on Problems of Bone Repair'.

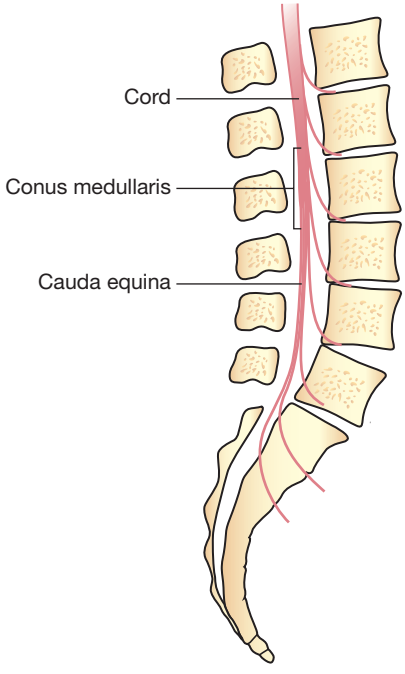

Figure 30.8 The spinal cord ends at L1/L2 at the conus medullaris, which gives rise to the cauda equina.

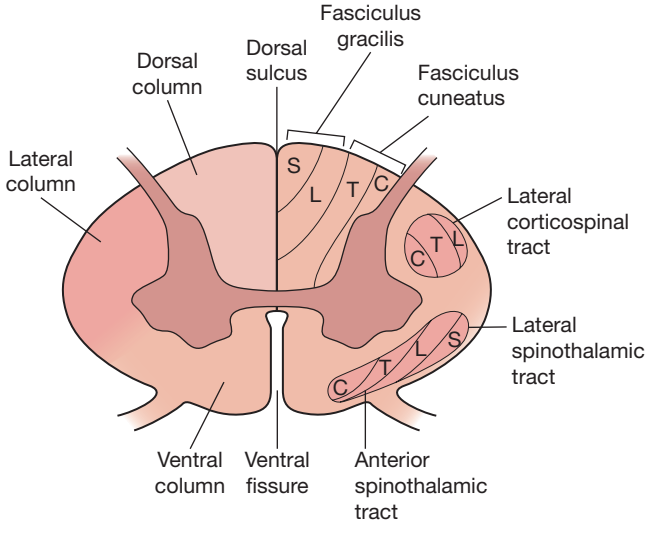

Figure 30.9 A cross-section of the spinal cord. C, cervical; L, lumbar; S, sacral; T, thoracic.

The lateral spinothalamic tracts transmit the sensations of pain and temperature, the lateral corticospinal tracts are responsible for motor function and the posterior columns transmit position, vibration and deep pressure sensation.

The spinothalamic tracts cross to the opposite side of the spinal cord within three levels of entering the cord. In contrast, the corticospinal tracts and the posterior columns decussate proximally at the craniocervical level. The tracts are topographically arranged; proximal body function is represented centrally, with distal body function arranged peripherally.

PATIENT ASSESSMENT

Basic points

The Advanced Trauma Life Support (ATLS) principles apply in all cases (see ***Chapters 26 and 27***). The spine should initially be immobilised using full spinal precautions, on the assumption that every trauma patient has a spinal injury until proven otherwise (***Figure 30.10***). The finding of a spinal injury makes it more (not less) likely that there will be a second injury at another level.

Spinal boards lead to skin breakdown in insensate patients, and are very uncomfortable for those with normal sensation (***Figure 30.11***). They should only be used for transferring patients.

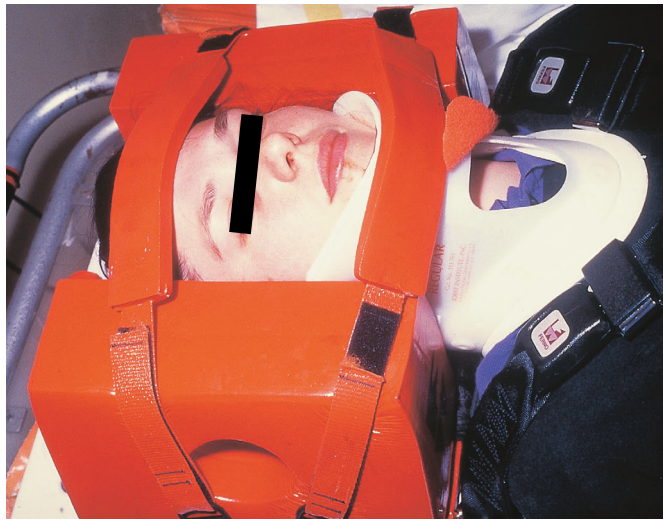

Figure 30.10 Spinal immobilisation.

Figure 30.11 Pressure sores may develop rapidly in insensate patients.

The unconscious patient

Definitive clearance of the spine may not be possible in the initial stages; if this is the case, spinal immobilisation should be maintained until magnetic resonance imaging (MRI) or equivalent can be used to rule out an unstable spinal injury.

Summary box 30.2

Patient assessment

- Use ATLS principles in all cases of spinal injury
- In polytrauma cases suspect a spinal injury
- A second spinal injury at a remote level may be present in 10% of cases
- Spinal boards cause pressure sores

PERTINENT HISTORY

The mechanism and velocity of injury should be determined at an early stage. A check for the presence of spinal pain should be made. The onset and duration of neurological symptoms should also be recorded.

PHYSICAL EXAMINATION

Initial assessment

The primary survey always takes precedence, followed by a careful systems examination paying particular attention to the abdomen and chest. Spinal cord injury may mask signs of intra-abdominal injury.

Spinal examination

The overlying skin should be inspected (e.g. for possible penetrating wounds) and the entire spine must be palpated. A formal spinal log roll must be performed to achieve this (***Figure 30.12***). Significant swelling, tenderness, palpable steps or gaps suggest a spinal injury. A rectal examination should be undertaken to assess anal tone and perianal sensation (see ***Neurological examination***). Seatbelt marks on the abdomen and chest must be noted, as these suggest a high-energy accident.

Neurological examination

The American Spinal Injury Association (ASIA) neurological evaluation system (***Figure 30.13***) is an internationally accepted method of neurological evaluation.

Motor function is assessed using the Medical Research Council (MRC) grading system (0–5) in key muscle groups

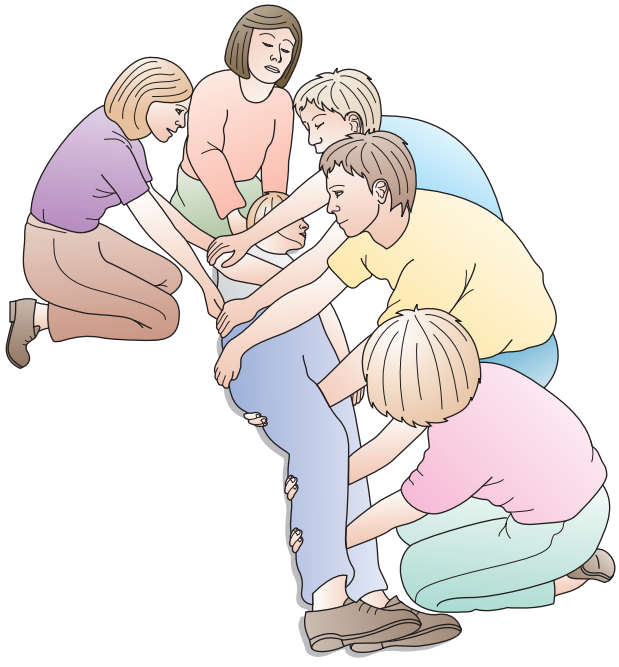

Figure 30.12 Spinal log roll.

(***Figure 30.13***). A motor score can then be calculated (maximum 100).

Sensory function (light touch and pin prick) is assessed using the dermatomal map (***Figure 30.13***). A total sensory score is then calculated.

Rectal examination is performed to assess anal tone, voluntary anal contraction and perianal sensation.

Level of neurological impairment

The extent of spinal cord injury is defined by the American Spinal Injury Association (ASIA) Impairment Scale (modified from the Frankel classification):

- **A:** complete spinal cord injury;
- **B:** sensation present, motor absent;
- **C:** sensation present, motor present but not useful (MRC grade <3/5);
- **D:** sensation present, motor useful (MRC grade ≥3/5);
- **E:** normal function.

Summary box 30.3

Physical examination

- The ASIA neurological scoring system should be used
- Functional motor power is MRC grade 3/5 or higher

Hans Ludwig Frankel, b. 1932, Clinical Director, The National Spinal Injuries Centre, Stoke Mandeville, UK.

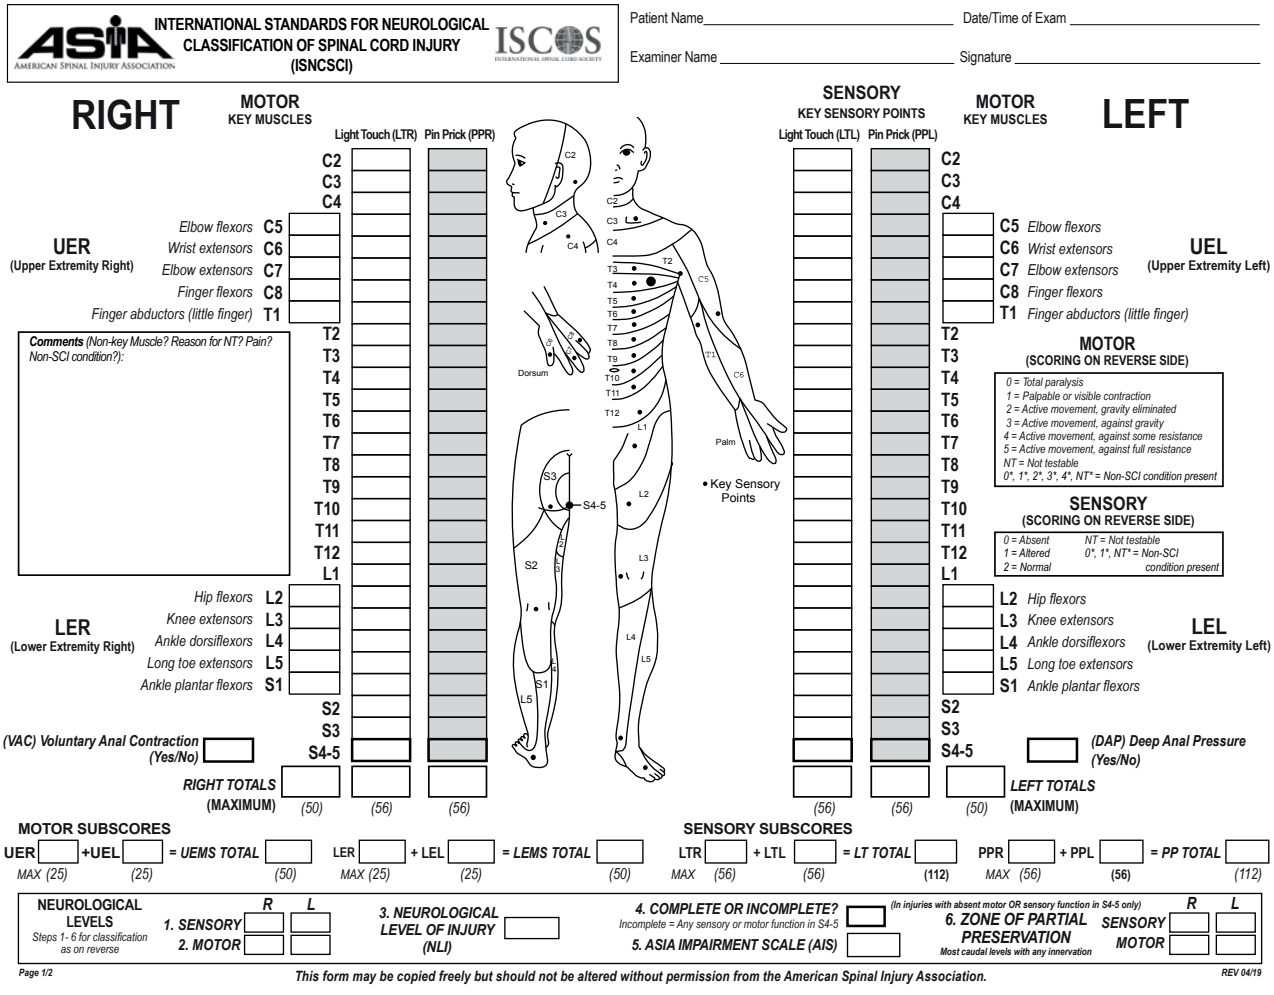

Figure 30.13 American Spinal Injury Association neurological evaluation. (Reproduced with permission from American Spinal Injury Association: *International standards for neurological classification of spinal cord injury*, revised 2019; Richmond, VA.)

DIAGNOSTIC IMAGING

Plain radiographs

A full cervical spine series includes anteroposterior and lateral radiographs of the whole cervical spine, and open mouth views. Clear visualisation of the cervicothoracic junction is essential in all cases of suspected spinal injury, as this is a common site for injury and often not seen on a plain radiograph. If a spinal fracture is identified then further imaging of the whole spine is required because there is a 15% incidence of a further spinal fracture.

A system for evaluation of the lateral cervical spine radiograph

1. Assess prevertebral soft-tissue swelling (***Figure 30.14***).
2. Assess sagittal alignment using three imaginary lines (***Figure 30.15***).
3. Assess for instability (***Figure 30.16***):
   - **a** 3.5 mm of sagittal translation;
   - **b** sagittal angulation of >11° (compared with the adjacent level).

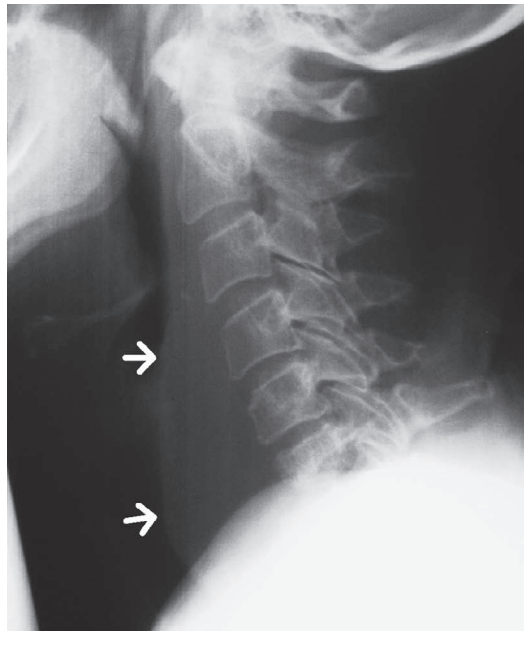

Figure 30.14 Large prevertebral haematoma (arrows).

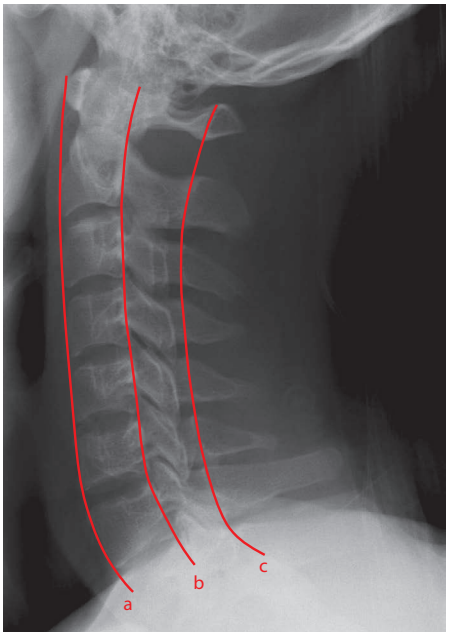

Figure 30.15 The anterior **(a)**, posterior **(b)** and spinolaminar **(c)** lines are useful in identifying anterior translation on lateral radiographs of the neck.

Figure 30.16 Lateral cervical spine radiograph showing obvious spinal instability with marked sagittal angulation and translation. This patient walked into the outpatient department.

Computed tomography

Computed tomography (CT) scanning with two-dimensional reconstruction remains the gold standard in spinal trauma and is indicated for patients with suspected or visible injuries on plain radiographs (***Figure 30.17***). Patients undergoing a head CT scan for closed head injury should also have a cervical screening CT. Often CT scans of the chest and abdomen are performed as part of the assessment of polytrauma patients and will usually include the spine.

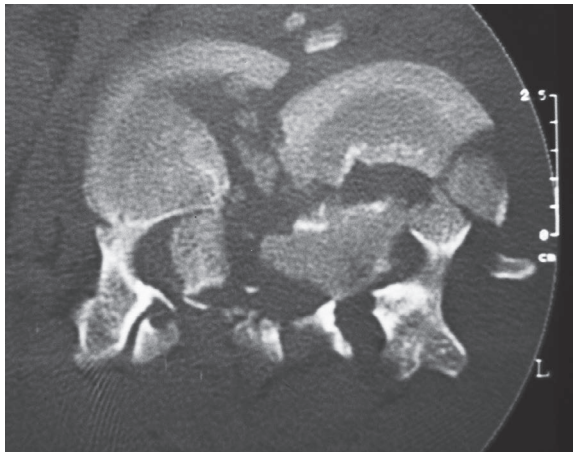

Figure 30.17 Axial computed tomography demonstrating a thoracolumbar fracture dislocation.

Magnetic resonance imaging

MRI is indicated in all patients with neurological deficit and where assessment of ligamentous structures is important (***Figure 30.18***).

Dynamic imaging

Lateral flexion–extension radiographs of the cervical spine should not be undertaken acutely, although they can have a role in assessing spinal stability in the longer term.

Figure 30.18 Sagittal T2-weighted magnetic resonance imaging scan demonstrating a cervical spine subluxation and spinal cord contusion.

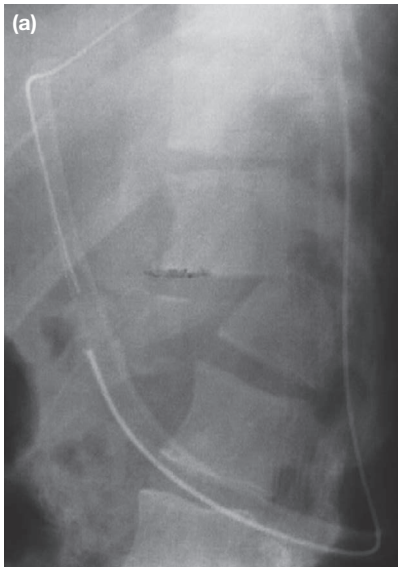
Summary box 30.4

Diagnostic imaging of spinal injuries

- Clear visualisation of the cervicothoracic junction is mandatory
- Plain cervical spine radiographs fail to identity 15% of injuries

CLASSIFICATION AND MANAGEMENT OF SPINAL AND SPINAL CORD INJURIES

Basic management principles



Spinal realignment

In cases of cervical spine subluxation or dislocation, skeletal traction is necessary to achieve anatomical realignment. This is done using skull tongs (***Figure 30.19***).

In many cases of spinal trauma, formal open reduction and stabilisation using internal fixation is also required (***Figure 30.20***).

Figure 30.19 Skeletal traction using skull tongs.

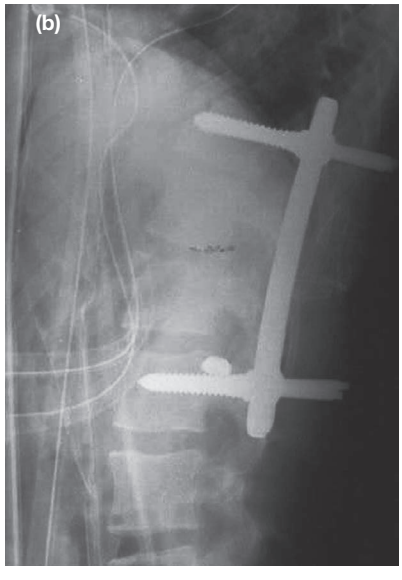


Figure 30.20 (a) Thoracolumbar fracture dislocation, **(b)** treated with open reduction and posterior fixation. **(c)** Bifacetal cervical spine dislocation. **(d)** Posterior stabilisation following closed reduction.

A halo brace can be used to perform a closed realignment and immobilisation of cervical fractures (***Figure 30.21***).

Stabilisation

The indication for operative intervention is influenced by the injury pattern, level of pain, degree of instability and the presence of a neurological deficit. The only absolute indication for surgery in spinal trauma is deteriorating neurological function.

Decompression of the neural elements

Realignment of the spine and correction of the spinal deformity may achieve an indirect decompression. A direct decompression of the neural elements may also be indicated if there are bone fragments causing residual compression or a significant haematoma (***Figure 30.22***). The timing of surgery in spinal cord trauma remains controversial.

Corticosteroids

Corticosteroids are no longer indicated in acute spinal cord injury because of a lack of evidence to support efficacy. Steroids do have a role in non-traumatic spinal cord compression, e.g. malignant spinal cord compression.

Figure 30.21 External immobilisation using a halo jacket.

Summary box 30.5

Management of spinal trauma

- Neurological deficit determines management
- Deteriorating neurological status requires surgical intervention
- Corticosteroids are ineffective

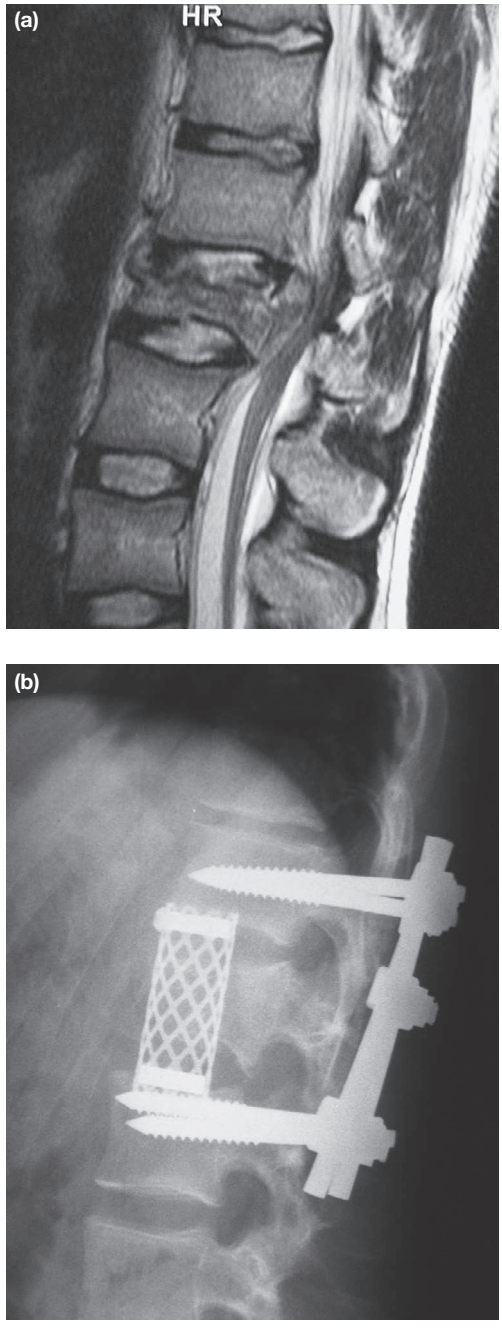

Figure 30.22 (a) Sagittal T2-weighted magnetic resonance imaging scan showing an L1 burst fracture and neural compression; **(b)** treated with combined anterior and posterior surgery.

SPECIFIC SPINAL INJURIES

Upper cervical spine (skull–C2)

Occipital condyle fracture

This is a relatively stable injury often associated with head injuries and is best treated in a hard collar for 6–8 weeks.

Occipitoatlantal dislocation

This injury is usually caused by high-energy trauma and is often fatal. The dislocation may be anterior, posterior or

vertical (*Figure 30.23*). Powers' ratio (*Figure 30.24*) is used to assess skull translation. Treatment is with a halo brace or occipitocervical fixation.

Atlas fracture (Jefferson fracture)

Fracture of the C1 ring is associated with axial loading of the cervical spine and may be stable or unstable (*Figure 30.25a,b*). Associated transverse ligament rupture may occur (*Figure 30.25c*). Most are treated non-operatively in a cervical collar or halo brace.

Figure 30.23 Vertical occipitocervical dislocation.

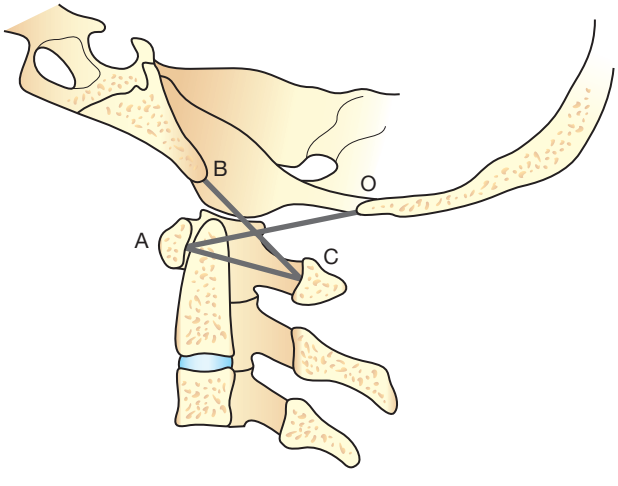

Figure 30.24 Powers' ratio. BC/OA ≥1 indicates anterior translation; ≤0.75 indicates posterior translation.

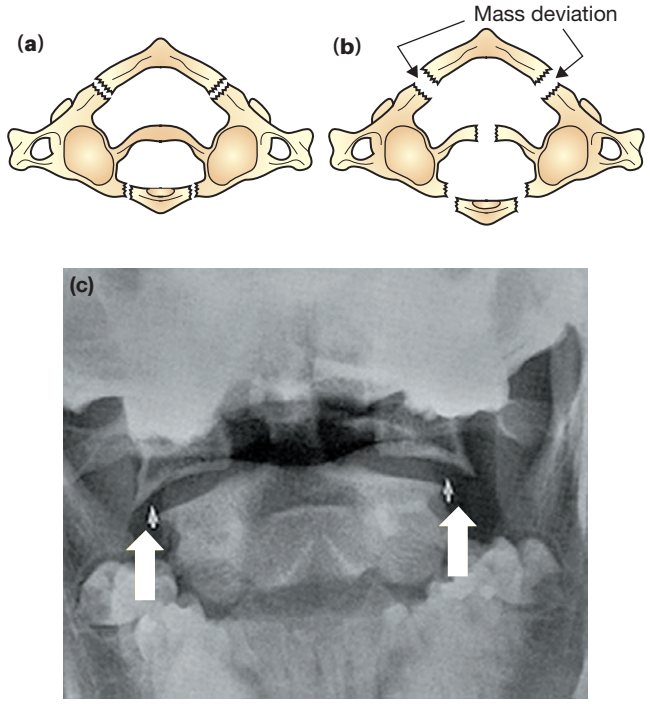

Figure 30.25 Stable **(a)** versus unstable **(b)** Jefferson's fracture of C1. **(c)** Open mouth view of C1/2 demonstrating C1 lateral mass deviation (arrows). Rupture of the transverse ligament is present when the combined lateral mass deviation exceeds 6.9 mm.

Atlantoaxial instability

This is defined as non-physiological movement between C1 and C2. It can be translational or rotatory and resolves either spontaneously or with traction followed by a cervical collar. Isolated, traumatic transverse ligament rupture leading to C1/2 instability is uncommon and is treated with posterior C1/2 fusion (*Figure 30.26*).

Odontoid fractures

There are three types of odontoid peg fracture (*Figure 30.27*). Neurological injury is rare. The majority of acute injuries are treated non-operatively in a hard collar or halo jacket for 3 months. Internal fixation with an anterior compression screw is indicated for displaced fractures (*Figure 30.28*), and a posterior C1/2 fusion is considered in cases of non-union. In the elderly, treatment in a soft collar should be considered on the basis that a relatively stable pseudarthrosis will occur.

Barry Powers, contemporary, Chief and Clinical Professor of Radiology, Duplin General Hospital, Kenansville, NC, USA, described his ratio in 1979.
Sir Geoffrey Jefferson, 1886–1961, Professor of Neurosurgery, University of Manchester, UK, became the UK's first Professor of Neurosurgery in 1939. In 1947 he was elected a Fellow of the Royal Society, a rare distinction for a practising surgeon. Although he became a neurosurgeon, he performed the first successful embolectomy in England in 1925 at Salford Royal Hospital.

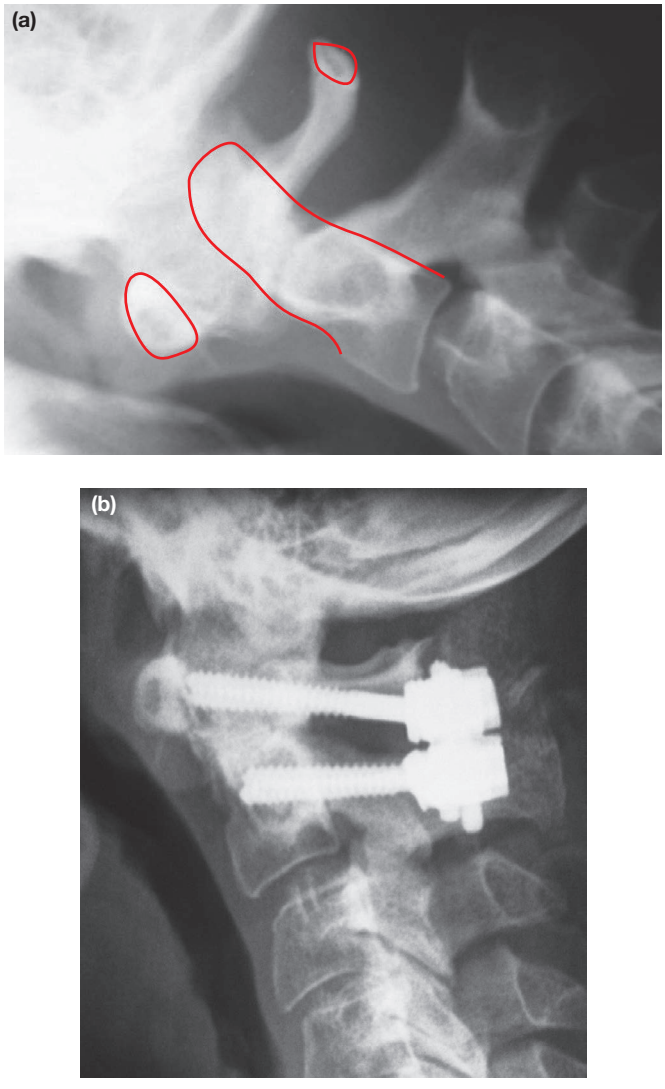

Figure 30.26 (a) Atlantoaxial subluxation. **(b)** C1/2 posterior fusion using C1 lateral mass and C2 pedicle screws.

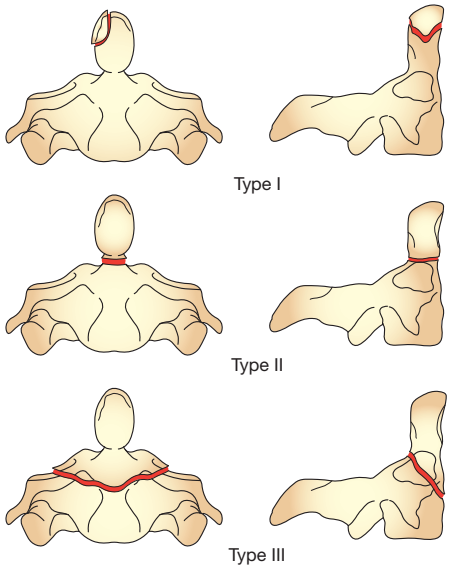

Figure 30.27 Types of odontoid fracture.

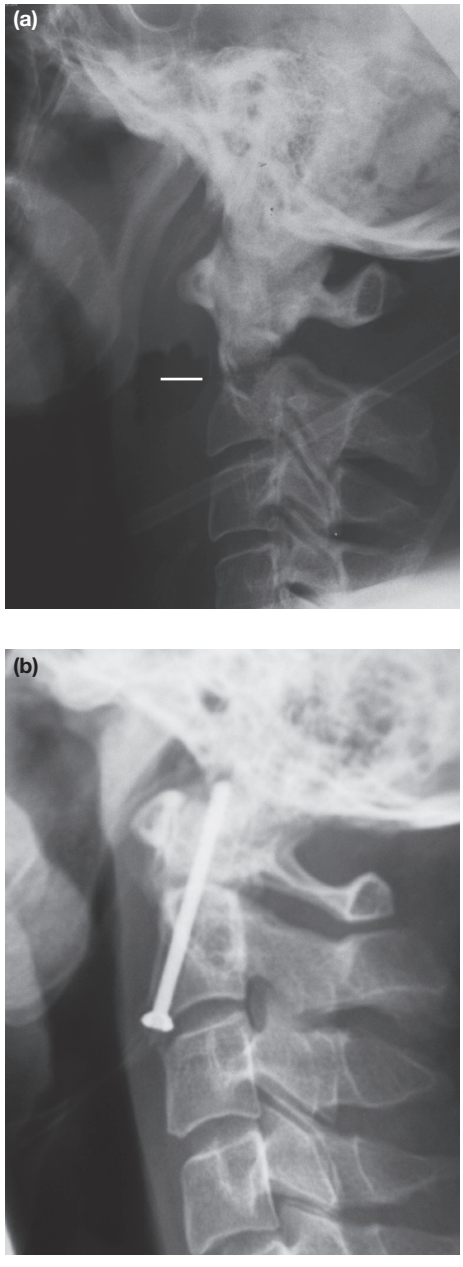

Figure 30.28 (a) Type II odontoid fracture (arrow); **(b)** treated with an anterior compression screw.

Traumatic spondylolisthesis of the axis (hangman's fracture)

This is a traumatic spondylolisthesis of C2 on C3. There are four types with varying degrees of instability (***Figure 30.29***). Those with significant displacement or associated facet dislocation are treated operatively, usually with posterior stabilisation.

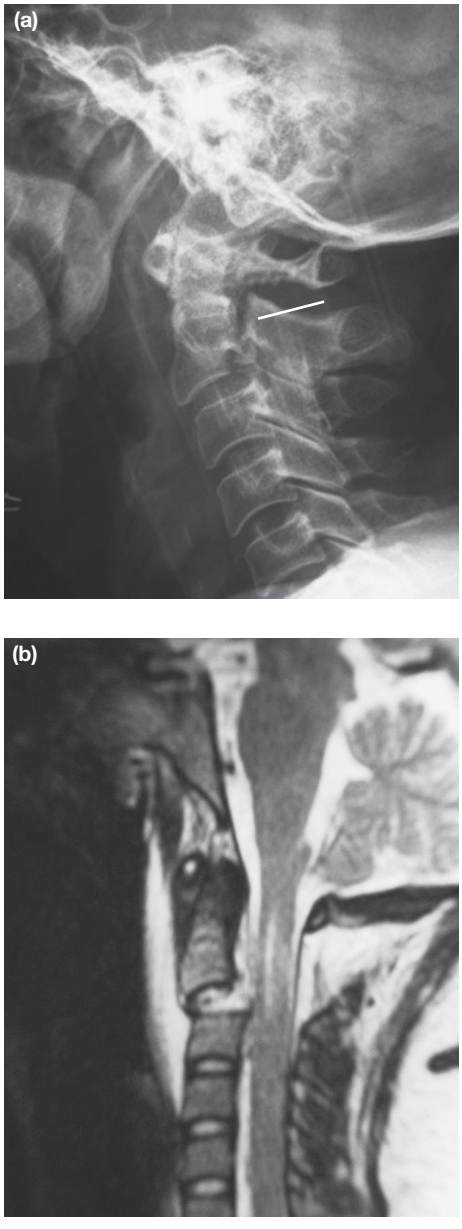

Figure 30.29 (a) Hangman's fractures of C2 with minimal forward translation (arrow). **(b)** C2/3 subluxation with spinal cord contusion.

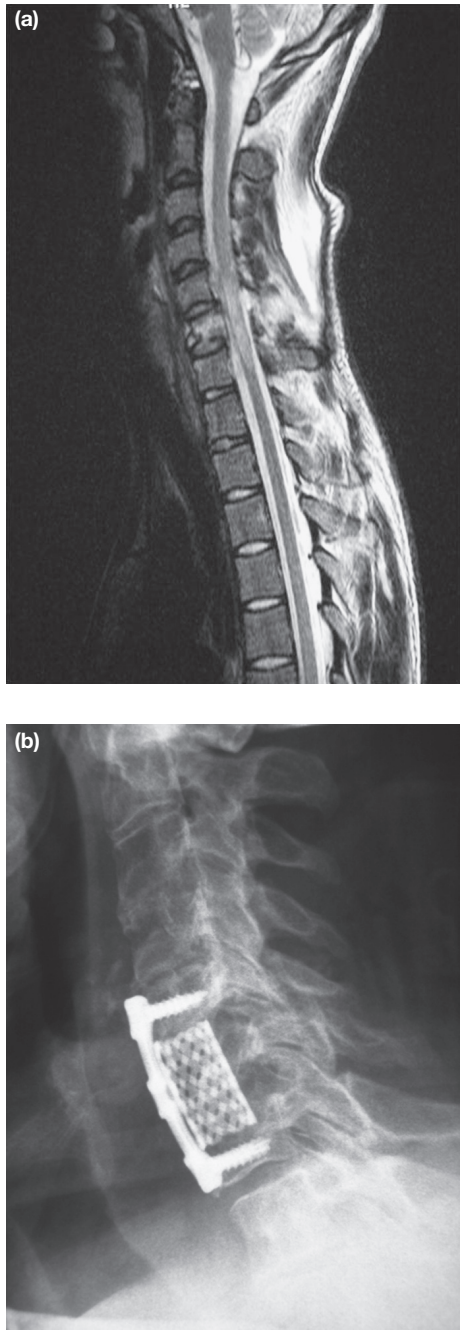

Figure 30.30 (a) Cervical burst fracture with spinal cord contusion; **(b)** treated with anterior decompression and reconstruction.

Subaxial cervical spine (C3–C7)

The pattern of lower cervical spine injury depends on the mechanism of trauma. These include compression fractures (hyperflexion), burst fractures (axial compression), facet subluxation/dislocation injuries (distraction–flexion), teardrop fractures (hyperextension) and fracture of posterior elements. The more severe injuries may have an associated spinal cord injury (***Figure 30.30a***). Operative intervention may be required to decompress the spinal cord and to stabilise the spine with internal fixation (***Figure 30.30b***).

Facet subluxation/dislocation ranges in severity from minor instability to complete dislocation with spinal cord injury (***Figure 30.31***).

Fractures in patients with ankylosing spondylitis

Ankylosing spondylitis is a seronegative inflammatory disorder that causes autofusion of the spine. These patients have a higher risk of spinal fractures and spinal cord injury than the normal population. Senior advice should be obtained, because application of a cervical collar may be contraindicated, and patients should be managed instead in a position of comfort. Surgical stabilisation is commonly indicated.

Figure 30.31 C5/6 bifacetal dislocation (arrows).

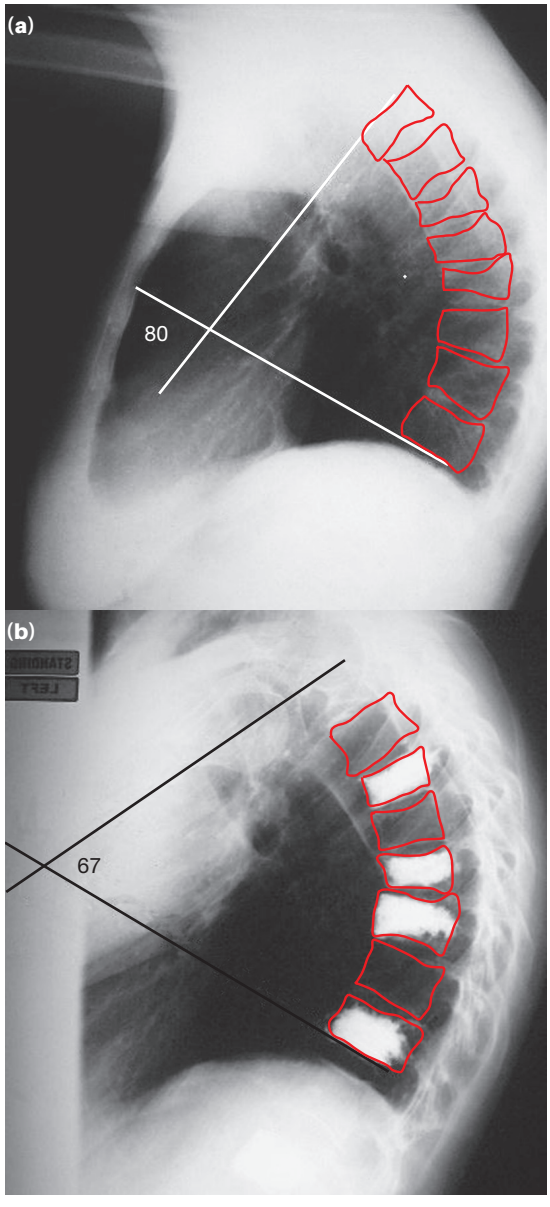

Figure 30.32 (a) Lateral radiograph showing multiple osteoporotic compression fractures. **(b)** Reduction in thoracic kyphotic deformity following four-level kyphoplasty.

Summary box 30.6

Cervical spine injuries

- The majority of upper cervical spinal injuries are treated non-operatively
- Spinal cord injury is more commonly associated with subaxial cervical spinal injuries

Thoracic and thoracolumbar fractures

The system developed by the AO (Arbeitsgemeinschaft für Osteosynthesefragen) can be used to classify these fractures. There are three main injury types, A, B and C, with increasing instability and risk of neurological injury.

Type A fractures are vertebral body compression fractures. Type B injuries involve distraction of the anterior or posterior elements and type C injuries are rotational and often coexist with type A or type B injuries. The majority of type B and type C injuries require surgical stabilisation.

Thoracic spine (T1–T10)

Osteoporotic wedge compression fractures in older adults are the commonest injury in this group. Most of these fractures heal, but symptomatic fractures can be treated with percutaneous bone cement augmentation, known as vertebroplasty or kyphoplasty (***Figure 30.32***).

In trauma cases, unstable fractures are associated with significant energy transfer to the patient and may be associated with major internal injuries, such as pulmonary contusion and spinal cord injury. The combination of thoracic spine disruption and a sternal fracture (***Figure 30.33***) also carries a significant risk of aortic rupture. Multiple posterior rib fractures and rib dislocations above and below a thoracic spinal injury signify a major rotational injury to the chest and can be associated with vascular injury and significant pulmonary contusion (***Figure 30.34***). Multimodality diagnostic imaging is recommended. Surgery is appropriate for most thoracic injuries if unstable.

Figure 30.33 Sagittal computed tomography reconstruction showing an upper thoracic spine fracture dislocation (long arrow) and an associated sternal fracture (short arrow).

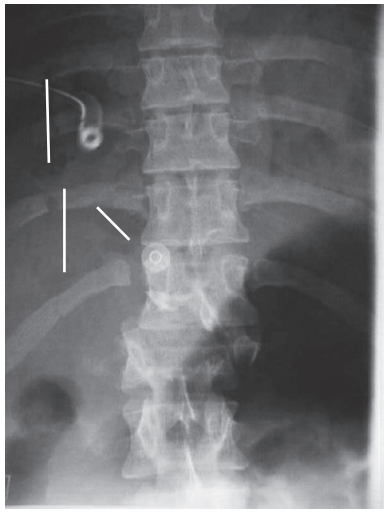

Figure 30.34 Rotational (type C) injury at the thoracolumbar junction. Note rib fractures (long arrows) and dislocation (short arrow), and the presence of a chest tube.

Thoracolumbar spinal fractures (T11–L2)

The thoracolumbar junction is especially prone to injury. This can vary from a minor wedge fracture to spinal dislocation (*Figure 30.35*). Burst fractures are comminuted fractures of the vertebral body. They are characterised by widening of the distance between the pedicles and can be associated with retropulsion of bone fragments into the spinal canal (*Figure 30.36*). Anterior surgery for this type of fracture is now very rarely used and the current treatment principles involve posterior fixation (*Figure 30.37*). Chance fractures

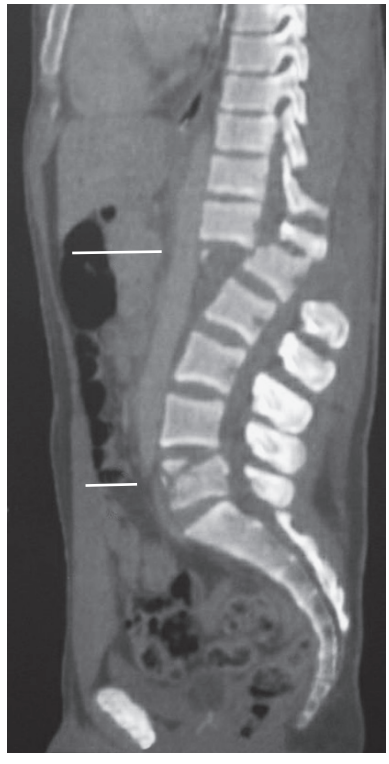

Figure 30.35 Total spinal sagittal computed tomography reconstruction demonstrating a thoracolumbar fracture dislocation (long arrow) and fracture of L5 (short arrow).

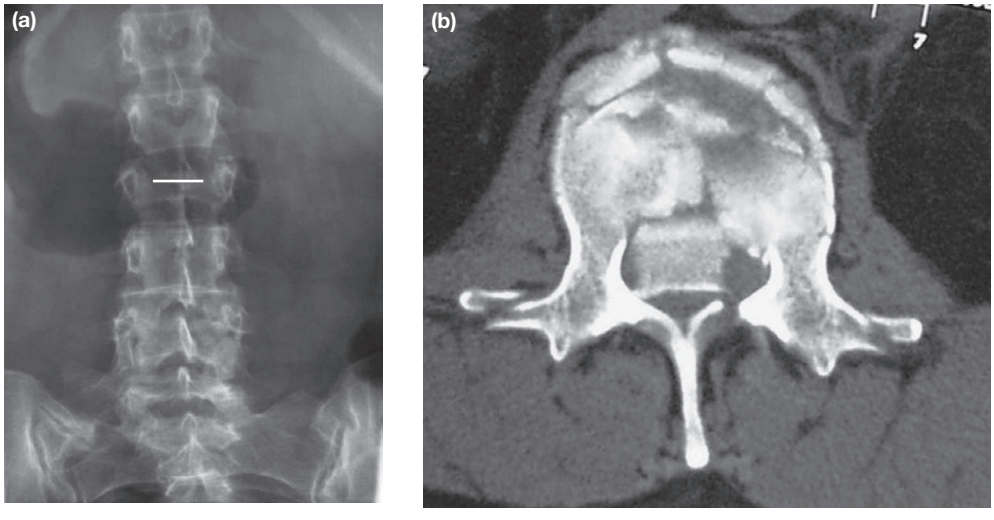

Figure 30.36 Lumbar burst fracture with an increase in the interpedicular distance (a) (arrow) and spinal canal compromise (b).

George Quentin Chance, Director of Diagnostic Radiology, The Derby Group of Hospitals, Derby, UK.

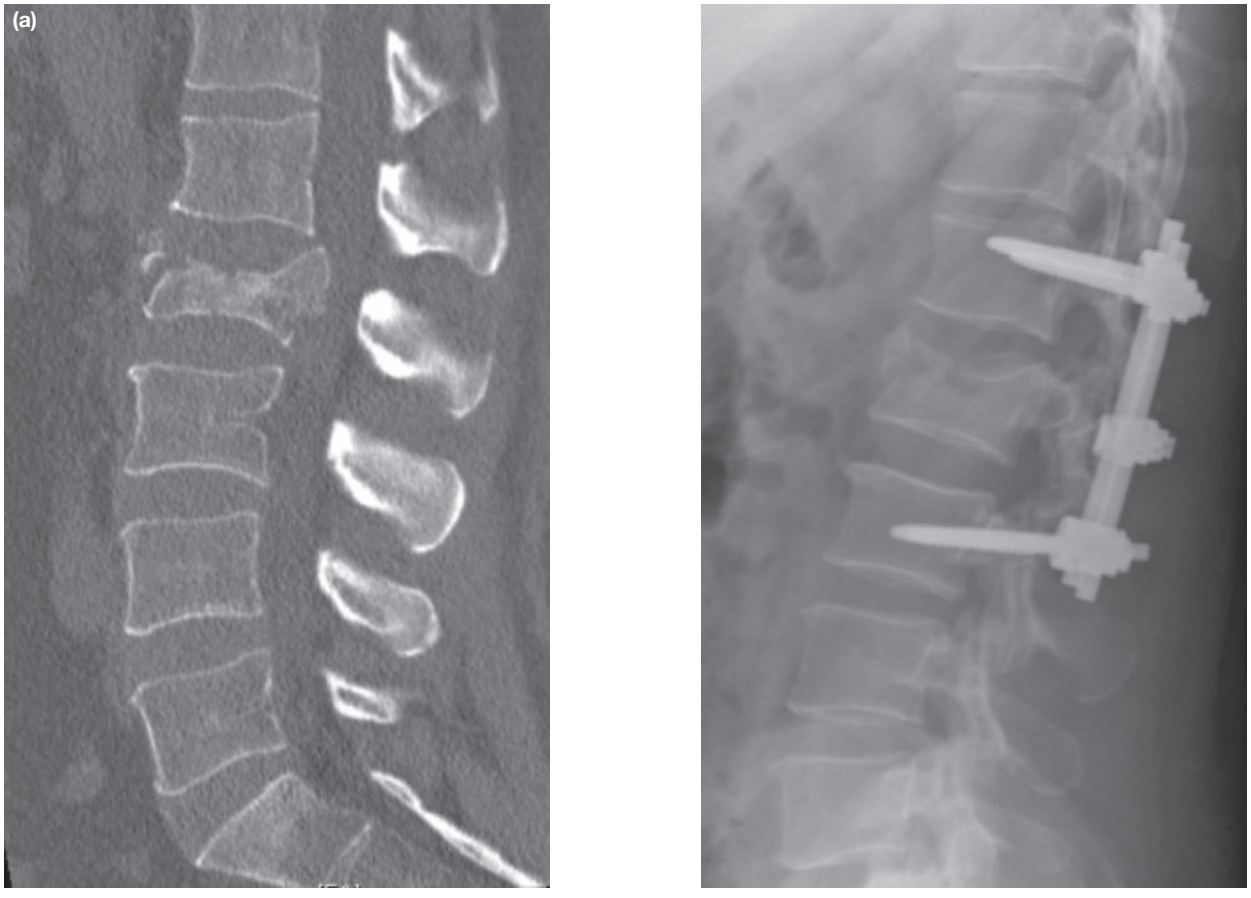

Figure 30.37 Lumbar burst fracture at L2 **(a)**, and posterior instrumentation with indirect reduction **(b)**.

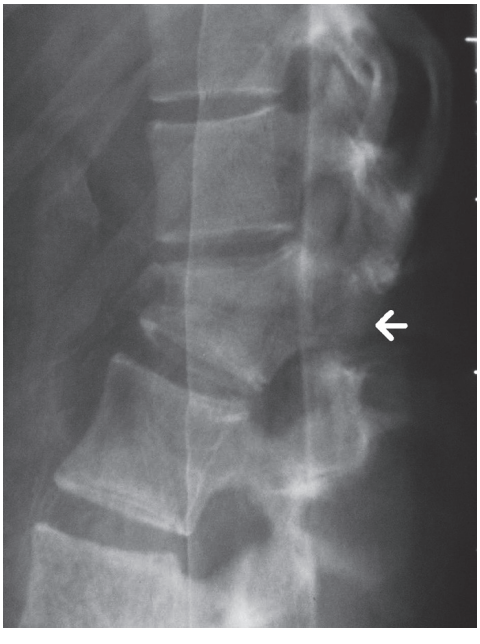

Figure 30.38 A bony Chance fracture at the thoracolumbar junction (arrow) secondary to a lap-belt injury.

are flexion–distraction injuries of the thoracolumbar junction and are classically associated with the use of lap belts (***Figure 30.38***). Duodenal, pancreatic and/or aortic ruptures are also associated with these injuries.

Lumbar spinal fractures (L3–S1)

Most fractures of the lower lumbar spine can be treated non-surgically because the incidence of neurological injury is lower. The neural canal is more capacious at this level (the spinal cord terminates at L1/L2). Owing to the lumbar lordosis, patients with these injuries are less likely to develop a kyphotic deformity than those with injuries at the thoracolumbar junction.

Summary box 30.7

Thoracic and thoracolumbar fractures

- Unstable thoracic spine fractures and thoracolumbar flexion–distraction injuries are commonly associated with vascular and/or visceral injuries

EPIDEMIOLOGY OF SPINAL CORD INJURY

The incidence and causation of spinal cord injury vary globally and reflect the demographics and industrialisation of society. Every year, around the world, between 250 000 and 500 000 people suffer a spinal cord injury according to the World Health Organization in 2013. Road traffic accidents remain the leading cause of spinal cord injuries worldwide. Men in the third decade of life are the most likely group to sustain serious spinal cord injury.

EVOLUTION OF THE MANAGEMENT OF SPINAL CORD INJURY

The development of specialised spinal cord injury centres has dramatically improved the survival rates, health and functional outcomes of individuals with spinal cord injury. The first spinal cord injury centre was established in the USA in 1936 by Dr Donald Munro. In 1944 The National Spinal Injuries Centre was established at Stoke Mandeville, UK, by Sir Ludwig Guttmann.

Summary box 30.8

Spinal cord injury

- The incidence of spinal cord injury remains constant
- The outcome is improved in regional/national spinal cord injury centres

PATHOPHYSIOLOGY OF SPINAL CORD INJURY

The primary injury

This is the direct insult to the neural elements and occurs at the time of the initial injury.

The secondary injury

Haemorrhage, oedema and ischaemia result in a biochemical cascade that causes the secondary injury. This may be accentuated by hypotension, hypoxia, spinal instability and/or persistent compression of the neural elements. Management of spinal cord injury must focus on minimising secondary injury.

Summary box 30.9

Pathophysiology of spinal cord injury

- The spinal cord contains various tracts that are topographically arranged
- Spinal cord injury involves both primary and secondary phases
- Therapeutic strategies are directed at reducing the secondary injury

Identification of shock

Three categories of shock may occur in spinal trauma

- **Hypovolaemic shock**. Hypotension with tachycardia and cold clammy peripheries. This is most often due to haemorrhage. It should be treated with appropriate resuscitation.
- **Neurogenic shock**. This presents with hypotension, a normal heart rate or bradycardia and warm peripheries. This is due to unopposed vagal tone resulting from cervical spinal cord injury at or above the level of sympathetic outflow (T5). It should be treated with inotropic support, and care should be taken to avoid fluid overload.
- **Spinal shock**. Spinal shock is a temporary physiological disorganisation of spinal cord function that starts within minutes following the injury. The length of effect is variable, but it can last 6 weeks or longer. It is characterised by paralysis, decreased tone and hyporeflexia. Once it has resolved the bulbocavernosus reflex (*Figure 30.39*) returns.

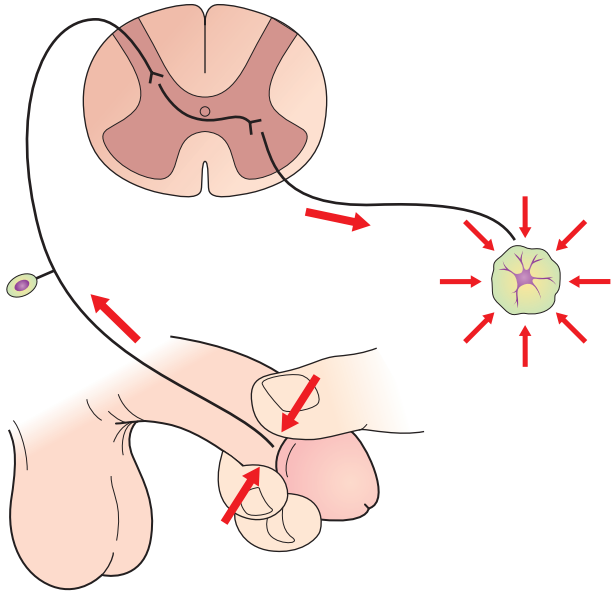

Figure 30.39 The bulbocavernosus reflex (this can be elicited in females by traction on the Foley catheter).

Donald Munro, 1889–1973, established the first spinal cord unit in the USA at the Boston City Hospital, Boston, MD, USA.
Sir Ludwig Guttmann, 1899–1980, considered by many to be the father of spinal cord medicine. He was a leading neurosurgeon in Germany, working at the Jewish Hospital in Breslau. He fled to England in 1939.
Frederic Eugene Basil Foley, 1891–1966, urologist, Ancker Hospital, St Paul, MN, USA.

Level of neurological injury

The level of neurological injury is simply the most caudal neurological level with normal neurological function.

Complete versus incomplete spinal cord injury

A spinal cord injury is incomplete when there is preservation of perianal sensation.

Types of incomplete spinal cord injury

There are several types of incomplete spinal cord injuries. These include:

- central cord syndrome;
- Brown-Séquard syndrome (hemisection);
- anterior spinal syndrome;
- posterior cord syndrome;
- cauda equina syndrome.

REHABILITATION AND PATIENT OUTCOME

The goal of spinal cord injury rehabilitation is based on a multidisciplinary approach. There is a focus on goal-setting, maximising remaining neurological function and reintegration into employment and society. The level of neurological impairment determines the functional outcome (***Table 30.1***).

Prognosis of spinal cord injury

Despite continuing improvements in patient care, life expectancy remains below normal following spinal cord injury. The median life expectancy is 33 years, but varies considerably (***Table 30.2***).

The prognosis for neurological recovery is strongly influenced by factors such as the level and completeness of the injury, ventilator dependence and the age at presentation.

TABLE 30.1 Expected functional outcome versus level of cervical spinal cord injury.

Level of injury	Functional goal
C3–C4	Power wheelchair with mouth or chin control. Verbalise care, communicate through adaptive equipment. May be ventilator dependent
C5	Power wheelchair, dress upper body, self-feed with aids, wash face with assistance
C6	Propel power wheelchair, possibly push manual wheelchair, transfer with assistance, dress upper body (lower body with assistance), self-groom with aids, bladder/bowel care with assistance, self-feed with splints, able to drive
C7	Manual wheelchair, independent transfer, dressing (with aids), feeding, bathing, self-care. Bladder and bowel care with assistance
C8–T4	Independent with most activities of daily living, and bowel and bladder care
T5–T12	As above but with more ease. Independent with all self-care
L1–L5	Independent. Walk with short or long leg braces
S1–S5	Independent, able to walk if able to push off (S1) (may need brace). Bladder, bowel and sexual function may remain compromised

TABLE 30.2 Life expectancy (years) post injury by severity of injury and age at injury.

Age at injury	No SCI	Motor functional at any level	Paraplegic	Low tetraplegic (C5–C8)	High tetraplegic (C1–C4)	Ventilator dependent at any level
a For people who survive the first 24 hours						
20	58.4	52.8	45.6	40.6	36.1	16.6
40	39.5	34.3	28.0	23.8	20.2	7.1
60	22.2	17.9	13.1	10.2	7.9	1.4
b For people surviving at least 1 year post injury						
20	58.4	53.3	46.3	41.7	37.9	23.3
40	39.5	34.8	28.6	24.7	21.6	11.1
60	22.2	18.3	13.5	10.8	8.8	3.1

SCI, spinal cord injury.

Charles Edward Brown-Séquard, 1817–1894, physiologist and neurologist who held a number of academic posts, among them Physician, the National Hospital for Nervous Diseases, London, UK (1860–1864), Professor of Medicine at Harvard University, Boston, MA, USA (1864–1878), and at the Collège de France, Paris, France (1878–1894). He described his syndrome in 1851.

Complications associated with spinal cord injury

Pressure ulcers

Many are preventable. Patients should be turned regularly on an appropriate mattress to minimise the risk of skin breakdown.

Pain and spasticity

Neurogenic pain is common. Once reflex activity returns following cord injury, spasticity may occur and can be problematic. Intrathecal infusion of baclofen may be required in resistant cases.

Autonomic dysreflexia

This is a paroxysmal syndrome of hypertension, hyperhidrosis (above the level of injury), bradycardia, flushing and headache in response to noxious visceral and other stimuli. It is most commonly triggered by bladder distension or rectal loading from faecal impaction.

Neurological deterioration

Post-traumatic syringomyelia may occur in around 28% of patients with spinal cord injury up to 30 years following injury. Approximately 30% of cases are symptomatic. Clinically, patients present with segmental pain at or above the level of injury, sensory loss, progressive asymmetrical weakness or increased spasticity. This warrants early MRI assessment. Expanding cavities require neurosurgical intervention.

Thromboembolic events

Deep vein thrombosis occurs in 30% of patients with spinal cord injury. Fatal pulmonary embolus is reported in 1–2% of cases. Thromboprophylaxis with compression stockings and low-molecular-weight heparin is indicated, provided there are no contraindications.

Osteoporosis, heterotopic ossification and contractures

Disuse osteoporosis is an inevitable consequence of spinal cord injury and fragility fractures may occur. Heterotopic ossification may affect the hips, knees, shoulders and elbows. It occurs in 25% of patients with spinal cord injury. Surgery is appropriate in selected cases. Soft-tissue contractures around joints may occur as a result of spasticity but can be avoided by appropriate physical therapy, positioning and splinting.

PART 4 | Trauma

CHAPTER

31 Maxillofacial trauma

Learning objectives

- To understand and identify potentially life-threatening injuries to the face, head and neck
- To safely perform a systematic examination of facial injuries, and describe the basic classification of soft-tissue and bony injuries
- To describe the principles of management of facial soft-tissue injuries
- To understand and describe the principles of management of fractures of various facial bones, and appreciate the initial management of dental injuries

EMERGENCY ASSESSMENT AND MANAGEMENT

Maxillofacial injuries that require hospital attendance are common and are most frequently related to trips and falls, road traffic accidents (RTAs), taking part in sports and interpersonal violence. Initial assessment requires a focused history of the mechanism of injury and a general medical and social history, followed by clinical examination. An injury to the body including facial trauma must be managed with an immediate assessment of the airway, breathing and circulation (ABC) in line with the established Advanced Trauma Life Support (ATLS) guidelines. Any visible object obstructing the airway should be removed if possible, and, if indicated, direct pressure should be applied to bleeding points. If the patient has midface bleeding where direct pressure cannot be applied, the conscious patient may sit forwards or be placed on their side in the standard recovery position to minimise the risk of blood obstructing the airway. Care should be exercised if there are concerns of concurrent spinal injury.

In severe injury to the midface skeleton, the maxilla can become detached from the skull base and displaced downwards and backwards (***Figure 31.1***). The patient may present with acute airway compromise if the midface impaction is also combined with a bilateral mandibular fracture, which can displace the tongue backwards. Such injuries are often associated with significant oedema of the soft palate and tongue (***Figure 31.2***). In these situations, the team must be prepared to undertake an endotracheal intubation, a needle cricothyroidotomy or an emergency surgical airway procedure if intubation proves difficult. There are certain techniques that can be used immediately to relieve airway compromise, while preparations are made for definitive airway management. In the obtunded or unconscious patient, the maxilla can be disimpacted and pulled forwards using fingers. The tongue can be pulled and held forwards, with a large suture or a towel clip, to help open up the airway. High-volume suction must be readily available

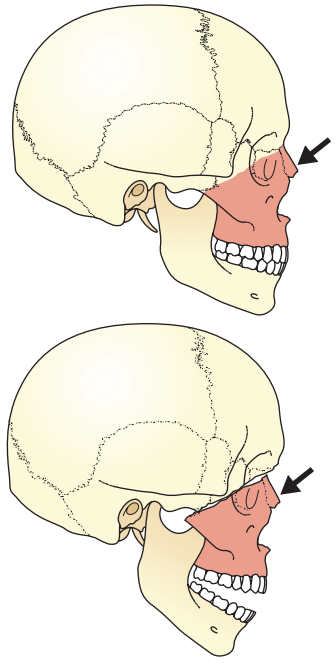

Figure 31.1 A severe blow to the midface may detach the facial skeleton from the base of the skull and push it downwards and backwards.

to clear the blood as well as tooth fragments and debris from the oral cavity and upper aerodigestive tract.

Torrential life-threatening haemorrhage may be seen in facial trauma that involves large soft-tissue lacerations, penetrating neck injuries or ballistic injuries. The source of such bleeding is likely to be from injury to the maxillary artery or pterygoid venous plexus in the grossly damaged midface, or branches of the external carotid artery or tributaries of the internal jugular vein in penetrating injuries of the neck. The management of severe bleeding may require application of

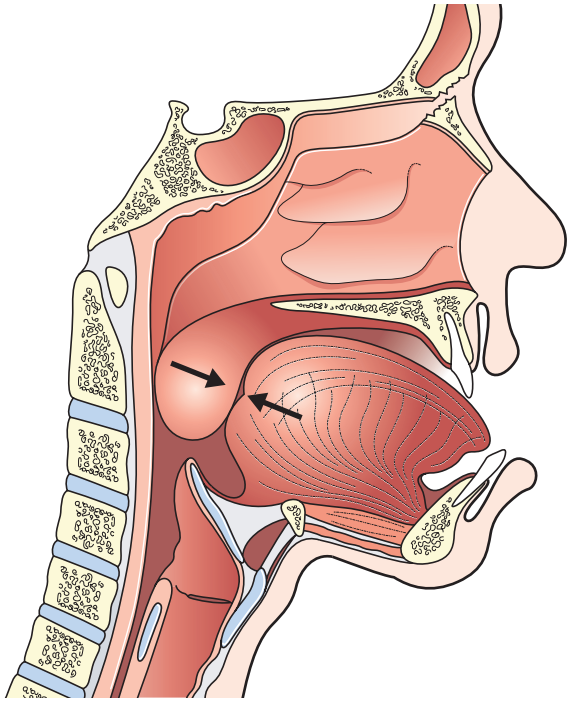

Figure 31.2 Loss of pharyngeal space secondary to oedema of the soft palate and the posteriorly displaced tongue may restrict the airway.

direct digital pressure or placement of anterior and posterior nasal packs. Specific inflatable balloon nasal packs or Foley urinary catheters may be utilised to exert pressure on the bleeding points. An endotracheal intubation or a surgical airway may be required if there is concern regarding extensive soft-tissue swelling secondary to injury or surgical intervention (***Figure 31.3***).

It is important to assess the maxillofacial patient for severe head injury that can result in significant cerebral damage. Patients with facial injury and particularly those with injury due to interpersonal violence are frequently intoxicated because of alcohol or drug abuse, which may mask the symptoms of head injury. Therefore, clinicians should have a low threshold for requesting a brain computed tomography (CT) scan to exclude significant intracranial injury. In such cases, it is prudent to include the facial bones in the CT request if indicated. Injuries to the midface are frequently associated with orbital damage, which can lead to loss of sight if not dealt with urgently. Retrobulbar haemorrhage, which can cause acute compression of the optic nerve if not treated immediately, may lead to loss of vision (see ***Orbital fractures***).

Summary box 31.1

Emergency assessment and management

- Immediate management must include assessment of ABC with cervical spine protection, following which a more detailed assessment should ensue
- Life- and sight-threatening facial injuries should be treated immediately
- The clinical team should be prepared for endotracheal intubation or, if required, a surgical airway

CLASSIFICATION OF FACIAL INJURIES

Bony injury

Maxillofacial bone fractures can be divided into several types: simple (isolated single), compound (communicates through the skin or oral/nasal mucosal surfaces), comminuted (multiple fragments), complicated (with neurological or vascular injury), greenstick (includes single cortex) and pathological (through an existing lesion such as neoplastic or inflammatory). Fractures can be further classified into undisplaced, minimally displaced or displaced.

The facial skeleton can be divided vertically into thirds using horizontal lines: upper face (from the level of the canthi upwards), midface (from the maxillary teeth to the canthi) and lower face (mandible and mandibular teeth). The midface can be further divided into central and lateral, with the naso-orbital–ethmoidal complex forming the central and the zygomaticomaxillary complex forming the lateral components. Orbital (eye socket) fractures can occur in isolation or in combination with other fractures. Orbital fractures can be classified into orbital floor, medial and/or lateral walls and the roof of the orbit.

Figure 31.3 Tracheostomy *in situ* perioperatively to protect the airway in a patient with extensive facial fractures secondary to a road traffic accident.

Frederic Eugene Basil Foley, 1891–1966, urologist, Ancker Hospital, St Paul, MN, USA.

Skull fractures including frontal and ethmoidal sinuses, in combination with facial fractures, are termed craniofacial fractures. A joint neurosurgical and maxillofacial approach is necessary in these cases because of the possibility of intracranial injury. Frontal sinus fractures are classified into those involving the anterior or posterior table, with or without damage to the frontonasal duct.

The most severe facial fractures involving bony injury at all levels of the facial skeleton are referred to as panfacial fractures. These usually imply that a significant degree of force has been involved, suggesting significant other injuries such as head, abdominal or chest injuries.

Soft-tissue injury

Lacerations are a result of crushing injuries where the soft tissues are compressed onto the underlying bone, usually by a blunt object. Sharp implements, such as a knife or glass, cause incised wounds. Any soft-tissue injury can present with or without tissue loss. Where the injury results in a communication between the skin and the mucosa of the oral or nasal cavity, the wound is termed 'through and through'. The soft-tissue injury may present with or without damage to the underlying bony structure.

Summary box 31.2

Classification of facial injuries

- There are multiple ways of classifying facial fractures, the simplest way is to divide the face into thirds and describe the specific bone involved
- Assess orbit independently
- Assess soft-tissue injury in terms of loss of tissue and damage to the underlying bone

CLINICAL ASSESSMENT

History

The history should include the mechanism of injury, past medical history and the postinjury events; it should be obtained directly from the patient and from witnesses and the first responding emergency services if required. Knowledge of the mechanism of injury will often help to identify potential occult injuries that may not be readily detectable on first inspection. Factors such as sharp or blunt trauma, wound contamination and energy transfer should be assessed and recorded. The medical history should gain information to indicate the general fitness of the patient for potential treatment under general anaesthesia. It is important to obtain previous tetanus vaccination history, and the vaccine should be given promptly if there is a high risk of contamination.

Examination

Primary survey

The primary survey is aimed at protection of the airway, control of bleeding, restoration and maintenance of the circulation and assessment for neurological deficits, including the Glasgow Coma Scale (GCS) score, with cervical spine control.

The head and neck region should be inspected, with wounds assessed for skin or soft-tissue loss and subsequently dressed appropriately to control any bleeding. The wound size, location and depth should be carefully recorded. Large and obvious foreign bodies should be removed but care should be exercised with penetrating wounds involving large fragments or blades, which can potentially penetrate important deep structures. These should be removed in the operating theatre, under more controlled conditions, after appropriate imaging.

Secondary survey

The secondary survey examination should be conducted in a systematic way, preferably following a top-down approach carefully examining all structures, recording obvious as well as less conspicuous injuries. The surface inspection should include the scalp, posterior neck and ears and then move to the frontal view. A brief cranial nerve examination should be undertaken as guided by the injury site. Particular attention must be paid to cervical spine examination as the patient with facial injury may have concurrent spinal injury, which may have been missed in the primary assessment.

Examination of the eyes should include visualisation of the periorbital tissues and assessment of globe position, visual acuity, diplopia (double vision), intercanthal distance and eye motility. This examination may be difficult if the eyelids are swollen and the eyes are shut. However, such an examination is crucial as inadequate examination may lead to a delay in the diagnosis of serious eye injury that may need urgent intervention to prevent blindness. Examination is possible even in the most swollen of eyes by gently pulling the eyelids apart with dry gauze, a cotton bud/roll or a microbiology swab stick. Gentle pressure on the eyelid for a brief period may reduce oedema, which may facilitate the opening of the eyelids. It may be helpful to ask a colleague to perform the eye examination if one is holding the eyelids apart to facilitate examination.

The facial bones should be palpated for signs of fractures, which may include step deformity, tenderness or bony asymmetry. A systematic approach would include palpation of the supraorbital ridge followed by the lateral orbital wall, inferior orbital rim, zygomatic bone, nasal bones, temporomandibular joint and the rest of the mandible on both sides.

The examination of the oral cavity should include inspection for any soft-tissue lacerations, bruising, haematoma, injury to dentition and assessment of occlusion (bite). Any blood and excessive secretions should be suctioned and a good light source used to facilitate thorough examination. The teeth should be examined and their presence or absence noted. Teeth may be knocked out completely (avulsed), displaced but still attached to soft tissues and/or bone (luxated) or fractured. It is important to account for all missing teeth or tooth fragments as aspiration is a major risk for developing chest infection. If it is unclear about the location of missing teeth, a chest radiograph should be considered.

A key feature of displaced mandibular or maxillary fractures is altered occlusion. The patient may be able to detect even a tiny alteration in their occlusion. If there is a fracture of the mandible, the overlying mucosa is often torn and there

Figure 31.4 Left parasymphyseal fracture of the mandible demonstrating a step deformity that could be confused with a missing tooth in inexperienced eyes.

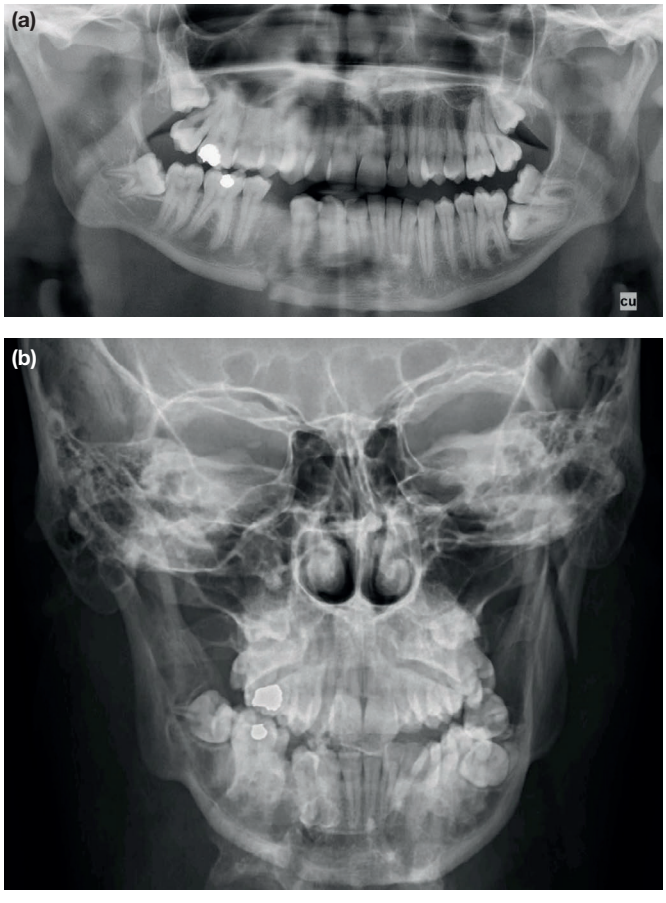

Figure 31.5 (a) Orthopantomogram (OPT) demonstrating a right mandibular body and left condylar fracture. **(b)** A posteroanterior mandible radiograph reveals the left low condylar fracture more clearly, which may not be as obvious as in the OPT to an inexperienced clinician.

may be an associated haematoma in the floor of the mouth (***Figure 31.4***). If the mandibular fracture is grossly displaced, the patient may have altered sensation in the region of the lip and chin, due to damage to the inferior alveolar nerve running along the canal within the mandible and involvement of the mental nerve, a sensory branch, which emerges from the mental foramen.

Figure 31.6 Occipitomental radiograph demonstrating a right zygomatic fracture. Note the right maxillary sinus opacification, which is one of the radiological hallmarks of zygomatic fracture due to collection of fluid in the sinus.

Investigations

The nature of the injury sustained will determine the specific investigations required to facilitate diagnosis. Systemic investigations may include routine haematology and biochemistry investigations, and imaging requests such as cervical spine, chest, abdominal or limb radiographs depending on the site of injury.

If a mandibular fracture is suspected, an orthopantomogram (OPT) and a posteroanterior (PA) radiograph of the mandible should be obtained (***Figure 31.5***). It is extremely important to have two views at right angles to each other to avoid missing any fractures. Very occasionally a lateral mandibular view may have to be utilised as a screening radiograph if the patient is unable to cooperate for the OPT (e.g. patients with dementia). For a suspected midface fracture, occipitomental (OM) radiographs at 10° and 30° should be obtained (***Figure 31.6***). A CT of the facial bones would be more suitable if an orbital fracture is suspected or in the case of a high-impact injury; this will provide the gold standard detail of bony structures and, as previously mentioned, should include the brain if there is any suggestion of a head injury. A three-dimensional (3D) reformatting of the CT scan allows for excellent visualisation of the maxillofacial bony structures.

Summary box 31.3

History, examination and investigation

- A detailed history of the mechanism of injury is crucial in any initial assessment
- A systematic approach should be adopted in examination of the craniomaxillofacial structures; a top-down approach is recommended
- The most common radiographs requested in facial fracture investigation are OPT and PA mandible for mandibular fractures, and OM facial views for midface fractures

SPECIFIC INJURIES

Soft-tissue injuries

Lacerations

Soft-tissue injuries of the face are a result of blunt or sharp trauma and should be carefully examined to exclude any associated nerve, parotid duct or underlying bony injury (***Figure 31.7***). These can mostly be repaired under local anaesthesia (LA) and should be treated within 24 hours of injury to avoid poor healing and an unsightly scar. Lacerations in uncooperative children and large contaminated wounds in adults usually require repair under general anaesthesia (GA). Uncomplicated wounds with no tissue loss should be cleaned and closed in layers. If the skin is contaminated with dirt, it should be gently scrubbed with a soft brush to prevent dirt tattoo. Facial skin has a rich blood supply, which contributes to its excellent healing; therefore, wounds should only be debrided of frankly necrotic tissue.

Intraoral wounds heal very well; if small, they can be left to heal by secondary intention, especially in children to avoid treatment under GA. Resorbable 3-0 or 4-0 sutures are placed intraorally and for the deep layers of the skin. The most superficial skin layer should be closed with a 5-0 non-resorbable monofilament suture, except in potentially uncooperative children when 5-0 or 6-0 resorbable sutures can be used. Some surgeons also use resorbable 5-0 or 6-0 skin sutures in adults. For some small superficial clean incised wounds, cyanoacrylate tissue glue can be utilised. This must be avoided in periocular skin because of the risk of spillage into the eye, which can lead to severe corneal damage.

Lacerations involving the eyelid margins and those crossing the vermilion border of the lip need special attention to avoid poor approximation of the skin edges, which can result in a poor cosmetic outcome. If there is tissue loss, adjacent skin can be undermined and mobilised to achieve primary closure, but incisions for local flaps or skin grafts should be avoided in the initial management. Very large areas of tissue loss may require free flap reconstruction if local tissue flaps are inadequate for resurfacing the defect.

Facial nerve

Facial nerve function should be routinely assessed in all facial lacerations. Any nerve injuries are best repaired primarily under high magnification and GA. In general, nerve injuries that lie lateral to the line drawn vertically down from lateral canthus of the eye are repairable, and this should be attempted. A nerve stimulator or monitor may be helpful in identifying the transected nerve ends.

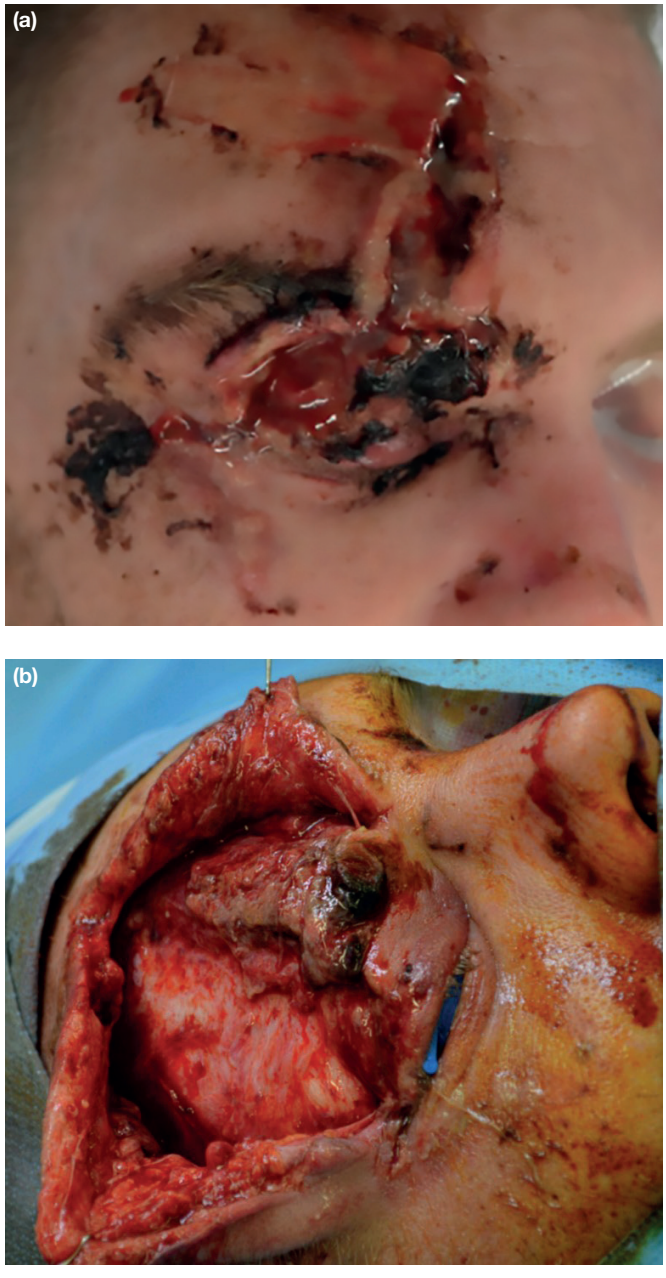

Figure 31.7 (a, b) Extensive soft-tissue laceration, the full extent of which may only be revealed on careful examination. Corneal protection *in situ*.

Parotid duct

The middle third of a line drawn from the tragus of the ear to the midpoint between the upper lip and the alar base represents the surface landmarking of the parotid duct. A careful examination of the wound may reveal saliva leak in the case of a duct injury. Methylene blue solution can be injected through the parotid duct opening intraorally (adjacent to the

upper molar teeth) and any leak assessed in the wound bed. The repair is best achieved under high magnification, over a cannula inserted through the duct opening under GA. The buccal branch of the facial nerve that closely follows the duct may also get transected in the injury; this requires careful examination.

Animal and human bites

Facial bites should be cleaned thoroughly and closed primarily in layers. Because of the high risk of wound infection, antibiotics must be prescribed according to local microbiology guidelines. With human bites, consideration should be given to testing the patient for human immunodeficiency virus (HIV) infection, and hepatitis serology is also sensible, if the patient is deemed to be at high risk of being infected as a result of the bite. If there is significant tissue loss, a staged reconstruction may be required.

Summary box 31.4

Soft-tissue injuries

- Examination of the function of both motor and sensory nerves should be conducted prior to the administration of LA
- All animal and human bites must be covered with prophylactic antibiotics
- Tissue loss may require staged reconstruction

Mandibular fractures

Fractures of the mandible are common in the context of facial injury and may frequently involve multiple sites. The commonest fracture patterns are parasymphysis and angle fractures, or parasymphysis and condylar fractures (contralateral sites in both cases). The specific sites in the mandible most prone to fractures are shown in ***Figure 31.8***. It is very important to record the presence or absence of any paraesthesia in the region of the lower lip and chin, which may be the result of damage to the inferior alveolar nerve.

Most displaced mandibular fractures are treated with antibiotics on admission followed by open reduction and internal fixation (ORIF). Typically, titanium miniplates and screws are placed (***Figure 31.9***) under GA with two or three postoperative intravenous antibiotic doses given. Undisplaced fractures may

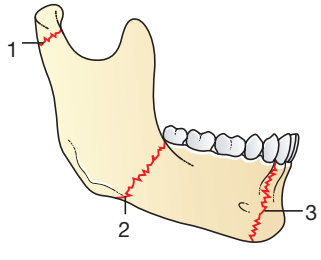

Figure 31.8 Fractures of the mandible. (1) The neck of the condyle is the most common site, followed by (2) the angle of the mandible. (3) The third point of weakness is in the region of the mental foramen.

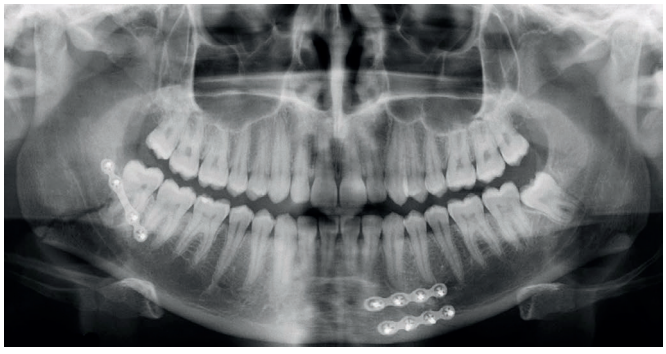

Figure 31.9 Postoperative orthopantomogram demonstrating fixation of a right angle and left parasymphyseal fracture with miniplates and screws.

be treated conservatively; this may include antibiotics, analgesia and a soft diet for 4 weeks. These patients need to be monitored closely to exclude failure of conservative management, which will commonly be indicated by increasing pain and a change in occlusion. In general, facial bones heal well after about 4 weeks. Occasionally, if the fractures are severely comminuted and difficult to fix with titanium plates, intermaxillary fixation (IMF) with wires can be considered; however, this is becoming exceedingly rare owing to the advances in osteosynthesis fixation techniques.

Simple mandibular fractures treated with the ORIF technique should have two 2-mm-diameter screws on either side of the fracture, engaging a single bone cortex (monocortical). These small plates are load sharing, which indicates that the fractures are reduced and load is shared between the bone and the plate. With more complex or comminuted fractures, heavy profile reconstruction plates and bicortical screws may be placed as a load-bearing fixation technique. In general, different mandibular sites determine the number of miniplates used; for example, a single plate is placed along the line of maximal tension for angle and body of mandible fractures, while two plates are placed 5 mm apart for parasymphyseal fractures to resist the torsional forces of the anterior mandible musculature. A transbuccal approach through a tiny incision in the cheek skin is frequently utilised for angle fractures to allow placement of screws perpendicular to the plate and the bone.

Most condylar fractures can be treated with closed reduction with IMF elastic guidance and a strict soft diet and analgesic regimen. However, displaced condylar neck fractures with significant loss of mandibular height are increasingly treated with ORIF techniques. Various approaches can be adopted depending on the condylar fracture location, although the most common approach is transparotid access with a retromandibular incision. There have been some advances towards endoscopic-assisted fixation of the condylar fractures in some maxillofacial units.

The optimal timing for the repair of a mandibular fracture is within 24–48 hours post injury. For a heavily displaced fracture where there is likely to be delay in taking the patient to theatre, a bridal wire that goes around the teeth to temporarily reduce the fractures may be useful in alleviating pain and facilitating oral intake.

Summary box 31.5

Mandibular fractures

- Always look for a second mandibular fracture as contralateral fractures are common
- It is important to record the presence or absence of paraesthesia in the distribution of the mental nerve
- Most mandibular fractures are treated with ORIF using titanium miniplates and screw fixation, ideally within 24–48 hours of injury

Zygomatic fractures

Zygomatic (cheek/malar) bone fractures are often the result of blunt trauma to the midface, such as from a fist. From a clinical perspective, it is helpful to consider the zygomatic bone as a four-legged stool, as shown in ***Figure 31.10***. The four legs comprise the zygomatic arch running anteroposteriorly, the zygomatic process running vertically to join the frontozygomatic (FZ) process of the frontal bone at the FZ suture, the infraorbital rim running horizontally and the maxillary buttress running vertically. Zygomatic fractures may include isolated or multiple fracture lines involving any of these legs, often in combination with orbital wall fracture.

Zygomatic fractures may be difficult to assess in the presence of significant facial swelling; therefore, patients are usually reviewed in clinic 1 week after injury to allow the swelling to subside. There may be periorbital swelling and bruising, step deformity and frequently a subconjunctival haemorrhage with no posterior border or limit (***Figure 31.11***). A concomitant orbital bone fracture also needs to be excluded; if suspected, a CT scan to include the orbits should be obtained.

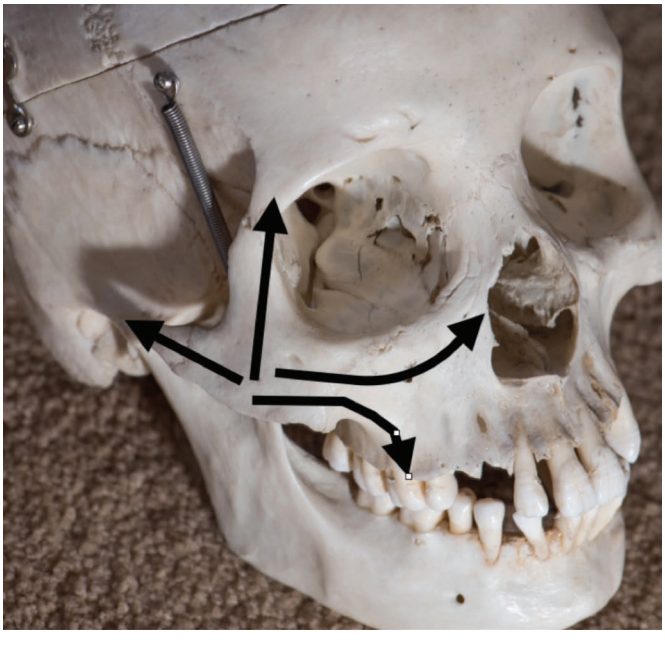

Figure 31.10 The 'four legs of the stool'.

Figure 31.11 Fractures of the zygoma may often be associated with periorbital swelling and subconjunctival haemorrhage without a posterior border or limit.

Undisplaced or minimally displaced zygomatic fractures are often treated conservatively, with patients being told to avoid any excessive pressure on the affected side for a minimum of 3 weeks. The indications for surgical intervention include asymmetrical cheek bone prominence, persistent eye symptoms such as diplopia, orbital deformity and restricted mouth opening due to impingement of the coronoid process by the bone fragment.

There are a variety of transcutaneous (including upper and lower lid) and intraoral surgical approaches for access, determined by the exact location of the fracture. The isolated zygomatic fracture is often reduced by a closed technique involving an incision in the temple (Gillies' lift) or intraorally (Keen's technique). The ORIF of FZ suture fractures and infraorbital rim or maxillary buttress fractures usually includes low-profile 1.5-mm midface titanium plates and screws. The provision for single-, double-, triple- or four-point fixation of the zygomatic fracture is dependent on the stability of the fracture post reduction and the degree of bone comminution.

Summary box 31.6

Fractures of the zygomatic bone

- Fractures of the zygomatic bone often require follow-up 1 week after the injury for the swelling to subside to allow full assessment
- Orbital fractures may occur in combination with zygomatic fractures
- There are a variety of transcutaneous or intraoral surgical approaches that are determined by the exact location of the fracture

Sir Harold Delf Gillies, 1882–1960, born New Zealand, studied medicine at the University of Cambridge, Cambridge, UK, pioneer of plastic surgical techniques during and after the First World War.
William Williams Keen, 1837–1932, pioneer American neurological surgeon.

Maxillary bone fractures

Maxillary fractures are classified according to their anatomical level, as originally described by René Le Fort (*Figure 31.12*). Le Fort I involves a fracture line extending from the pterygoid plates through the lateral wall of the maxillary sinus and piriform aperture of the nose. Le Fort II involves the whole of the dentition-bearing portion of the maxilla and the nasal bones. The fracture line extends from the pterygoid plates to the inferior orbital rim and across the bridge of the nose. Le Fort III fracture essentially is where the whole of the midface is separated from the skull base. The fracture line runs from the pterygoid plates to the base of the zygomatic arch, the lateral walls of the orbit through the FZ suture and the nasal bridge.

The Le Fort classification is simple to describe, but the clinical presentation may not be as clear-cut as the fractures at these levels rarely occur in isolation. There may be significant commination owing to the thin composition of the maxillary bone as well as the differing pattern of fracture on two sides.

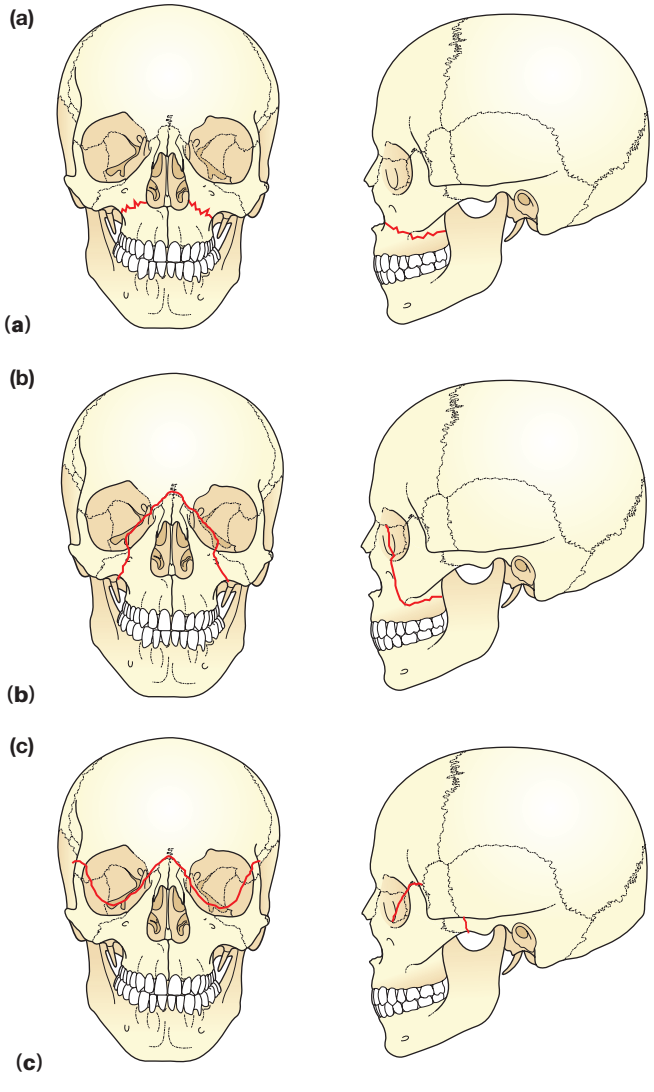

Figure 31.12 Maxillary fractures as classified by Le Fort. **(a)** Le Fort I; **(b)** Le Fort II; **(c)** Le Fort III.

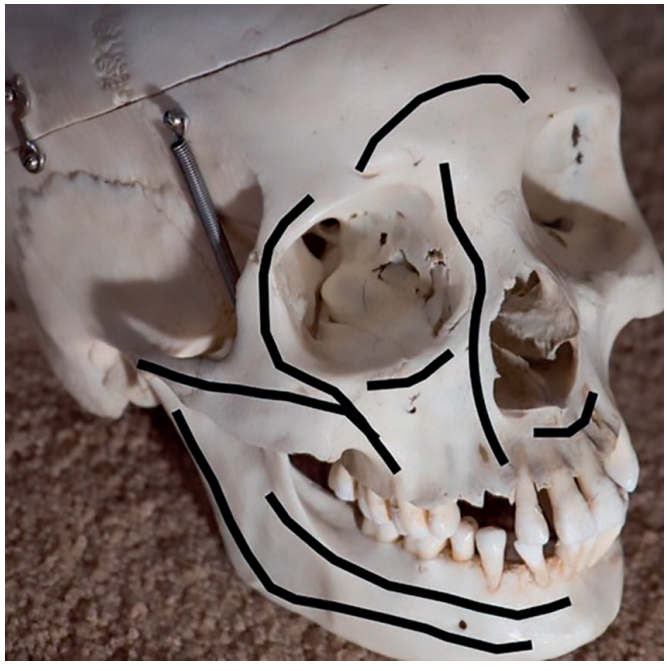

Figure 31.13 The buttresses of the facial bones. These are the strongest part of the facial skeleton and may help with fixation because of good bone quality.

Undisplaced or minimally displaced factures are best treated conservatively with a soft diet and analgesia. The indications for ORIF include a mobile, unstable maxilla, deranged occlusion such as an anterior open bite and loss of facial projection and width resulting in obvious facial deformity. Fixation is achieved with midface 1.5-mm miniplates and screws, with various surgical approaches for access depending on the location of the fracture. Plates are usually placed along the main facial buttresses, which provide the optimal strength and bone quality to be able to hold the screws (*Figure 31.13*).

Summary box 31.7

Maxillary bone fractures

- Maxillary fractures occur at various levels, which may not follow the typically described Le Fort classification pattern owing to comminution and asymmetry of the fracture
- Maxillary fractures may be associated with significant bleeding (often from the pterygoid plexus), which may require packing of the nasal cavity

Orbital fractures

Orbital fractures may be isolated or more commonly occur in conjunction with zygomatic or maxillary complex fractures. They most frequently involve the orbital floor, followed by the medial wall, lateral wall or the roof, which may present in

René Le Fort, 1869–1951, French surgeon, classified facial fractures after macabre research in which he dropped rocks and other heavy objects onto the faces of cadavers.

Figure 31.14 Coronal computed tomography (CT) scan demonstrating a left orbital blow-out fracture, with soft-tissue herniation into the maxillary antrum.

combination or as isolated injuries. Isolated orbital injuries are described as 'blow-out' or 'blow-in' fractures. An example of a blow-out fracture is shown in ***Figure 31.14***.

Orbital floor fractures may lead to restricted upward gaze owing to trapping of orbital fat and fibrous septae resulting in diplopia on looking upwards. Occasionally, the inferior rectus or inferior oblique muscles may also be trapped. Inferior rectus muscle entrapment in children may present as the oculocardiac reflex: a triad of bradycardia, nausea and syncope. This needs to be treated as an emergency because irreversible damage related to muscle necrosis can occur within hours. In these cases, on imaging, the orbital floor may appear undisplaced or minimally displaced, which means that a trapdoor defect has opened and then closed again, entrapping the muscle. They are also described as a 'white eye' blow-out fracture as children often present with no subconjunctival haemorrhage (***Figure 31.15***). In addition to the restricted eye movement, orbital wall fractures can lead to changes in globe position, with inferior positioning of the globe (hypoglobus) or sinking in of the globe due to an increase in orbital volume (enophthalmos). These globe position changes may only become visible after the initial swelling has subsided; the true extent is only revealed 2–4 weeks after the injury.

The indications for surgical repair of orbital fractures include enophthalmos or persistent diplopia resulting from restricted eye motility as a result of extraocular muscle entrapment within the fracture line. It is important to seek orthoptic assessment; this is helpful in differentiating between muscle entrapment and muscle dysfunction (secondary to inflammation), both of which may cause diplopia. Diplopia secondary to muscle dysfunction is likely to resolve spontaneously with time. Repair of the orbital rim is usually accomplished with ORIF techniques and the orbital walls repaired with preformed or patient-specific titanium implants or less commonly autologous materials such as cranial bone grafts.

Figure 31.15 This 11-year-old boy presented with an oculocardiac reflex secondary to a 'white eye' blow-out left orbital floor fracture following a rugby injury.

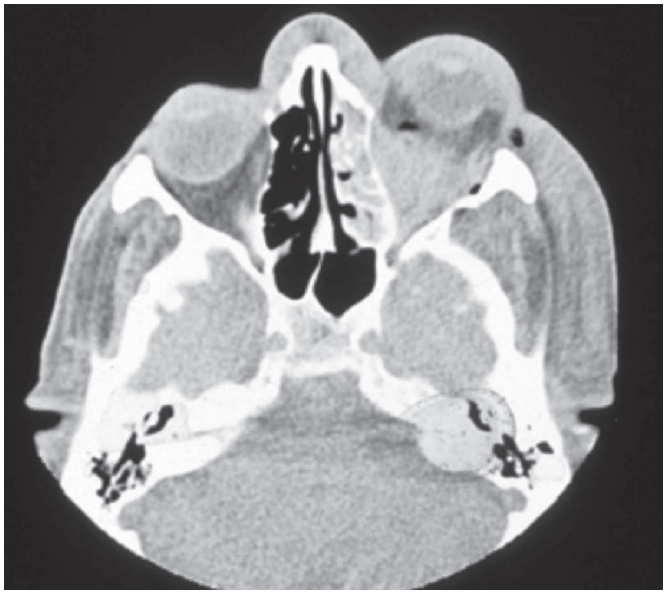

Figure 31.16 An axial CT scan demonstrating left retrobulbar haemorrhage and severe proptosis. This should be a clinical diagnosis and treated immediately, rather than as a finding on the CT scan later.

A retrobulbar haemorrhage is an acute surgical emergency as it can lead to blindness secondary to pressure-induced reduced flow on the retinal artery, leading to ischaemic damage to the optic nerve (***Figure 31.16***). It presents with tense proptosis, increasing pain, reduced visual acuity and loss of the pupillary response. One of the early signs may be altered perception of red colour in the affected eye. If this is suspected, preparation should be made for immediate bedside lateral canthotomy and cantholysis under LA to allow the globe to bulge forwards and relieve the pressure posteriorly. Concomitant medical management should also be initiated with mannitol, acetazolamide and steroids.

Summary box 31.8

Orbital fractures

- Orbital fractures may be isolated or in combination with zygomatic or maxillary fractures
- Children may present with a trapdoor orbital floor fracture that may cause an oculocardiac reflex, requiring urgent surgical intervention to prevent muscle necrosis
- Retrobulbar haemorrhage is a surgical emergency treated with bedside lateral canthotomy and cantholysis under LA to prevent blindness

Frontal sinus fractures

As frontal sinus fracture signifies a large amount of force applied to the cranium, any concomitant intracranial injuries must also be identified and treated appropriately. Frontal sinus fracture may be classified according to whether the anterior, posterior or both tables are involved with or without fracture of the sinus floor, which raises concern for possible injury to the nasofrontal duct (***Figure 31.17***). If combined with a dural tear, there may be cerebrospinal fluid (CSF) rhinorrhoea, which can be confirmed by sending the fluid sample for β_2-transferrin assay.

The aim of fracture management is to achieve a 'safe sinus', which means establishing normal sinus function, protecting intracranial structures and preventing short- and long-term complications such as meningitis, Pott's puffy tumour and mucocele. Minimally displaced (<2 mm) fractures of the anterior or posterior table can be managed conservatively with nasal decongestants and long-term observation to exclude complications. The indications for surgical intervention include anterior table disruption with significant forehead deformity, frontonasal duct involvement/obstruction and significant displacement of the posterior table with underlying neurological injury.

Isolated anterior table fractures are usually accessed via a coronal flap; they are reduced and fixed with low-profile titanium miniplates. Posterior table fractures are jointly treated with neurosurgeons and require cranialisation of the frontal sinus with obliteration of the sinus cavity and frontonasal duct. A pericranial flap is placed between the brain and the cranial vault to add an additional barrier against potential postoperative infection. A CT scan at 6 months to 1 year is recommended to ensure that there are no signs of complications.

Summary box 31.9

Frontal sinus fractures

- Frontal sinus fractures may be associated with significant neurological injury because of the significant amount of force directed at the cranium
- The aim of fracture management is to achieve a 'safe sinus'
- Follow-up with a CT scan at 6 months to 1 year is important to exclude long-term complications, which can have severe consequences

Isolated nasal and nasoethmoidal fractures

Isolated nasal bone fractures are common, and the full extent of the deformity may not be apparent for several days after injury. A follow-up appointment 1 week after the initial assessment is important (when the swelling is expected to subside) as it allows for accurate examination. The indications for surgical treatment include a cosmetic defect resulting from deviation and nasal obstruction. Closed reduction with digital manipulation under LA is common, but GA may be required if the nasal bone needs significant disimpaction. A mouldable nasal splint may be utilised to protect the bone reduction from inadvertent force.

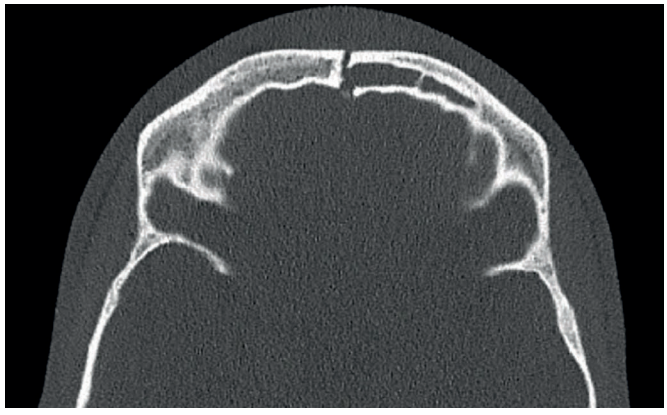

Figure 31.17 An axial CT scan demonstrating a frontal bone fracture through the anterior and posterior table of the frontal sinus.

Nasoethmoidal fractures occur secondary to significant force transfer across the bridge of the nose and the base of the frontal bone. Comminution is common as the nasal and ethmoidal bones are both thin and delicate. The clinical features of nasoethmoidal fractures include periorbital ecchymosis, a depressed nasal bridge, an upturned nasal tip (piggy nose) and telecanthus (increased distance between the inner corners of the eyelids with a normal interpupillary distance), a result of displacement of the bone where the medial canthal ligament is attached. The nasal septum should be inspected for haematoma and a CSF leak excluded.

It is important to identify and treat nasoethmoidal fracture in the primary setting as the untreated fracture can lead to unsightly deformity, which is extremely difficult to correct later. Treatment is often delayed for 7–10 days post injury to allow for the swelling to subside. The key to successful reduction is accurate repositioning of the medial canthus, which can be technically challenging because of the comminuted nature of the fracture.

Summary box 31.10

Nasoethmoidal fractures

- Nasoethmoidal fracture presents with typical features such as a depressed nasal bridge, an upturned nose and telecanthus
- ORIF can be challenging as it requires repositioning of the medial canthal attachment

Panfacial fractures

Combined fractures involving multiple levels such as the mandible, maxilla, zygoma, orbit or frontal bone are described as panfacial fractures. These are some of the most complex of facial injuries and indicate that a significant amount of force

Percival Pott, 1714–1788, surgeon, St Bartholomew's Hospital, London, UK, described the 'puffy tumour' in 1760.

has been applied to the facial skeleton. Panfacial fractures are often associated with severe intracranial, spinal or other organ injuries. Reformatted 3D CT imaging is helpful in demonstrating the full extent and the nature of these fractures (***Figure 31.18***).

Fractures are treated with ORIF once the patient has been stabilised from other significant injuries, and the soft-tissue swelling has sufficiently resolved, usually at a week from injury. The key to panfacial fracture management is in the 'sequencing' of repair, with individual fractures fixed in a similar way to those already described above. The repair of multiple fractures can be difficult because there may be little normal anatomy or intact bony buttresses to act as a guide. Most surgeons experienced in managing this type of injury would tailor the sequence to the particular fracture pattern, optimising the use of normal or near-normal anatomy as a guide.

One of the most common sequencing techniques is a 'top-down' and 'outside-in' approach. This includes first repairing the frontal bone and zygomatic arch fractures followed by orbital rim, nasoethmoidal and mandible fractures. The Le Fort I level maxillary and orbital floor fractures are repaired last. A tracheostomy is often placed because of difficulty with nasal endotracheal intubation and the need to check occlusion during fracture repair, which means oral intubation is not desirable. Alternatively, a submental intubation technique may be one that allows for the occlusion to be checked during fracture repair.

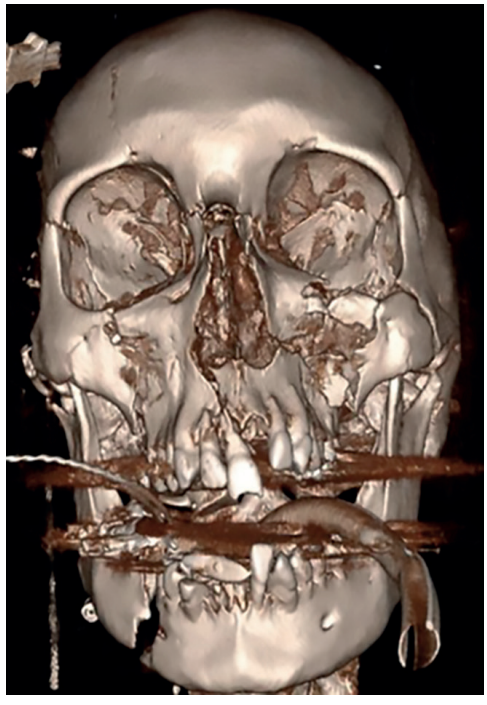

Figure 31.18 A three-dimensional reformatted CT scan demonstrating extensive midface and mandibular fractures (endotracheal and intracranial pressure tubes *in situ*).

Summary box 31.11

Panfacial fractures

- Reformatted 3D CT imaging is very useful in demonstrating the extent and nature of fractures
- Panfacial fracture management requires a 'sequencing' approach, which allows for the fractures to be treated in a systematic way

Dental injuries

The first permanent teeth usually erupt around the age of 6 years; usually lower incisors are followed by upper incisors. Between the ages of 6 and 13, the primary (deciduous) dentition is expected to be exfoliated and replaced by permanent (adult) teeth.

Fractures of the teeth may involve enamel only or enamel in combination with dentine with or without pulp exposure. Exposed dentine and pulp can be exquisitely painful and may benefit from a simple temporary dental dressing.

Avulsed primary teeth should not be reimplanted. Avulsed adult teeth are best reimplanted into the socket immediately after the injury. However, this is generally not possible during prehospital care, and therefore the tooth should ideally be stored in a suitable medium such as milk, saliva or normal saline until expertise is available. The reimplanted tooth needs to be splinted to other teeth with wire and a composite resin material for 2 weeks (sometimes a custom-made splint can be made instead), and the patient treated with antibiotics, chlorhexidine mouthwash and a tetanus vaccine booster as appropriate.

Adult luxated (displaced) teeth mostly require repositing and splinting for 4 weeks. A dentoalveolar fracture (part of the jawbone that includes the teeth) is repositioned and supported with a dental splint for 4 weeks. Luxated primary teeth are generally treated conservatively, or extracted if they are interfering with occlusion.

All dental injuries should be followed up by a dentist for splint removal or monitoring and dental treatment as appropriate.

Summary box 31.12

Dental injuries

- It is important to account for all missing teeth and/or dental fragments – a chest radiograph may be indicated
- An avulsed adult tooth should be reimplanted into the socket as soon as possible or stored in milk, saliva or normal saline
- All dental injuries should be followed up by a dentist

PART 4 | Trauma

CHAPTER
32 Extremity trauma

Learning objectives

To gain an understanding of:

- How to identify whether an injury exists
- The important injuries not to miss
- The principles of the description and classification of fractures
- The range of available treatments
- How to select an appropriate treatment

INTRODUCTION

In several chapters the importance of life-threatening trauma is emphasised, but numerically for every patient who dies following a traumatic event there are three who are left with a lifelong functional impairment. Extremity trauma can be thought of as injury in isolation or in the context of trauma to the whole body. In the latter scenario extremity trauma and the mode in which it is managed may be important, as is the physiological stability of the patient – a concept known as damage control orthopaedic surgery. Furthermore, extremity trauma not only involves the bones, most obviously through a fracture, but also involves the surrounding soft-tissue envelope and thus could describe injury to nerves, other connective tissue and skin.

The goal of extremity trauma management is to return the injured area to optimal function as quickly as possible and therefore return function to the patient. The management of extremity trauma is step-wise and involves initially saving the patient's life by the identification and treatment of life- and limb-threatening injuries, according to the Advanced Trauma Life Support (ATLS) principles. ATLS principles are a useful starting point in the evaluation of extremity trauma. They put the injury into context, attributing to it a priority in the management of all the patient's injuries; for example, a traumatic head injury may require management before operative femoral fracture stabilisation with an intramedullary nail, yet the application of traction to the affected limb, or an external fixator, may reduce the physiological insult to the patient as a whole. Therefore, the context of extremity trauma is extremely important. Applying the principles of ATLS in the initial assessment, followed by damage control orthopaedics in the ongoing surgical management, provides a framework for patient management.

One could summarise this by noting that treatment depends on patient factors, injury-specific factors and surgeon factors, including the resources available.

It is imperative for the clinician to involve the patient in the decision-making process when it comes to the choice of treatment for that individual. Moreover, treatment priorities, functional demands and risk versus benefit vary from individual to individual.

DIAGNOSIS

The diagnosis of extremity trauma begins with the taking of a pertinent history followed by focused physical examination and appropriate special tests.

History

It is important to ascertain the mechanism of injury and the amount of force involved in the injury. Take time to gather sufficient detail in order to do this. The mechanism of injury gives an indication to the clinician of the energy and forces imparted onto the patient. Certain injury mechanisms result in classical injury patterns; for example, electrocution or seizure activity may lead to a posterior dislocation of the shoulder. In your mind translate the mechanism of injury into the common anatomical injury patterns. For example, a head-on collision between two cars each travelling at 40 miles per hour coming to a dead stop should be interpreted by the history taker as a rapid deceleration injury, which then allows anticipation of likely injuries, such as rupture of the aortic arch. Similarly, a fall onto an outstretched hand might be associated with wrist, elbow, shoulder and clavicular injuries.

Following the history of the presenting complaint, it is important to collect information beyond that of the injury. The AMPLE mnemonic is an abbreviated system taught in ATLS that is designed to provide key information quickly in a focused way.

A: Allergies
M: Medication – important to ask about anticoagulant and antiplatelet therapies, corticosteroid use and any possible immunosuppressive treatment
P: Past medical and surgical history – has the patient had an anaesthetic in the past and were there any complications

L: Last time – something to eat or drink
E: Events – events that led to the injury

In the multiply injured patient or patients with altered levels of consciousness, gain as much collateral history as possible. Listen to the account of prehospital personnel; for example, the amount of cabin intrusion in a vehicle or whether a collision was head-on or side-on.

Examination

An initial general examination, including vital signs and general assessment, should be conducted. Is this an isolated injury or do you need to start right at the beginning, considering the A, B, C approach as advocated by ATLS? Examination of the individual extremity only begins once you are sure the patient is stable and life- and limb-threatening conditions have been excluded.

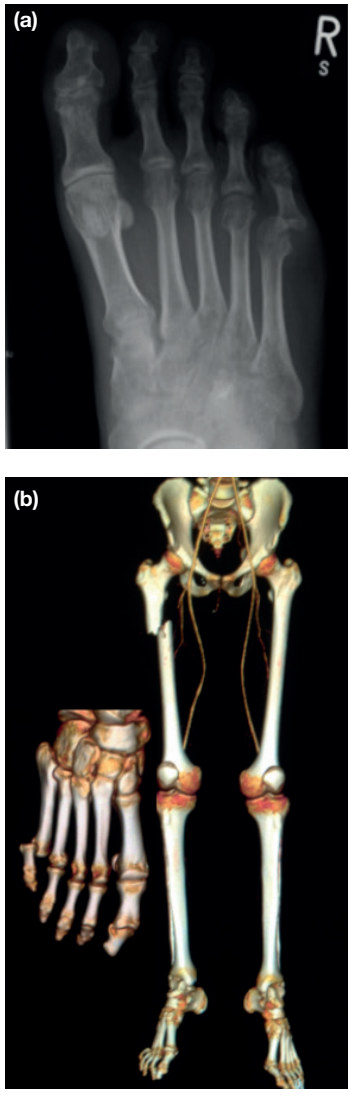

Figure 32.1 (a) Missed dislocation of the metatarsophalangeal joint of the little toe, picked up at 8 weeks. **(b)** Initial trauma computed tomography angiogram. In retrospect, on close inspection the dislocation is visible on the angiogram; do not be distracted by the obvious femoral shaft fracture.

It is crucial to undertake a thorough top-to-toe evaluation in the secondary survey. Often the minor extremity injuries are missed (***Figure 32.1***) and can cause significant long-term problems (***Table 32.1***).

A top-to-toe evaluation is achieved by a systematic approach (see ***Chapter 35*** and ***Apley's system of orthopaedics and fractures [Further reading]***) to the injured extremity:

- look;
- feel;
- move (active and passive);
- special tests;
- special investigations.

TABLE 32.1 Extremity injuries that are notorious for being missed.

- Posterior dislocation of the shoulder
- Lateral condylar mass fracture of the distal humerus
- Perilunate dislocation
- Scaphoid fracture
- Tarsometatarsal fracture dislocation
- Compartment syndrome
- Vascular injury with knee dislocation
- Talar neck fracture
- Slipped upper femoral epiphysis
- Achilles tendon rupture

Ensure you examine the joint above and the joint below the site of injury. Consider the events and mechanism of injury and examine the areas that could possibly be affected. For example, a patient who falls from a height may fracture the calcaneus, which is an obvious diagnosis with a very swollen hindfoot and extremely tender heel. The concomitant lumbar spine fracture may not become evident until a few days later when the distracting pain in the heel starts to subside.

Look

It is important to look at the whole limb, back and front, noting any localised swelling, bruising and any obvious deformity. A shortened externally rotated leg in an older patient suggests a fracture of the proximal femur. A slightly flexed, adducted internally rotated leg might suggest a posterior dislocation of the hip.

Any break in the skin or abrasion needs to be noted and the treating orthopaedic surgeon informed, even if you do not think it communicates with the fracture. A graze over the knee in a closed tibial fracture may preclude intramedullary nailing until the wound has healed over, or perhaps an alternative treatment may have to be considered.

Ideally a photograph (with appropriate consent) should be taken to document the injury and obviate the need for repeated manipulation of the dressings (see ***Open fractures***).

Achilles, the Greek hero, was the son of Peleus and Thetis. When he was a child, his mother dipped him in the Styx, one of the rivers of the Underworld so that he should be invulnerable in battle. The heel by which she held him did not get wet, and was, therefore, not protected. Achilles died from a wound in the heel received at the siege of Troy.

Note the colour of the limb and the degree of general swelling. A compartment syndrome may still be present even when a limb does not appear to be very swollen (see ***Compartment syndrome***), but if it is grossly swollen, note, document and pass on the information.

Look for pre-existing scars; a scar at the back of the elbow or over the cubital tunnel might signify an anterior transposition of the ulnar nerve. Scars might signify previous metalwork that remains *in situ* or has been removed in the past.

Feel

Start gently examining the limb away from the zone of obvious injury, gaining the patient's trust and gathering as much information as possible beforehand, and without causing the patient pain or discomfort. Feel for bony tenderness and note the degree of swelling and tenseness of the compartments. It should be noted that it is not possible to exclude a compartment syndrome based on how tense the limb feels. The deep posterior compartment of the lower leg cannot be felt when palpating the skin.

The characteristic crepitus of subcutaneous air can be felt in the setting of open fractures, air-jet injuries and around the chest in the presence of a pneumothorax.

The examiner should feel for pulses and assess capillary return (see ***Neurovascular examination***) as well as feeling for temperature changes.

Move

Movement as part of the examination should once again be approached carefully and without causing the patient pain and discomfort. Two types of movement can be assessed:

1. active – active movement is movement initiated and maintained by the patient;
2. passive – passive movement is when the examiner moves the limb.

Special tests

There are often special tests to detect injury in precise anatomical locations and many are described elsewhere in the book; for example, looking for a ruptured Achilles tendon by placing the patient prone with the foot over the edge of the bed and squeezing the calf; plantarflexion of the foot and ankle then suggests the Achilles tendon is intact.

The examiner should be aware of gravity simulating active movements. For example, a leg lying flat, fully extended on the couch does not mean the extensor mechanism of the knee is intact. In all knee injuries make sure the patient can actively straight leg raise and get their leg off the couch.

Similar pitfalls exist in the upper limb with gravity straightening the elbow. In order to assess triceps function and elbow extension, ensure that the patient can actively extend against resistance from the examiner or against gravity.

Beware of trick movements. Patients with a complete rupture of the quadriceps can still walk with the leg locked in full to slight hyperextension by using the iliotibial band. Patients with complete rupture of the Achilles tendon can still actively plantar flex the foot and ankle using the long toe flexors.

Neurovascular examination

This is an important part of extremity examination and summary terms such as 'neurovascularly intact' are best avoided. It is preferable to clearly document the examination performed and its findings, along with a conclusion about the function of the particular neurological or vascular anatomy tested. On occasion you may not be able to examine all movements because of injury or casts.

It is important to examine and document findings before and after any manipulation or cast application to ensure no change. A radial nerve palsy in association with a humeral shaft fracture that occurs at the time of injury may be treated expectantly. If, however, radial nerve function is lost after application of a cast or brace, the nerve should be explored. Most peripheral nerves have a motor and sensory component; document both sensibility and motor function.

Laceration or rupture of major vessels may result in life- and limb-threatening injury and should be dealt with as an emergency (see ATLS principles discussed in ***Chapter 27***). Complete laceration or occlusion of a major vessel is obvious and seldom missed. In contrast, occult vessel injuries must be considered and actively excluded. In 30% of knee dislocations (tibiofemoral dislocation) a vascular injury will occur (***Figure 32.2***).

The presence of palpable pulses does not exclude a significant vascular injury and an intimal flap may develop, progress and thrombose over time. Repeated evaluation is necessary, before and after any intervention, for example a manipulation or cast application.

In injuries commonly associated with vascular injury, such as knee dislocations, occult injury should be actively excluded with an angiogram. If an angiogram is not performed, repeated thorough vascular evaluation of the limb should be undertaken for the first 24–48 hours.

Open fractures also demand attention to the neurological and vascular status of the limb. In the more severe injuries, there may be both neurological and vascular injury requiring immediate surgical attention through rapid spanning of the limb, creation of an arterial shunt to provide urgent inflow and subsequent vascular grafting. Once flow has been restored, usually at the same or another surgical sitting, the fracture can then be stabilised definitively with appropriate soft-tissue cover. Performing the arterial shunt before temporary stability has been achieved can compromise the later arterial reconstruction as length, rotation and alignment would not have been restored, thereby pulling on the graft. Open fractures require multiple specialty input.

Investigations

The mainstay of extremity trauma investigation remains radiography of the affected limb to see if there is a bony injury. However, this is not the sole investigation available.

Haematological investigations

Simple haematological investigations are seldom useful in the evaluation of a single limb injury. In the polytrauma patient a full blood count, serum biochemistry, clotting factor and

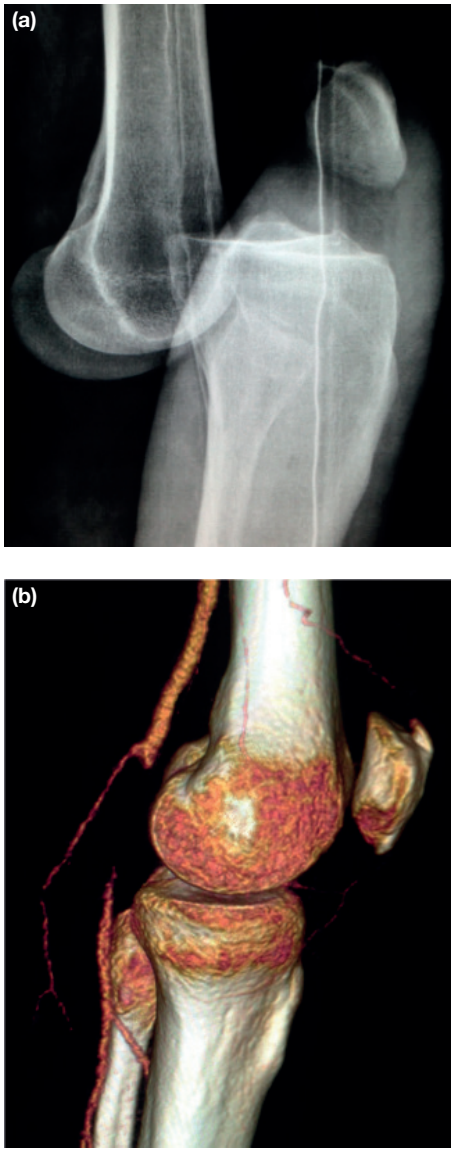

Figure 32.2 (a) Initial anterior tibiofemoral dislocation. **(b)** Postreduction computed tomography angiogram showing complete blockage of the popliteal artery with reconstitution distally from a collateral blood supply.

creatinine kinase may be useful. A blood gas, including pH, base excess and lactate, can be useful to show the severity of the injury and the response to resuscitation.

Ultrasound

Ultrasound is very useful to define soft-tissue injuries. Fractures of the bones can be visualised on ultrasound but generally it is reserved for the soft tissues. One limitation of ultrasound is the variability depending on the experience of the sonographer.

Radiography

Radiographs are the mainstay in the initial evaluation of suspected extremity trauma. The rule of 2s should be remembered:

- 2 views – ensure acquisition of two views in orthogonal planes to avoid missing a fracture out of plane on the first radiograph view. For shoulder injuries ensure at least an anteroposterior and axillary or modified axillary view (***Figure 32.3***).
- 2 joints – radiographs are required of the joint above and the joint below the fracture.
- 2 occasions – sometimes the fracture may not be initially visible; a second series of radiographs should be undertaken after 10–14 days if suspicion of bony injury persists. The classic injury here is a scaphoid fracture. If initial scaphoid views are normal, consider repeating them 10–14 days later if pain and tenderness in the anatomical snuff box (***Figure 32.4***) persist.
- 2 sides – in paediatric injuries it can be useful to consider a radiograph from the opposite and uninjured side if doubt exists. With improved access to atlases of normal variants this is less important.

Computed axial tomography

Computed axial tomography (CT) is very good for characterising the bony anatomy of injuries, allowing for multiplanar reconstruction of injury anatomy and providing other three-dimensional information. It is very useful for periarticular injuries, where the exact characterisation of the bony injury is essential. A CT with contrast creating a CT angiogram provides very useful information regarding the vascularity and its association with the fracture. The CT angiogram also gives an indication to plastic reconstruction surgeons of reconstructive options for limb trauma.

Surface volume rendering is a useful addition allowing for easier visualisation of the injury (***Figure 32.1b***). CT angiography (***Figure 32.2b***) may be added, providing information on the vascular anatomy. One disadvantage of CT is the dose of radiation involved.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) provides three-dimensional information without the radiation involved in CT. It provides useful information, particularly about the soft tissues. MRI can provide information on the blood supply to the bone; for example, avascular necrosis of the proximal pole of the scaphoid.

One disadvantage of MRI is the time taken to acquire the image; patients suffering from claustrophobia find the experience traumatic. It is essential to ensure patient safety and consideration should be given to potential risks of MRI that may apply, for example with certain implanted devices and metallic foreign bodies, e.g. in the eye (see MHRA guidance in ***Further reading***).

MRI angiography can also be performed, providing information about the vascular anatomy.

Nuclear medicine scans

Technetium-99 nuclear medicine scans register osteoblastic activity and may be used to demonstrate occult fractures; for example, an undisplaced scaphoid fracture.

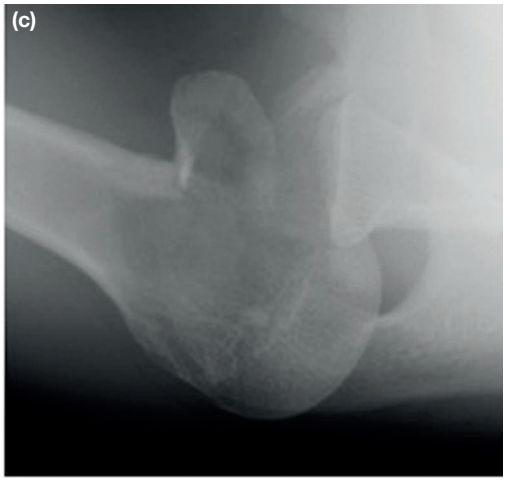

Figure 32.3 Radiographic series of the same patient demonstrating the value of two views in two planes and the true value of the axillary view in shoulder trauma. **(a)** Anteroposterior radiograph of the shoulder, initially reported as normal. **(b)** Lateral scapula radiograph, initially reported as normal; humeral head slightly posteriorly directed. **(c)** Axillary view – true value of the axillary view shown with obvious posterior dislocation of the glenohumeral joint.

Summary box 32.1

History, examination and investigations

- Follow a systematic approach
- History requires sufficient detail of injury
- History can be organised in the AMPLE format
- Examination follows look, feel, move, special tests approach
- Investigations will include radiographs with the rule of '2s' observed
- Selective use of special investigations can help diagnosis

DESCRIPTION AND CLASSIFICATION OF THE INJURY

Soft-tissue injury

There are several classification systems for soft-tissue injuries: the Tscherne classification for closed injuries, the Gustilo and Anderson for open injuries (***Table 32.2***) and the Ganga classification of severe open injuries.

The first step in soft-tissue injury characterisation is to decide if this is an open or closed fracture – an open fracture being any fracture where the fracture haematoma communicates with a breach in the epithelial lining, not just skin. For example, an open pelvic fracture may communicate with the vagina or rectum and a mandibular fracture through the mucosa of the mouth (see ***Open fractures***).

Consider all the soft tissues crossing the zone of injury, as it is possible to get a closed rupture or avulsion of tendons without a break in the skin. Consider the possibility of a neurovascular injury (see ***Neurological injury***). Severe soft-tissue injury in the presence or absence of a fracture may still lead to compartment syndrome (see ***Compartment syndrome***).

Harald Tscherne, b. 1933, Austrian trauma surgeon, Director of the Trauma Department, Medical Graduate School, Hannover, Germany.
Ramon Balgoa Gustilo, surgeon, Hennepin County Medical Center, Minneapolis, MN, USA.
John T Anderson, surgeon, Hennepin Medical Center, Minneapolis, MA, USA.

TABLE 32.2 Gustilo and Anderson open fracture classification.

Type	
I	A low-energy open fracture with a wound less than 1 cm long and clean
II	An open fracture with a laceration more than 1 cm long without extensive soft-tissue damage, flaps or avulsion
III	Characterised by high-energy injury irrespective of the size of the wound. Extensive damage to soft tissues, including muscles, skin and neurovascular structures, and a high degree of contamination. Multifragmentary and unstable fractures
Subgroups of type III	
A	Adequate soft-tissue cover of a fractured bone after stabilisation
B	Inadequate soft-tissue cover of a fractured bone after stabilisation (i.e. flap coverage required)
C	Open fracture associated with an arterial injury requiring repair

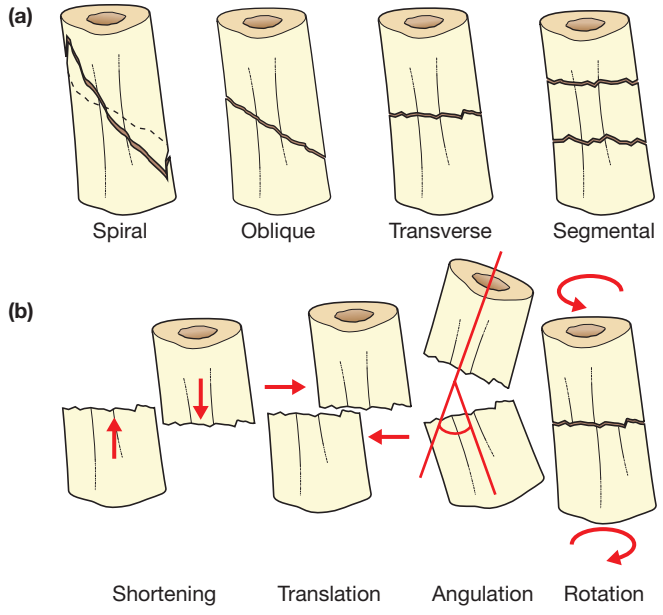

Figure 32.5 Descriptive terms for fractures **(a)** and type of displacement **(b)**.

Peripheral nerve injury

Seddon classified nerve injuries into neurapraxia, axonotmesis and neurotmesis:

- Neurapraxia – no loss of nerve sheath continuity or peripheral Wallerian degeneration. If the pressure is removed from the nerve, recovery potential is good but may take months.
- Axonotmesis – nerve sheath remains intact, with internal nerve fibre damage and associated Wallerian degeneration. The neural tube (endoneurium) can guide the regenerating nerve fibres to their target. Good potential for recovery; nerve fibre regrowth is at 1 mm per day.
- Neurotmesis – complete division of the nerve, nerve sheath and nerve fibre. Functionally poor outcome without surgical intervention to restore continuity of the nerve sheath.

Although the Seddon classification is useful in understanding the pathoanatomy, the critical discriminator in defining recovery, and need for possible surgical intervention, is the presence or lack of continuity of the enveloping nerve sheath.

Bony injury

Description

Describing the bony injury depends on several characteristics and includes the:

- name of the bone that has been injured;
- region of bone injured (epiphysis, metaphysis, diaphysis);
- pattern of fracture line: transverse, oblique, spiral, segmental or multifragmentary (***Figure 32.5***);
- presence of compression: compression fractures occur when cancellous bone collapses; for example, vertebral wedge compression fracture;
- presence of displacement of the fracture fragments: undisplaced or displaced;
- type and degree of displacement: shortening, translation, angulation, rotation (mnemonic STAR) (***Figure 32.5***); occasionally, the magnitude of rotational displacement can be quite dramatic (***Figure 32.6***) or, indeed, very subtle to assess on a radiograph – hence the need for standardised radiographs assessing the area in question and the joint above and below, but also clinical corroboration;
- presence of pre-existing pathology (e.g. fracture through a tumour or in close proximity to a joint replacement); associated joint pathology: dislocation or subluxation.

In children and adolescents the fracture line may be incomplete because of the plastic, less brittle nature of their bones (***Figure 32.7***). These incomplete fractures are called greenstick (***Figure 32.8***) fractures, where one tension cortex fails. If the compression cortex buckles, they are called torus (***Figure 32.9***) or buckle fractures. Paediatric bone may also simply undergo plastic deformation without a visible fracture line.

Summary box 32.2

Describing an injury

Use plain language to describe:

- Location
- Soft-tissue component
- Bony injury

Sir Herbert J Seddon, trained at St Bartholomew's Hospital, London University and the Royal National Orthopaedic Hospital, Stanmore, UK. He became the second Nuffield Professor of Orthopaedic Surgery in Oxford, UK.

Augustus Volney Waller, 1816–1870, general practitioner of Kensington, London, UK (1842–1851), subsequently worked as a physiologist in Bonn, Germany; Paris, France; Birmingham, UK; and Geneva, Switzerland.

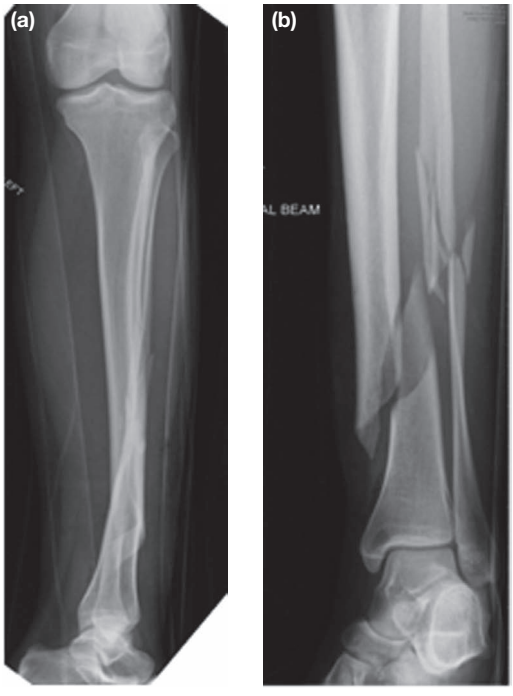

Figure 32.6 Describing fractures: the importance of rotation. **(a)** Anteroposterior (AP) view of the knee seen at the top of the radiograph and lateral view of the ankle at the bottom, showing a spiral fracture at the junction of the middle and distal thirds of the tibia. **(b)** AP radiograph of the ankle on the same patient. Note the varied diameter of the fracture fragments; this implies rotational deformity. The distal fragment has translated laterally by 50%. There is no significant angulation on this view.

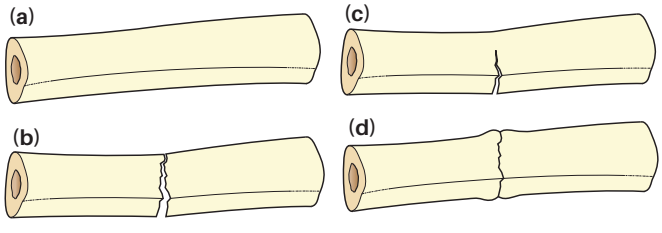

Figure 32.7 Types of bony injury: **(a)** uninjured bone; **(b)** adult transverse fracture failure across the whole bone; **(c)** greenstick fracture; the bone has failed on the tension side; **(d)** torus or buckle fracture; the bone has failed on the compression side.

Classification

For each specific bony injury there may be several injury-specific classification systems.

AO classification

The AO (Arbeitsgemeinschaft für Osteosynthesefragen) system provides a comprehensive classification of all fractures (*Figure 32.10*). The first number defines the bone injured and the second number the segment of bone injured: proximal metaphysis, diaphysis, distal metaphysis. The letter and number that follows further defines the nature of the injury

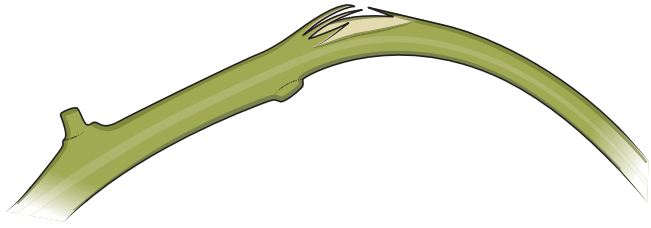

Figure 32.8 Greenstick fractures take their name from the way in which a 'green' stick (one that is alive and has sap flowing through it) breaks.

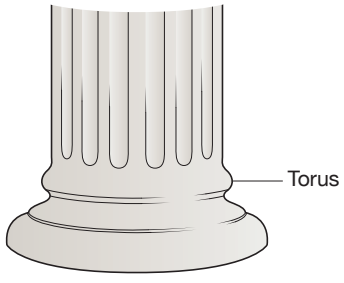

Figure 32.9 Torus fractures take their name from an architectural torus, which is the 'bulge' at the base of a column.

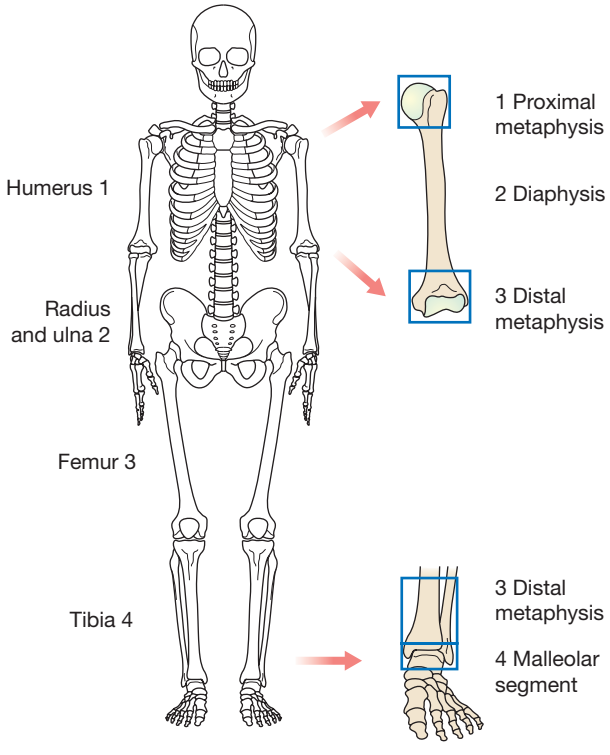

Figure 32.10 The AO classification system: the first two numbers specify the site of the fracture.

AO, Arbeitsgemeinschaft für Osteosynthesefragen, may be translated from the German as 'Working Party on Problems of Bone Repair'.

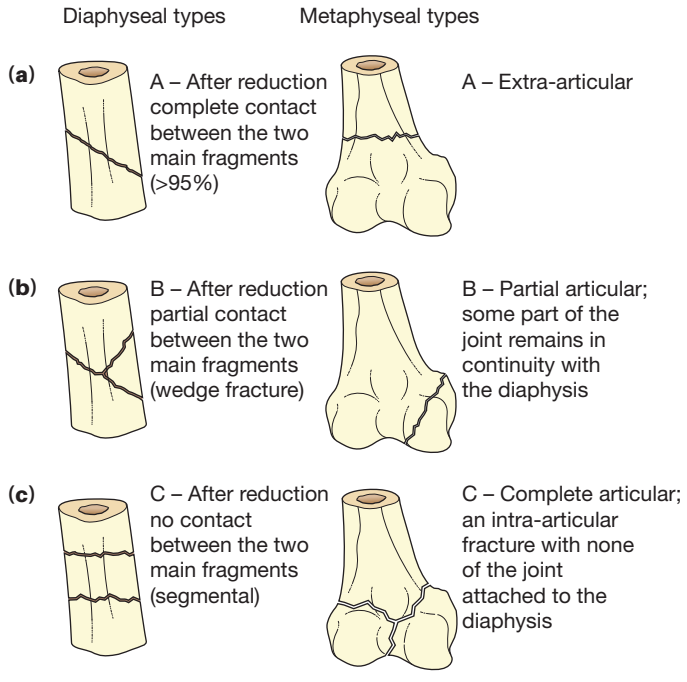

Figure 32.11 The AO classification system: the letter defines the nature of the fracture.

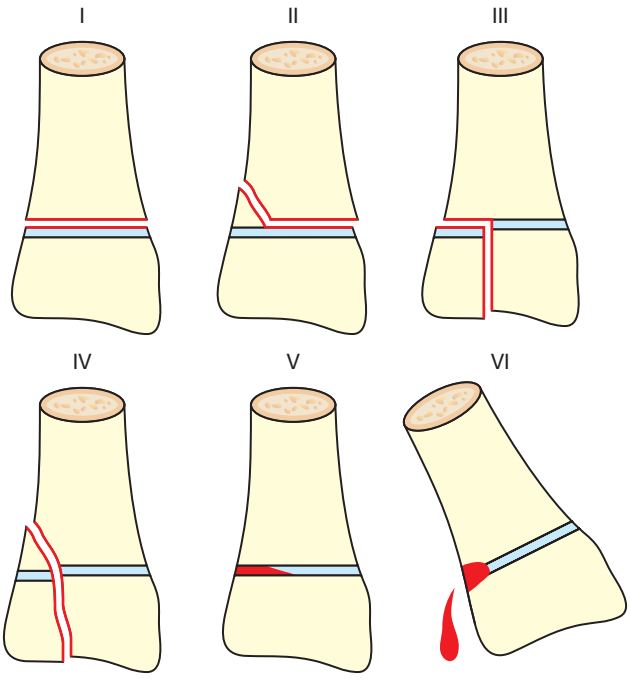

Figure 32.12 The Salter–Harris classification of growth plate injuries.

(***Figure 32.11***). For example, the previously described humeral fracture would be 12-A1 (1 humerus, 2 diaphysis, A simple, 1 spiral). (For more detail see ***Further reading***.)

Growth plate injury classification

In child and adolescent injuries involvement of the growth plate (physis) can lead to abnormal growth or growth arrest, either complete or partial. Complete growth arrest will result in length abnormalities and partial growth arrest might result in angular deformities. The severity of injury to the physis is classified in the Salter–Harris classification, which considers whether the fracture line passes through the epiphysis, physis, metaphysis or combinations of all the above. Salter–Harris described five and Mercer Rang added the sixth (***Figure 32.12***):

- Type I – simple fracture line just involving the physis. Seldom affects growth.
- Type II – fracture line through the physis exiting through the metaphysis, producing a metaphyseal fragment. Seldom affects growth.
- Type III – fracture line through the physis exiting through the epiphysis (intra-articular). Seldom affects growth, but intra-articular affecting joint surface.
- Type IV – fracture line across the epiphysis, across the physis and across the metaphysis. This injury can cause focal fusion of the physis, leading to abnormal growth.
- Type V – a crush injury of the physis. Growth disturbance is common and may be the first radiological sign of an injury.
- Type VI – injury to perichondral structures by direct trauma. Rare injury, high chance of abnormal growth.

FRACTURE HEALING

It is useful to review fracture healing, as it relates to treatment and outcome. Following a fracture, bone can heal in two different ways: direct (primary) bone healing or indirect (secondary) bone healing. One can conceptualise direct bone healing as being akin to a wound that is stitched together whereas indirect bone healing is similar to forming a scab that over time turns to normal tissue. Through intervention, the clinician is able to influence the healing response of the tissue: direct bone healing being more likely if the two bone ends are squeezed together (compression), and indirect healing should there be movement (termed strain) at the fracture site. If there is too much movement, i.e. the fracture is too unstable, healing of the fracture may not occur.

- **Direct bone healing**, as the name implies, heals directly with bone and without callus formation. It happens in an environment of cortical apposition and absolute stability with no movement or gap between the fracture fragments.

Robert Bruce Salter, 1924–2010, Professor of Orthopaedic Surgery, University of Toronto, Ontario, Canada. A pioneer in the field of paediatric orthopaedic surgery, he received international awards for medical science and the Distinguished Achievement for Orthopaedic Research award.
W Robert Harris, 1922–2005, formerly Professor, University of Toronto, President of the Canadian Orthopaedic Foundation (1968) and President of the Canadian Orthopaedic Association (1975 and 1976).
Charles Mercer Rang, 1933–2003, British orthopaedic paediatric surgeon.

The normal osteoclastic-mediated remodelling of bone is directed across the fracture interface. Osteoclastic cutting cones cut across the fracture line, with following osteoblasts laying down lamellar bone across the fracture. This is similar to the normal remodelling process that occurs in bone all the time as part of skeletal homeostasis.

- **Indirect bone healing** involves a transition from one tissue to another with callus formation. It is the most common form of bone healing. Following the injury, haematoma fills the gap at the fracture site. In response to a varying strain and under the influence of bone-stimulating factors, the tissue undergoes differentiation, from haematoma to fibrous tissue and then to soft callus, followed by mineralisation and formation of mature bone. The amount of strain determines the nature of tissue it differentiates into: under 100% leads to fibrous tissue, under 10% soft callus, less than 2% hard callus and progressive mineralisation (Perren's theory of bone healing). Hence a little movement is good, too much movement is bad.

Bone healing requires not only an advantageous mechanical environment but also an advantageous biological environment. Principally this can be described in terms of blood supply and the preservation of blood supply from the surrounding soft tissues, the periosteum and the nutrient arterial supply to bone. Should the inflow be affected through trauma or peripheral vascular disease, or should there be an extensive soft-tissue injury causing poor bone perfusion, bone healing can be affected. Similarly, microscopic inflow issues at the tissue perfusion level, e.g. as a result of diabetes, may also lead to poor bone healing. Infection may also create a biological insult to bone healing; therefore, open fractures with their extensive soft-tissue injury and increased probability of infection are prone to impaired bone healing.

Terminology of bone healing after fracture

Union

The fracture has healed sufficiently from a clinical perspective to withstand physiological loads, with very little pain and minimal tenderness at the fracture site. Radiologically a fracture has united when the callus bridges the fracture site.

Delayed union

This description can be applied to a fracture that is slow to heal and that has not healed in the expected time frame.

Non-union

This description can be applied to a fracture that has not healed and shows no potential to heal without further intervention. A non-union can also be defined as a fracture that fails to demonstrate clinical or radiological improvement over 3 months. In general, you do not describe a fracture as 'non-union' until 6 months after the injury.

There are a number of different types of non-union: atrophic, hypertrophic and infected. It is useful to consider certain factors with regard to the non-union: the biology of the fracture, the mechanical environment and the host (patient factors such as diabetes and smoking).

In an atrophic non-union, the problem is generally a biological one, with a lack of stimulus or blood supply. A hypertrophic non-union generally occurs when there is too much movement at the fracture site.

Consolidation

This follows union and demonstrates that the bone has returned to normal strength. Radiologically it is demonstrated by the return of the normal cortical pattern.

Remodelling

In children, and to a lesser degree in adults, bone remodels based on the forces passing through it.

Summary box 32.3

Fracture healing

- Direct – cortical apposition and absolute stability
- Indirect – secondary bone healing, requires some movement

TREATMENT

The main principle of extremity fracture management builds on the classical concept of reduction and stabilisation of the fracture. Treatment can be considered under the following headings (see ***Apley's system of orthopaedics and fractures [Further reading]***):

- reduce;
- hold;
- heal;
- rehabilitate.

The main objective of any treatment is to return the patient to normal function as soon and as safely as possible. Broadly speaking, treatment may be operative or non-operative, with differing risks and benefits (***Table 32.3***).

Reduce

The first thing to consider is the degree of displacement of the fracture fragments. It is useful to ask the following question: if the bone were to heal in this position, would it be compatible with optimum function in the short and long term?

In general, fractures involving the articular joint surface need to be reduced perfectly back to their original anatomical position, to restore normal joint movement in the short term and avoid degenerative joint disease in the long term – **intra-articular fracture = anatomical reduction**.

Stephan M Perren, 1932–2019, Director, AO Research Institute, Davos, Switzerland, 1967–1996.

TABLE 32.3 Risks and benefits of fracture treatment.

Benefits	Risks
• Pain relief • Prevention of infection • Restoration of anatomy • Early movement of the limb • Early movement of the patient • Improved function • Reduced risk of secondary arthritis • Financial cost (time off work)	• Anaesthesia • Introduction of infection • Damage to soft tissues and neurovascular structures • Devitalising bone • Need for implant removal • Financial cost (cost of treatment)

Fractures that do not involve the joint surface generally require restoration of mechanical alignment of the joints above and below. The fracture fragments do not need to be reduced perfectly. Focus on acceptable alignment, length and rotation – **extra-articular fracture = mechanical alignment**.

In children an extra-articular fracture has the ability to remodel, and therefore an increased degree of displacement can be accepted.

If a fracture requires reduction, it can be reduced open or closed. A closed reduction is where the bones are manipulated and moved without exposing the bone. Often the best way to reduce a fracture is to reverse the sequence of injury, without tearing or further damaging the intact soft tissues and periosteum. On occasion this may mean exaggerating the deformity (*Figure 32.13*).

Open reduction is utilised if an acceptable closed reduction is not achieved or likely to succeed. A combination of closed and open methods can be used to reduce a fracture. Care should be taken during an open reduction not to unduly devitalise the fracture fragments by stripping intact periosteum. A balance between maintaining a blood supply to the fracture fragments (biology) and achieving anatomical reduction needs to be maintained.

Adequacy of reduction is complex and depends on many factors. If intra-articular, the joint surface involved needs to be considered. By way of an example, 2 mm of residual displacement of the articular surface may be acceptable in the patella and tibial plateau and may be acceptable in fractures involving the distal radius, but is not acceptable in the condylar joints of the fingers. In general consider the relative thickness of the articular surface involved.

On occasion consideration of how you intend to subsequently hold the fracture may affect the primary form of reduction.

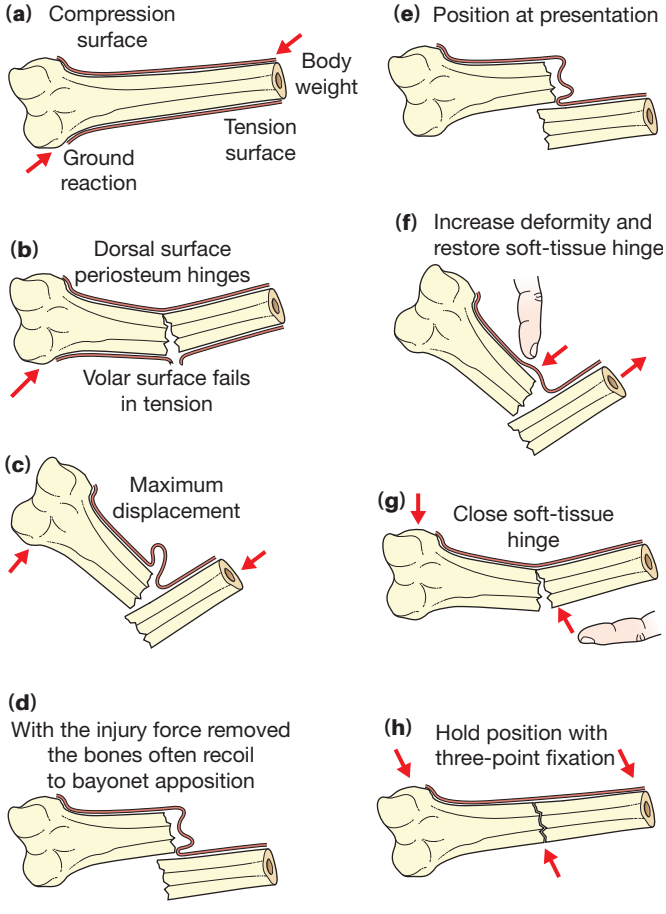

Figure 32.13 (a–d) Representation of how the mechanism of injury causes the bony and soft-tissue injury. **(e–h)** Representation of how the residual mechanical properties of the tissues may be used to effect and hold a reduction.

Summary box 32.4

Reduction

- Reduction has two components: reducing the fragments and assessing adequacy of reduction
- Reduction can be performed open or closed
- The principle is to reverse the movement that created the fracture
- Over-angulation allows the intact periosteum to guide the fragments into position

Hold

If the fracture fragments are in an acceptable position, or have been reduced into an acceptable position, they then need to be held in that position until they heal. When choosing a method to hold a fracture the aim is to:

- optimise the biological and mechanical environment to create the most favourable conditions possible for fracture healing;
- minimise the period of disability by speeding up the healing process or providing enough stability to return to normal function while the fracture heals.

There are several methods of holding fracture fragments in place:

- plaster cast/splints;
- traction;
- Kirschner (K-) wires;

Martin Kirschner, 1879–1942, Professor of Surgery, Heidelberg, Germany, introduced the use of skeletal traction wires in 1909.

- external fixation;
- plates and screws;
- intramedullary nails.

Note: Arthroplasty may be used where fragments cannot be held together.

On occasion a combination of holding methods may be used; for example, K-wires and a moulded cast in the case of a simple extra-articular distal radial fracture. It is important to consider the way of holding the reduction in terms of outcome and ensure that this is part of the overarching goal to optimise the patient's return to function as safely and as fast as possible.

For example, a displaced clavicle fracture in a 10-year-old has a 99% chance of sound union within a few months if treated non-operatively. In contrast, a displaced multifragmentary middle third clavicle in a 35-year-old woman will carry a 35% chance of going on to a non-union at 6 months. Therefore, even though this fracture may heal with non-operative treatment, with appropriate explanation and shared decision making, a patient may choose to have surgery early in order to get back to normal function as soon as possible.

Stability can be absolute or relative:

- **Absolute stability**. Implies no displacement or movement and is achieved by accurate anatomical reduction with compression across the fracture fragments to optimise the environment for direct bone healing. This is desirable in intra-articular fractures, where callus at the fracture site might inhibit movement. Intra-articular fractures require an anatomical reduction and absolute stability.
- **Relative stability**. Allows a little movement at the fracture site, optimising the environment for callus formation and indirect bone healing.

Selected examples of achieving absolute and relative stability are shown in ***Figure 32.14***.

Plaster cast and splints

Plaster casts and splints are generally used to hold stable fractures or supplement the fixation of unstable fractures (e.g. below-elbow cast applied to a distal radial fracture after K-wire fixation [see ***Kirschner wires***]).

Plaster casts come in two forms: plaster of Paris and synthetic casting materials. Plaster of Paris is the preferred method in acute fractures; where more support is needed, it is easier to mould plaster of Paris than a synthetic cast. In acute injuries, where there is a risk of swelling and compartment syndrome, a backslab will often be applied. A backslab is not always positioned on the dorsal surface as the name suggests, but is a partial cast where a layer of plaster of Paris or synthetic cast is applied along roughly half the circumference. An alternative to a backslab includes a full cast that is split along its full length to allow for swelling. The use of an incomplete cast does not remove the risk of swelling and compartment syndrome and must always be accompanied by close clinical observation.

Moulding of the cast is an art form requiring appropriate skill to achieve the desired effect. Three-point moulding is used to control the position, often using the intact dorsal periosteal hinge to mould against (***Figure 32.13***). Often, a correctly

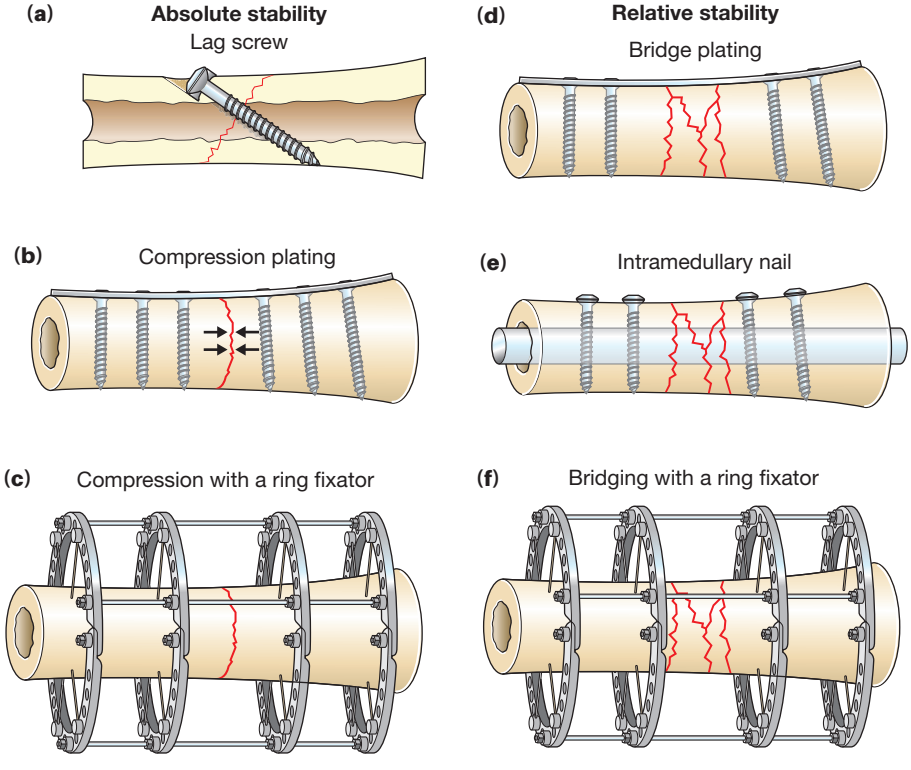

Figure 32.14 (a–f) How absolute and relative stability can be achieved. The same implants may be used to achieve different mechanical effects.

Plaster of Paris is a white crystalline powder, calcium sulphate hemihydrate $CaSO_4 \cdot 0.5H_2O$, which sets hard when water is added to it.

moulded cast will look crooked, leading to the adage 'bent casts make straight bones' (***Figure 32.15***).

Commercially available upper limb and lower limb splints provide comfort, support and social protection to stable fractures. Ease of application and the ability to remove them make them very useful for patients to return to activities of daily living, including bathing and showering.

The advantages and disadvantages of plaster cast and splint usage are described in ***Table 32.4***.

TABLE 32.4 Advantages and disadvantages of casting and splinting.

Advantages	• No wound • No interference with the fracture site • Cheap • Adjustable • No implants to remove
Disadvantages	• Limited access to the soft tissues • Cumbersome (particularly in the elderly) • Interferes with function • Poor mechanical stability • 'Plaster disease' – joint stiffness and muscle wasting

Traction

Traction is defined as a stretching force on a limb to pull a fracture straight. After appropriate pain control, simply pulling on the limb using manual traction will help realign fracture fragments, returning overall length and alignment. If the fracture is simple and off-ended (displaced so the two bone ends are translated and misaligned), it may require more than simply pulling to reduce it (see reduction in ***Figure 32.13***). Once reduced, however, continued longitudinal traction will often hold it reduced.

A traction force can be applied and maintained by a variety of systems and techniques. It is easy to apply traction to any extremity; however, it is cumbersome and requires a fixed point to pull on. This can require the patient to be fixed to one place and limit return to normal function (see ***Table 32.5*** for advantages and disadvantages of traction).

TABLE 32.5 Advantages and disadvantages of traction.

Advantages	• No wound in zone of injury • No interference with fracture site • Materials cheap • Adjustable
Disadvantages	• Restricts mobility of patient • Expensive in hospital time • Skin pressure complications • Pin site infection • Thromboembolic complication

Traction is often used in the treatment of femoral shaft fractures in adults as a temporary measure for comfort and to allow transfer of the patient, until definitive fixation can be undertaken. A Thomas splint is applied to the limb initially in a static fashion (***Figure 32.16a***) and then, once in bed, balanced traction is applied to help pull the leg out to length and pull the splint off the ischial tuberosity (***Figure 32.16b***).

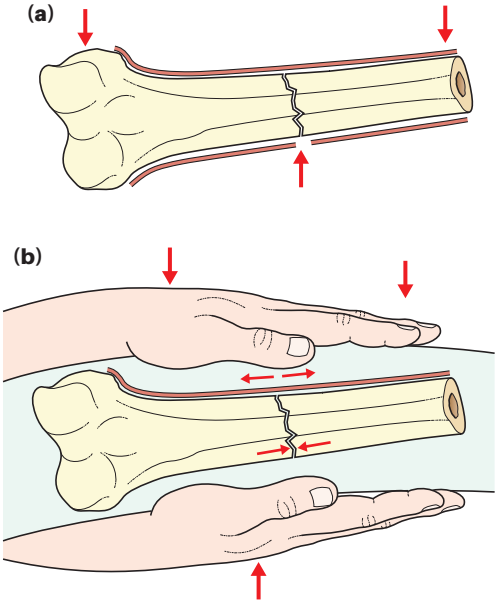

Figure 32.15 (a) The position achieved at the end of the manipulation described in ***Figure 32.13***. **(b)** Demonstration of how, by moulding the cast, the intact periosteum is kept under tension and the bone under compression; thus, the remaining mechanical properties are used to achieve stability.

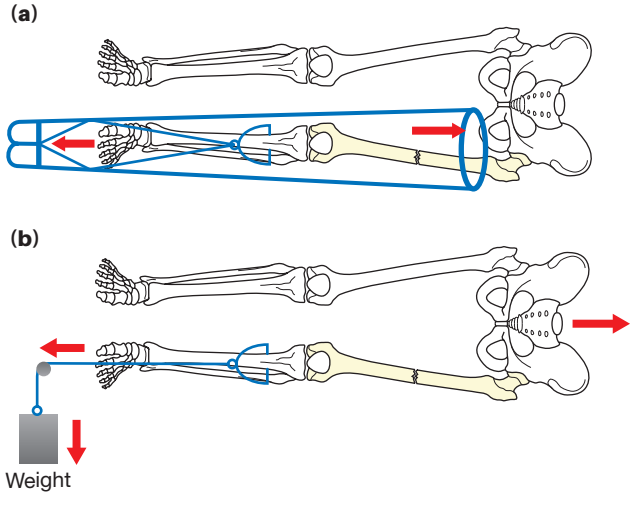

Figure 32.16 (a) Static traction with a Thomas splint. The force and counterforce are contained within a static system. The load is applied to the patient through the tibial traction pin via a cord tightened with a Spanish windlass. The counterforce is applied through pressure by the splint on the ischial tuberosity. **(b)** A dynamic system in which the load is applied by weights suspended from the tibial pin and the counterforce is the patient's own weight.

Hugh Owen Thomas, 1834–1891, general practitioner of Liverpool, UK, is regarded as the founder of orthopaedic surgery, although never holding a hospital appointment and preferring to treat patients in their own homes. He introduced the Thomas splint in 1875.

The anchor point on the limb may be either skin, by applying an adhesive or non-adhesive bandage, or skeletal traction, where a pin is placed in the proximal tibia or distal femur.

A common everyday example of traction is the use of a collar and cuff in proximal humeral fractures. When the patient is upright, the lower part of the arm, under the action of gravity, provides longitudinal traction, thus aligning the fracture fragments.

Kirschner wires

Kirschner wires (also called K-wires) are smooth, non-threaded, thin flexible wires often between 0.9 and 2.5 mm in diameter. They are used to hold small fragments in place. They may be used in a temporary fashion intraoperatively to hold fracture fragments in place until definitive fixation with plates and screws can be performed. They are inexpensive and simple to use. Moreover, they are extensively used for definitive fixation of injuries around the hand and wrist. The flexible nature of the wires can often require supplementation, as a hybrid construct of K-wires and plaster cast fixation.

In distal radial fractures the wires are placed percutaneously after closed reduction, with the trailing end of the wire left proud of the skin and the end bent to limit wire migration. K-wires around the distal radius can be removed in the clinic setting 4–6 weeks after insertion. Complications of K-wires include pin site infection, wire breakage, loss of fixation and wire migration. Wire migration may be a potentially serious problem in certain locations. It is not advisable to use non-threaded K-wires around the shoulder girdle and clavicle as migration into the thoracic cavity and heart has been reported (*Table 32.6*).

TABLE 32.6 Indications for K-wire insertion.

- Temporary fixation
- Definitive fixation – with small fracture fragments (e.g. wrist fractures and hand injuries)
- Tension band wiring (fractures of the patella and olecranon)
- Temporary immobilisation of a small joint

External fixation

External fixation involves percutaneous placement of metal rods or fine wires into bone to anchor a metal frame on the outside (*Table 32.7*). The frame construct itself may consist of tubular rods with connectors, or a circular ring construct – the 'Ilizarov' frame. Hybrid variations are infinite, with combinations of anchor fixation modalities and frame constructs. The Taylor spatial frame allows for gradual correction of deformity (*Figure 32.17*).

The major drawback of external fixation is that they can be cumbersome to the patient and pin site infection can be a problem (*Table 32.7*).

Specific indications for external fixators include:

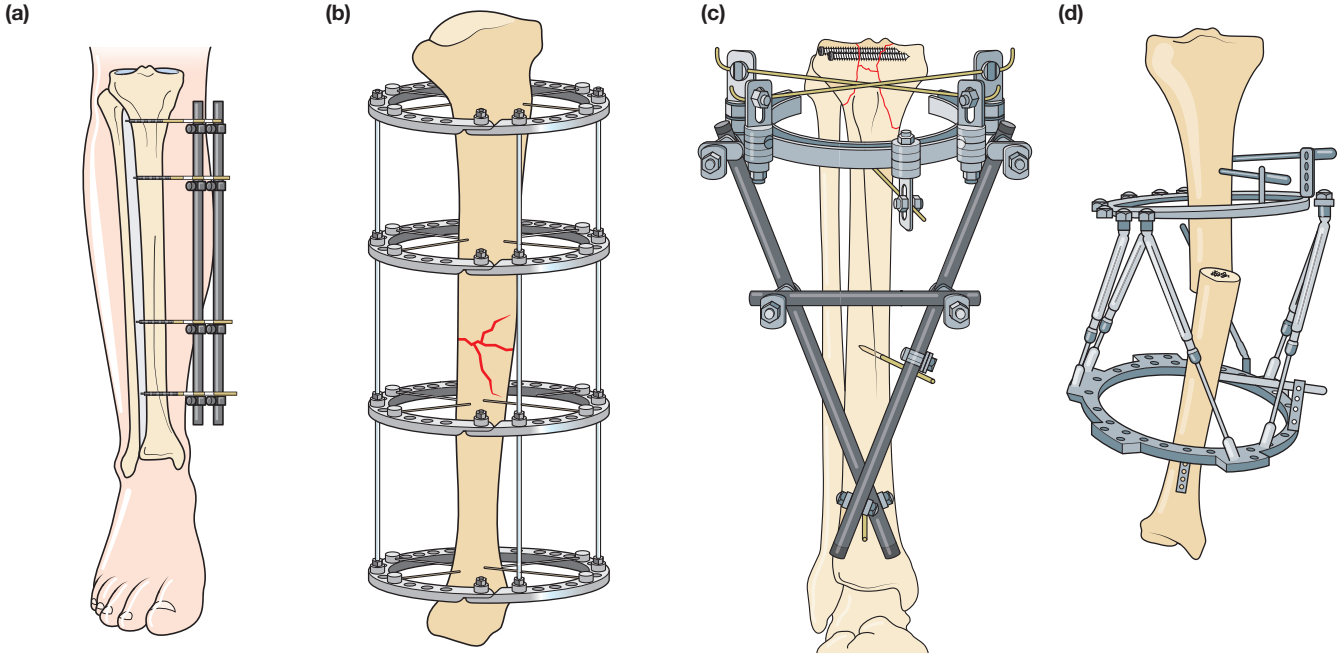

Figure 32.17 (a) Monolateral tubular frame with a metal rod (half pin anchorage to bone). **(b)** Circular ring fixator with fine wire anchorage to bone. **(c)** Hybrid circular/tubular rod frame construct with a combination of half pin and fine wire anchorage to bone. **(d)** Taylor spatial frame; allows for gradual correction of deformity.

Gavriil Abramovich Ilizarov, 1921–1993, orthopaedic surgeon, Kurgan, Western Siberia, Russia. He did not attend school until he was 11 years old as his family was too poor to buy him shoes.

J Charles Taylor, orthopaedic surgeon, Memphis, TN, USA.

TABLE 32.7 Advantages and disadvantages of external fixation.

Advantages	• No interference with fracture site • Adjustable after application: alignment; biomechanics • Soft tissues accessible for plastic surgery • Rapid stabilisation of fracture • Hardware easy to remove
Disadvantages	• Pin site infection • Interferes with plastic surgical procedures • Soft-tissue tethering • Cumbersome for the patient

- emergency stabilisation of a long bone fracture in the polytrauma patient thought too unwell to have other interventions – damage control orthopaedics;
- stabilisation of a dislocated joint after reduction (e.g. a spanning fixator across the knee joint while the vascular surgeons repair an arterial injury with a knee dislocation);
- complex periarticular fractures to provide temporary stabilisation and allow the soft-tissue damage to recover before definitive fixation (e.g. a distal tibial [pilon] fracture);
- fractures associated with infection;
- treating fractures with bone loss.

Plates and screws

Plates and screws can be used in many different ways. A 'lag screw' can be used to generate compression across a fracture site, optimising the environment for direct bone healing. Similarly, compression can be achieved using a dynamic compression plate. A plate might also be used simply to neutralise forces, buttress a fracture or work as an internal–external fixator (***Figure 32.14***).

In general, plates and screws are used where possible in articular and periarticular fractures where an anatomical reduction is required, often via open means, followed by the application of the plate and screws to achieve a rigid construct. In extra-articular fractures, where mechanical alignment is required together with relative stability, one option is the use of locking plate technology. This allows a closed reduction and percutaneous placement of the plate with locking screws to create an internal construct, which behaves like an external fixator. Injury-specific plating systems have revolutionised the ability to treat certain injuries, with plates pre-bent and pre-shaped for specific anatomical regions and specific injury patterns (see ***Table 32.8*** for the advantages and disadvantages of plate fixation).

TABLE 32.8 Advantages and disadvantages of plate and screw fixation.

Advantages	• Can be used when anatomical reduction is required • Allows early mobilisation • Can provide absolute or relative stability
Disadvantages	• May interfere with the fracture site • Periosteal/soft-tissue damage • Does not normally allow for immediate load-bearing • Potential for infection • Metalwork complications • Possible need for plate removal

Intramedullary nails

Diaphyseal fractures are best suited for intramedullary nailing. Where mechanical alignment is required together with relative stability, they allow for indirect bone healing. After nail insertion, mechanical alignment is checked particularly for length, alignment and rotation. Locking screws are then placed proximally and distally to maintain length and alignment. Intramedullary nailing of metaphyseal and articular fractures is a challenge. However, with improved implant design and the ability to lock the nails very distally and in multiple directions, the indications for intramedullary nailing are expanding.

Intramedullary nails may be placed in an unreamed or reamed fashion. Reaming is the process whereby the intramedullary canal is widened slightly to allow passage of a larger diameter nail, relating to the last reamer size used. ***Table 32.9*** compares reamed with unreamed nails.

Intramedullary nailing can be a technically demanding procedure. The advantages and disadvantages are summarised in ***Table 32.10***.

TABLE 32.9 A comparison of reamed and unreamed nailing (an assumption is that nails used unreamed are usually thinner than those used reamed).

IMN, intramedullary nail.

TABLE 32.10 Advantages and disadvantages of intramedullary nailing.

	• Minimally invasive • Early weight-bearing • Less periosteal damage than open reduction and internal fixation • Seldom need removal
	• Increased risk of fat emboli/chest complications • Infection difficult to treat • Difficult to remove if broken

Arthroplasty

Arthroplasty is indicated in certain acute circumstances: articular fractures that are not reconstructible or injuries where the vascularity of the articular segment is compromised (e.g. displaced intracapsular femoral neck fracture in an older patient).

The patient's demographics and functional demands need to be considered in choosing arthroplasty as a treatment option. Implant longevity and level of activities following implant insertion need to be matched. Traditionally, arthroplasty for trauma was limited to hip and shoulder hemiarthroplasty.

Total hip replacement, acute distal femoral replacement, radial head replacement, total and hemielbow arthroplasty and reverse polarity shoulder arthroplasty are current treatment options for older patients with osteoporotic periarticular fractures. The selection of a particular technique will depend on clinical evidence and our previously stated aim to return patients to optimal function as soon as possible. It should be considered in the context that it can be expensive and require considerable other resources to make the procedure safe and long-lasting.

Heal

Time to fracture healing depends on several factors: patient comorbidities, the age of the patient, bone involved (upper limb or lower limb), patient factors (diabetes) and choice of treatment. Well-known factors that slow down bone healing include diabetes mellitus (doubles time to union), diminished blood supply (peripheral vascular disease, vascular injury at the time of injury), smoking, non-steroidal anti-inflammatory drugs and infection at the fracture site.

Several chemical and mechanical methods have been attempted to enhance fracture healing, including bone marrow injections into the fracture site and other orthobiologics such as bone morphogenic proteins. Mechanical methods include controlled axial micromotion (using an external fixator), electromagnetic stimulation and low-intensity pulsed ultrasound. There is good basic scientific evidence to support their theoretical benefit; however, to date there is little clinical evidence for their use in the primary treatment of closed fractures. The surgical strategy is important in determining how bones heal. As surgeons, our technique helps dictate whether the injury heals by primary bone healing, through compression; secondary bone healing, through forming callus that becomes ossified to bone over time; and, indeed, whether the fracture heals at all. Respecting the biological and biomechanical environment of the fracture is an important consideration when planning operative and non-operative management of fractures.

TABLE 32.11 Indications for surgery in limb trauma. The main indication is that operation will produce a better outcome; the principles are given in the text.

- A fracture requiring treatment that is unsuitable for non-operative measures
- Open fractures
- Failed non-operative management
- Multiple injuries
- Pathological or impending pathological fractures
- Displaced intra-articular fractures
- Fractures through the growth plate, where arrest is possible (Salter–Harris types III–V)
- Avulsion fractures that compromise the functional integrity of a ligament/tendon around a joint (e.g. olecranon fracture)
- Established non-unions or malunions

Rehabilitate

The main aim of treatment is to return the patient to a similar level of premorbid function as quickly as possible. Rehabilitation begins as soon as feasible. It is often not necessary to wait until bone union before beginning rehabilitation. It is important to move the affected joints and the joints in close proximity to the fracture (e.g. elbow and shoulder exercise while in a cast for a distal radial fracture), limiting global stiffness and wasting of the muscles on that limb.

TREATMENT BY FRACTURE LOCATION

In general, the principles of treatment described above are dependent on the fracture location: diaphyseal, metaphyseal and intra-articular.

Table 32.11 outlines some indications for operative stabilisation.

Diaphyseal fractures

Extra-articular fractures do not require an anatomical reduction, but rather a mechanical restoration by correction of length, alignment and rotation (*Figure 32.18*).

Angular malunion of a diaphyseal fracture of the weight-bearing long bones will lead to abnormal joint forces on the joint above and below, leading to pain and secondary degenerative joint disease.

Diaphyseal fractures are generally well suited to intramedullary fixation techniques, as previously discussed.

Summary box 32.5

Diaphyseal fractures

- Restore length, alignment and rotation
- Consider whether primary or secondary bone healing is the objective
- Radius and ulna need precise reduction to function

Metaphyseal fractures

In the AO classification metaphyseal fractures are classified into A type – extra-articular, B type – partial articular, and C type – complete articular.

In A-type fractures, joint congruity is not an issue and as such the principles of mechanical alignment, length and rotation need to be considered. Fixation of metaphyseal fractures is less predictable with intramedullary nailing, therefore plate and screw fixation, external fixation or, in the smaller joints, K-wire fixation is used. Metaphyseal fractures are close to the joint and so consideration is given to stable fixation to allow early joint movement and rehabilitation.

Intra-articular fractures

AO type B and type C fractures are intra-articular and as such the principles of treating intra-articular fractures need to be

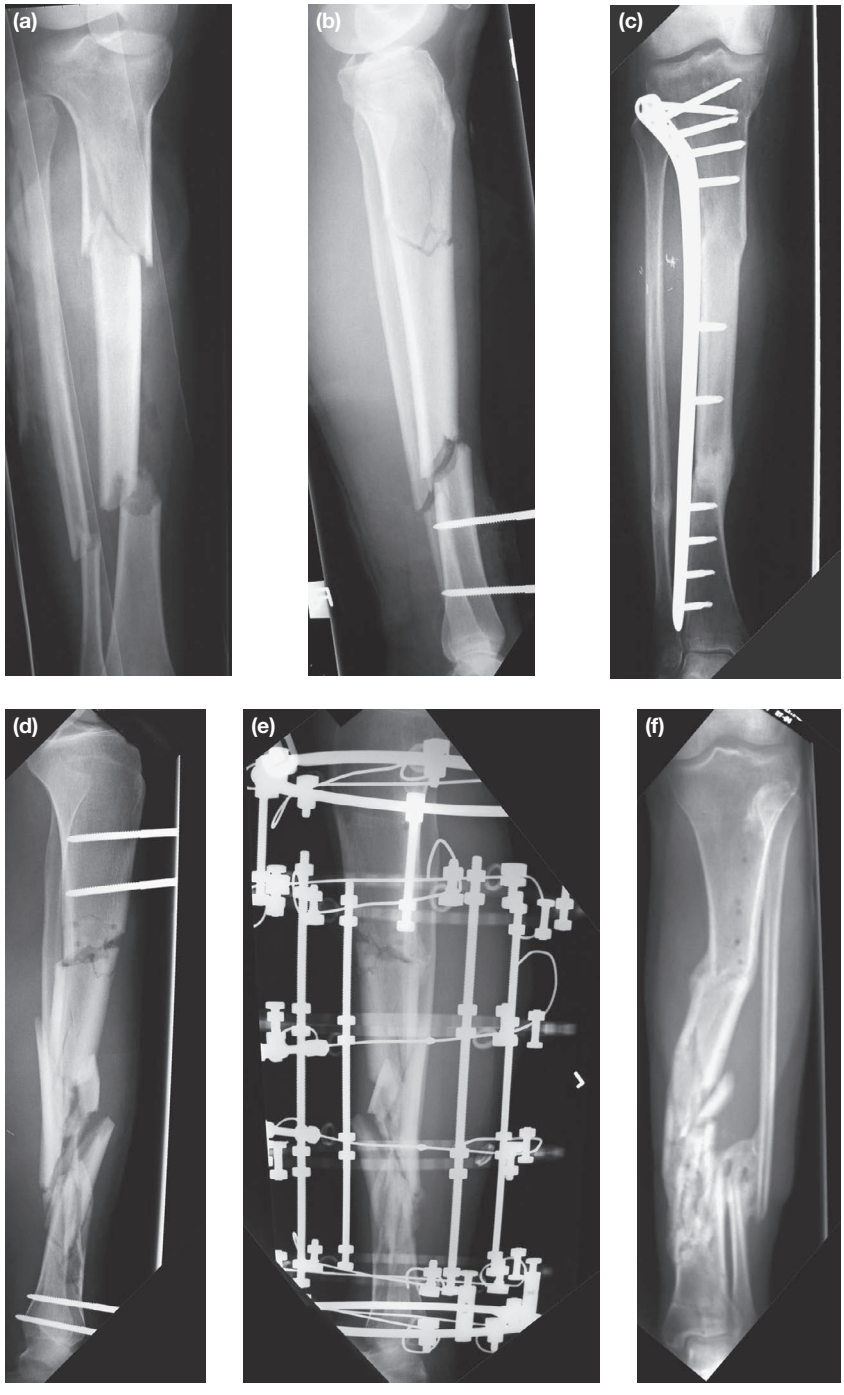

Figure 32.18 (a) and **(d)** are C-type or segmental tibial fractures. Each was a high-energy injury; **(b)** and **(e)** show a temporary spanning external fixator applied in each case; **(c)** and **(f)** show definitive relative stability was achieved with different methods of bridging fixation. Healing was by indirect means in both cases. Despite irregularities at the fracture sites the overall alignment in coronal and sagittal planes was satisfactory and function was good.

respected; namely, anatomical reduction of the articular surface and rigid stabilisation to allow early joint movement and avoidance of degenerative joint disease (*Figure 32.19*). However, these principles have to be balanced with the increased wound complications of open surgery and devitalising bone fragments with excessive exposure of the bone.

Osteoporotic intra-articular fractures are a considerable challenge. Although anatomical reduction may be achieved, rigid fixation devices may cut out of soft bone, particularly in the metaphysis of the bone where pull-out strength of the fixation is reduced. Plate design and the introduction of locking plates where the screw secures itself into the plate are design

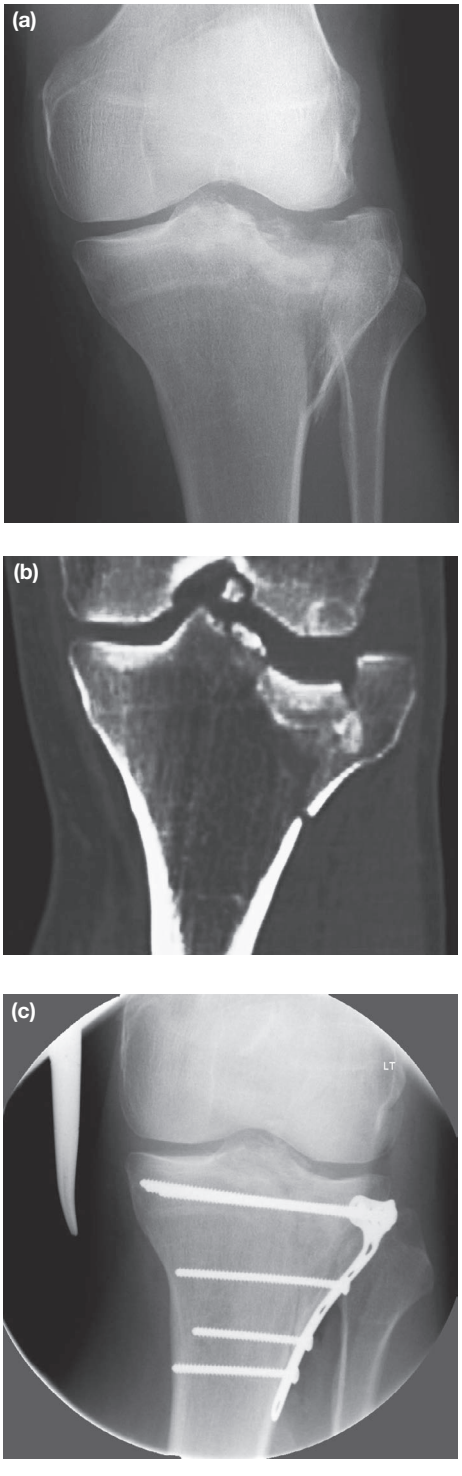

Figure 32.19 A B-type or partial articular fracture. **(a)** Plain radiograph; **(b)** computed tomography clarifies the injury; **(c)** fixation with plate and screws achieving compression across a previously reduced fracture.

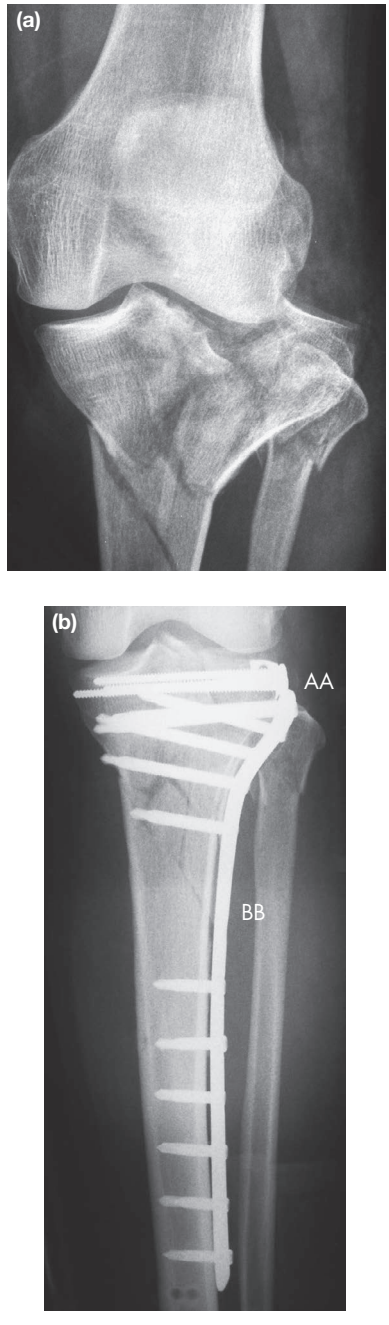

Figure 32.20 (a) A C-type proximal tibial articular fracture (i.e. none of the joint remains attached to the diaphysis). **(b)** The small plate and screws (AA) are used to compress the joint fragments, aiming for absolute stability. The heavy duty fixed angled device (BB) spans the fracture and provides relative stability. Although the image is historical and techniques vary with time, there has been good restoration of alignment and joint congruity.

features to help improve cut-out strength and may help reduce failure of fixation in osteoporotic bone. Injectable bone substitutes may be used to fill bone voids and augment fixation. If stable fixation is not possible, then consideration might be given to non-operative treatment and delayed joint replacement or, on occasion, primary joint replacement may be undertaken.

In type C fractures where the articular surface has separated from the metaphysis, the articular surface is initially anatomically reduced and held with temporary K-wires or lag screws and then the articular block is reattached to the shaft using methods as described above – plate, nail or frame (*Figure 32.20*).

TREATMENT BY REGION (FROM TOP TO TOE)

Scaphoid fracture

The blood supply to the scaphoid enters distally and supplies the scaphoid in a retrograde fashion. As such, a displaced waist of scaphoid fracture interrupts the blood supply to the proximal pole, leading to avascular necrosis. An undisplaced fracture of the scaphoid may not be visible on the initial radiographs. If a fracture is not evident on the initial radiographs and the patient is tender in the anatomical snuff box following a fall on the outstretched hand, special scaphoid view radiographs should be requested (***Figure 32.21***).

If a fracture is not evident on the initial radiographs and the patient remains tender in the anatomical snuff box, then treat as a suspected scaphoid fracture until a fracture is actively excluded. The standard protocol of a suspected scaphoid fracture is to immobilise the wrist and examine again 10–14 days later. If tenderness remains, repeat the scaphoid views. If facilities and resources allow, an earlier diagnosis may be made with a bone scan, MRI or CT.

Undisplaced fractures can be treated non-operatively in a below-elbow cast. It is not necessary to include the thumb as a routine. In displaced or unstable fractures (>1 mm) consideration should be given to open reduction and rigid fixation with a headless compression screw. Complications of scaphoid fractures include: non-union, avascular necrosis, malunion and carpal instability.

Carpal instability

The most commonly involved carpal bone is the lunate. A lunate dislocation is where the lunate bone dislocates out of the radiocarpal joint. In a perilunate dislocation the lunate remains in the radiocarpal joint and the rest of the carpus dislocates around the lunate. Lunate and perilunate dislocations are easily missed unless careful attention is paid to carpal alignment on the lateral radiograph (***Figure 32.22***). Review of the radiographs should particularly ensure the anatomical location of the lunate in the radiocarpal fossa and that the capitate in the 'cup' of the lunate is maintained.

Acute injuries should be reduced closed initially to remove pressure from the median nerve. Anatomical carpal alignment is difficult to hold and therefore surgical reconstruction of damaged intrinsic ligaments, together with K-wire fixation of the carpal bones, is often undertaken. Ligamentous healing is slow and may be incomplete. K-wires are kept in place for 8 weeks and the wrist casted or splinted for 3 months.

Thumb metacarpophalangeal ulnar collateral ligament

Injury to the thumb metacarpal ulnar collateral ligament is a unique injury often termed 'gamekeeper's thumb' or 'skier's thumb'. Owing to the unique anatomical arrangement of adductor pollicis, if the ligament undergoes complete rupture the aponeurosis may become interposed, inhibiting

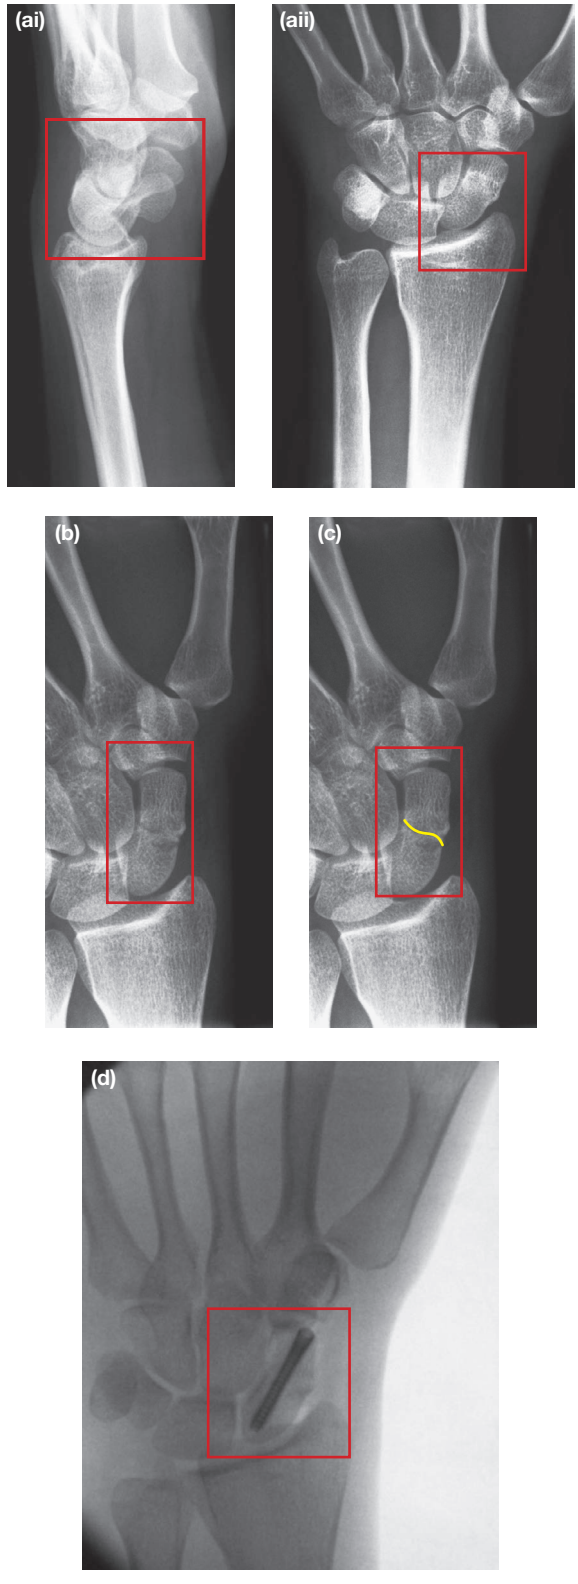

Figure 32.21 Scaphoid fracture. **(a)** Anteroposterior **(i)** and lateral **(ii)** views in which the injury is difficult to see; **(b, c)** oblique views with the fracture line highlighted; **(d)** in this case of a young patient, the fracture was treated with early fixation.

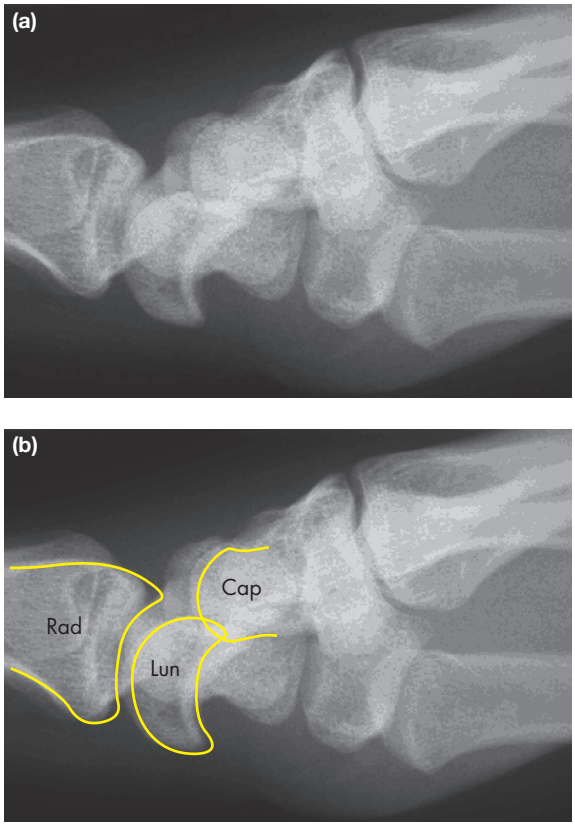

Figure 32.22 Perilunate dislocation. **(a)** A plain lateral radiograph of the wrist; **(b)** the outline of the perilunate dislocation is highlighted. Cap, capitate; Lun, lunate; Rad, radius.

ligament-to-bone healing. A rupture of the ulnar collateral ligament should be suspected when an ulna-directed force is directed across the metacarpophalangeal (MCP) joint. A tender swelling on the ulnar side of the MCP joint may signify the Stener lesion. Increased laxity may be clinically evident; if there is uncertainty, stress radiographs can demonstrate the degree of injury. Complete ruptures with a Stener lesion (interposed aponeurosis) require open reduction of the ligament to restore bone contact, with a suture anchor repair of the associated ulnar collateral ligament.

Distal radial fractures

Extra-articular (type A) fractures of the distal radius may displace in a volar or dorsal direction. It is possible to reduce volar displaced fractures (Smith's fracture) of the distal radius with a closed technique. However, they tend to be unstable and displace if held in a cast. Hence most volar displaced extra-articular distal radial fractures are reduced and held with a volar buttress plate (***Figure 32.23***).

Most dorsally displaced fractures (Colles fracture) can be addressed with closed reduction and held in a cast. However,

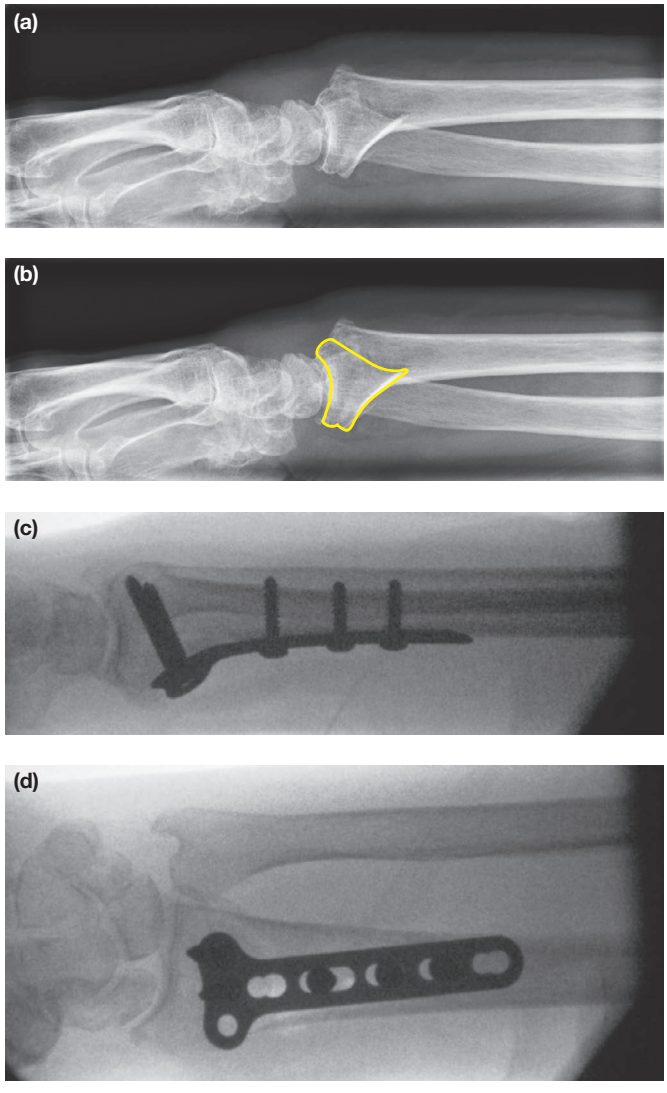

Figure 32.23 An A-type or extra-articular metaphyseal fracture. A plain lateral radiograph of this Smith-type fracture **(a, b)**. Fracture fixed to a plate. There is no interfragmental compression. The plate is pushing against or buttressing the distal fragment **(c, d)**.

some will slip or collapse with cast treatment, and so close review for the first few weeks is advocated.

Fractures with significant initial displacement and dorsal comminution are at risk of early and late collapse. After thorough counselling the patient may choose to have the fracture reduced and then held surgically with K-wires, plate and screw fixation (volar or dorsal) or external fixation. The K-wires may be placed across the fracture fragments or intrafocally, going through the fracture site. The latter can be used to help reduce the fracture and then used to lock the fracture fragments in place (***Figure 32.24***).

Treatment is individualised based on patient and fracture pattern factors. Intra-articular fractures (types B and C) of the

Bertil Stener, 1920–1999, Swedish orthopaedic surgeon, described the anatomy and treatment of a displaced ulna collateral ligament injury to the thumb in 1962.
Robert William Smith, 1807–1873, Professor of Surgery, Trinity College, Dublin, Ireland, described the reverse Colles fracture in 1847.
Abraham Colles, 1773–1843, President of the Royal College of Surgeons of Ireland (1802), Professor of Anatomy, Physiology and Surgery (1804) and described distal radial fracture in 1814.

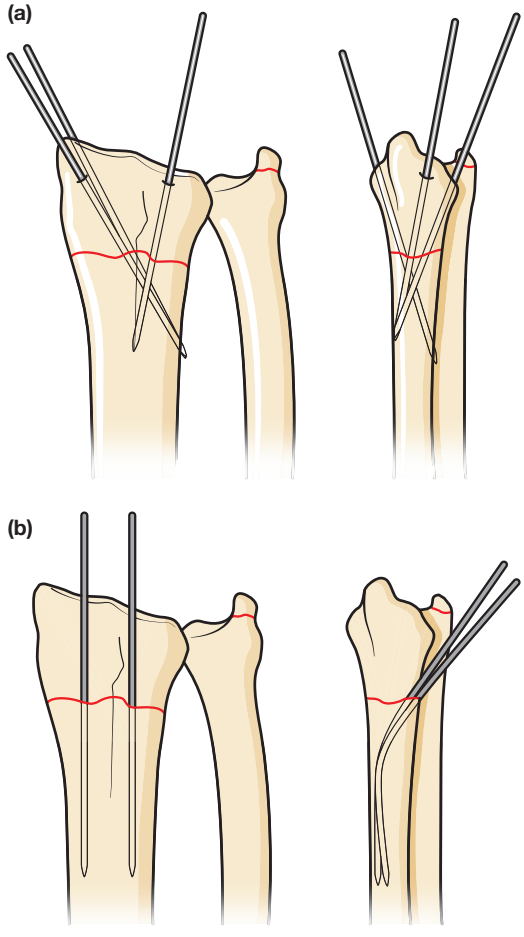

Figure 32.24 (a) K-wires placed across fracture fragments; **(b)** intrafocal K-wires used to help reduce the fracture.

distal radius require anatomical reduction of the joint surface; a gap or step of less than 2 mm can be accepted in the radius. The distal radius fails fairly predictably with splitting of the lunate fossa fragment in the coronal plane and separation of the radial styloid.

If a closed reduction can be achieved with manipulation, the fracture fragments can subsequently be held with K-wires, plate and screw fixation or external fixation. The most common form of treatment is closed reduction and percutaneous K-wire fixation, supplemented with a plaster cast for 4–6 weeks.

Forearm fractures (radius and ulna)

Fractures of the diaphyseal shaft of the radius and ulna are technically, in the anatomical sense of the word, extra-articular. However, the forearm bones work together, being coupled at the proximal and distal radioulnar joints to allow for forearm pronation and supination. Therefore, when considering treatment the principles that apply to intra-articular fractures need to be considered: anatomical reduction and rigid fixation to allow for early joint motion. Most fractures that involve both radius and ulna in adults require open reduction, anatomical alignment and rigid plate fixation.

Isolated fractures of the ulna, the so-called nightstick fracture, are a little more controversial, as non-operative management is possible but in this location risks delayed union and non-union, hence treatment depends on patient factors. Operative fixation with plate and screw fixation is technically simple and allows early predictable return to function.

Olecranon fractures

Olecranon fractures may be displaced or undisplaced. Undisplaced fractures with <2 mm gap or step at the articular surface can be treated non-operatively. In displaced fractures the extensor mechanism is interrupted and the articular surface requires anatomical reduction and stable fixation to allow early movement. Fixation may comprise K-wire and figure-of-eight tension band wiring or plate fixation. In multifragmentary fractures or fractures associated with an elbow dislocation, increased stability is required with the use of a plate and screws.

Humeral fractures

Fractures of the diaphyseal portion of the humeral shaft are extra-articular fractures and as such require mechanical alignment. Non-operative treatment with functional bracing will achieve union in an acceptable position within 12 weeks in over 80% of cases. Gravity can provide traction on the arm and in conjunction with a humeral brace helps to hold alignment and allow early range of motion of the elbow. Active shoulder abduction is avoided until fracture union to prevent varus deformity.

Shoulder movement must not be absent during treatment and so gravity-assisted pendulum exercises are instituted early on to prevent shoulder stiffness. As the fracture approaches the metaphyseal region of the humerus it becomes more difficult to control with humeral bracing. Distal third extra-articular fractures of the humerus can be treated non-operatively in a humeral brace but have a tendency to go into varus. Articular fractures of the distal humerus require anatomical reduction and stable fixation to allow early joint movement.

Internal fixation is indicated for displaced intra-articular fractures, non-union or delayed union, open fractures, multiple injuries and those fractures not held in an acceptable position with brace treatment. Fixation of diaphyseal fractures can be achieved with intramedullary nailing or plate and screw fixation. Plate fixation is associated with higher union rates and lower rates of reintervention (***Figure 32.25***).

The radial nerve is the most commonly injured nerve in humeral shaft fractures. Treatment of a humeral shaft fracture with a concomitant radial nerve palsy remains topical. Most will recover spontaneously. In general, if the nerve injury occurs at the time of the original injury, non-operative treatment can be considered. If it occurs after the injury, for example at the time of brace application, then it should be explored. When exploring the radial nerve, plate and screw fixation is then undertaken to stabilise the humerus.

Fractures of the proximal humerus

In fractures of the proximal humerus consideration is given to the vascularity of the humeral head. The most common

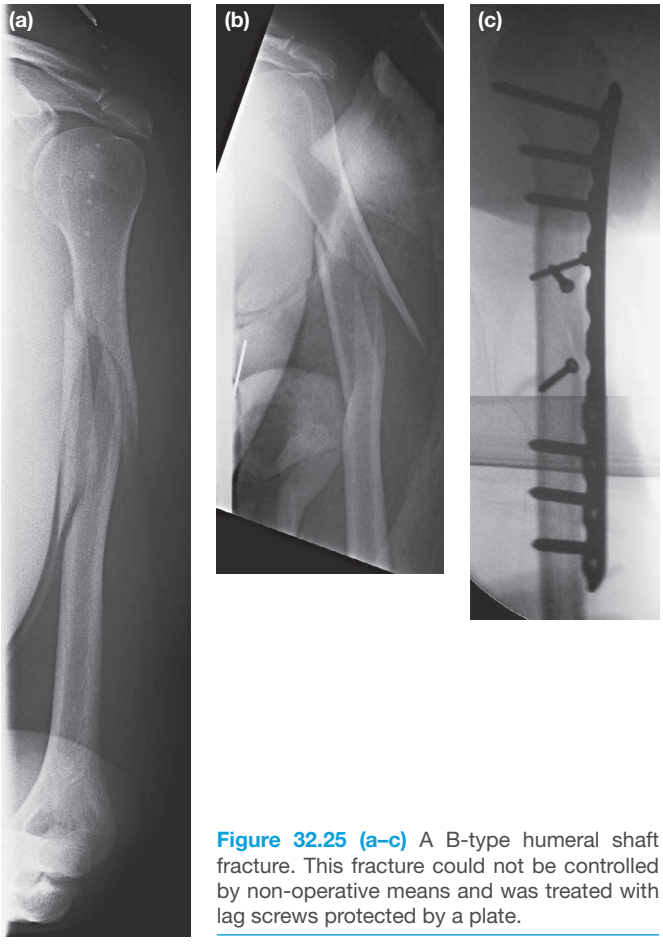

Figure 32.25 (a–c) A B-type humeral shaft fracture. This fracture could not be controlled by non-operative means and was treated with lag screws protected by a plate.

classification of the proximal humerus is the Neer classification, which looks at the four individual pieces of the proximal humerus (articular head fragment, lesser tuberosity, greater tuberosity and the shaft).

If a fragment is displaced by more than 1 cm or angulated by more than 45° in respect of another fragment, it is considered a part. As such, based on the fracture pattern, it may be undisplaced, or in two parts, three parts or four parts. Consideration is then given to potential joint dislocation, anterior or posterior. The greater the number of parts, the higher the chances of interruption of the vascularity to the humeral head and the more complex the injury.

Three factors can be used to predict avascularity of the humeral head:

1 fracture through the anatomical neck;
2 loss of the medial hinge;
3 less than 8 mm of bone along the medial calcar.

In situations where there is a high risk of failure of both fixation and non-operative treatment, owing to avascular necrosis or implant fixation failing from bone loss or loss of function (e.g. with displaced fractures in lower demand patients and those with osteoporosis and other comorbidities), consideration may be given to replacing the humeral head. This may take the form of an anatomical hemiarthroplasty. One of the limitations of trauma hemiarthroplasty for proximal humeral fractures involves reliable healing of the tuberosities and the rotator cuff. Increasingly, a primary reverse polarity shoulder prosthesis is being used. This implant does not rely on tuberosity healing, as it functions under the power of the deltoid muscle.

In younger patients reduction and fixation may be considered. A variety of fixation methods are available: percutaneous fixation, intramedullary nails and plate fixation.

Clavicle fractures

Diaphyseal fractures of the middle third of the clavicle have traditionally been treated non-operatively with a broad arm sling for comfort and social protection, followed by increasing use of the arm.

Most mid-third fractures of the clavicle will unite with non-operative treatment. There is, however, a subset of clavicle fractures that may be slow to heal and that do impact on shoulder girdle function. Displaced, comminuted fractures show a propensity to be slow to heal and increasing age and female gender further negatively impact on fracture healing. It has been shown that 2 cm of shortening of the clavicle impacts on shoulder girdle function, with weakness and fatigability when working above shoulder height.

Internal fixation with an intramedullary device or plate and screw construct can restore length, alignment and rotation. This can improve the speed and amount of functional restoration, but carries all the risks of surgical treatment. Treatment is individualised to patient needs and expectations.

Proximal femoral fractures

The blood supply to the femoral head is a prime consideration in treating femoral neck fractures. The blood supply comes via the hip capsule and although vascular anatomy is variable it is chiefly through the medial and lateral branches of the deep circumflex femoral artery in addition to the occasionally redundant artery of the ligamentum teres (a branch of the obturator artery). The joint capsule anteriorly inserts along the intertrochanteric line and posteriorly half-way along the femoral neck. Fractures proximal to the hip capsule are intracapsular and those distal to the capsule are extracapsular fractures.

Intracapsular femoral neck fractures

Intracapsular fractures are further broken down into whether they are displaced or undisplaced. Undisplaced intracapsular fractures are generally stable and interruption of the blood supply to the femoral head is rare. Therefore, treatment is aimed at ensuring that the head fragment does not displace during rehabilitation. This can be achieved with cannulated screws inserted along the femoral neck into the head.

A displaced intracapsular fracture may cause disruption of the blood supply either through direct injury to the arteries

Charles Sumner Neer II, 1917–2011, American orthopedic surgeon, emeritus professor at Columbia University, developed a widely used shoulder prosthesis and also developed a common classification system for proximal humerus fractures.

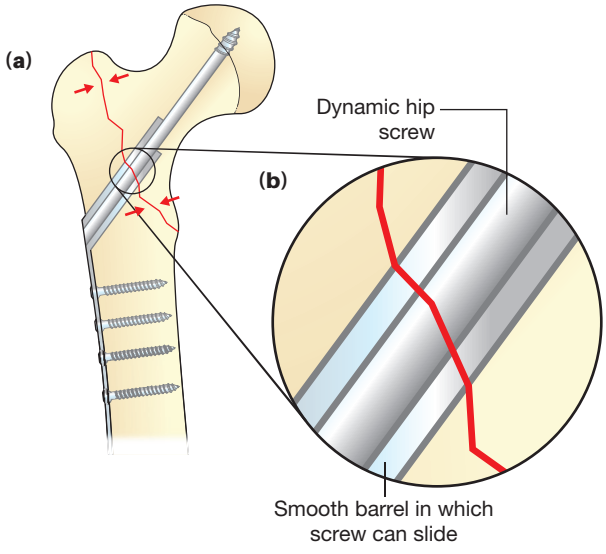

Figure 32.26 (a) A dynamic hip screw for fixing a trochanteric proximal femoral fracture. This allows for compression at the fracture site on load-bearing and protects the femoral head from penetration by the screw when the osteoporotic bone settles; **(b)** insert to show the sliding screw in the barrel.

or joint capsule intra-articular haematoma can affect the survival of the femoral head, leading to avascular necrosis. If the patient is physiologically young, reduction and internal fixation with cannulated screws or a dynamic hip screw might be attempted to preserve the native head.

If the patient is older and would benefit from a single operation, the head may be sacrificed and replaced with a prosthetic head. Arthroplasty of the proximal femur may take the form of hemiarthroplasty or total hip replacement, depending on the patient's functional demands.

Extracapsular femoral neck fractures

If the fracture is extracapsular, vascularity of the head is not an issue. Extracapsular femoral neck fractures are subdivided into stable or unstable. Unstable fractures include a reverse oblique pattern or where the medial calcar is a comminuted (lesser trochanter) fracture. Stable extracapsular fractures simply require connection of the head to the shaft, often using a dynamic hip screw (***Figure 32.26***).

In unstable fractures a dynamic hip screw can also be used, but, owing to the unfavourable mechanical environment relating to the loss of the medial calcar or a reverse oblique pattern, an intramedullary device might be considered.

Femoral shaft fractures

It is possible to treat diaphyseal fractures of the femoral shaft non-operatively. The fracture can be reduced and held in position until union with traction; however, it takes 3 months. This is a long time to be in hospital and carries all the potential risks of prolonged bed rest. Most femoral shaft fractures are treated with a locked intramedullary nail.

With modern locked intramedullary implants, the patient will be up and out of bed the following day and, if it is an isolated injury, home within a few days. Weight-bearing depends on the fracture pattern and implant used. If there is a simple fracture pattern with cortical apposition, it will be possible to mobilise with crutches, weight-bearing as comfort allows. Although it may still take 3 months or more for the fracture to unite, the implant will be able to carry the load until union, allowing earlier return to function out of the hospital.

Distal femoral fractures

Metaphyseal osteoporotic fractures of the distal femur are amenable to internal fixation with locked intramedullary nails or plate and screw fixation. If the fracture extends into the articular surface, reconstruction may be undertaken with cannulated screws augmented with intramedullary nailing or injury-specific locking plates for the distal femur. More commonly now these injuries are often next to a knee replacement (periprosthetic fracture), which can add technical complexity; surgical decision making is influenced by whether the implant is attached to bone or is loose, the amount of bone to fix into and the health status of the patient. More recently, primary and revision arthroplasty have been considered in these situations to allow early mobilisation.

Patellar fractures

Similar to olecranon fractures, undisplaced fractures in which the extensor mechanism is intact can be treated non-operatively. A simple assessment of this is if the patient can straight leg raise to test the extensor mechanism, but beware of the patient who is able to 'cheat' by using the iliotibial band to internally rotate the leg to compensate for the deficient extensor mechanism. Displaced fractures require anatomical reduction of the articular surface and reconstitution of the integrity of the extensor mechanism. The cartilage on the patella is very thick; as such, increased amounts of displacement compared with other joints may not lead to degeneration.

Surgical treatment of simple displaced fractures can be achieved with two K-wires and figure-of-eight tension band wiring.

Multifragmentary patellar fractures can be very challenging. Patellar excision is an option but significantly reduces the mechanical advantage of the extensor apparatus. A tension band construct may be augmented by using circumferential wiring of the patella.

Tibial plateau fractures

Intra-articular fractures of the tibial plateau are common. Injuries may involve the lateral or medial side or both. The joint articular surface may be split, depressed or a combination of both. A CT scan should be performed to see the full extent of the injury. Undisplaced fractures may be treated non-operatively with a hinged knee brace and progressive protected weight-bearing over 8–12 weeks. The surgical considerations here are to restore alignment and joint congruity.

Displaced fractures require reduction and stabilisation. The articular surface, once reduced, is often held with plate and screw fixation or fine wire external fixation.

Tibial shaft fractures

For an undisplaced non-comminuted fracture of the tibial shaft, closed reduction and an above-knee cast is a safe and inexpensive treatment. At 4–6 weeks this may be converted to a patellar tendon below-knee cast to allow knee movement. Prolonged casting can lead to stiffness of the knee and the subtalar joint. Cast treatment requires close and constant monitoring of the position of the fracture site. To correct minor angular deformities the cast can be wedged.

A patient may choose to have an intramedullary nail to allow free knee and ankle movement. This, however, risks infection of the implant and anterior knee pain. This is another situation in which information and shared decision making can allow the patient to select the most appropriate treatment option.

For comminuted and complex fractures of the tibial shaft, although cast treatment is possible, intramedullary nailing is preferred despite the potential complications of infection and anterior knee pain. Fractures at the diaphyseal–metaphyseal junction at the knee and ankle are difficult to hold with an intramedullary nail and as such may be held with a plate and screws.

Tibial fractures are also very amenable to external fixation with either a monolateral frame or fine wire circular construct, particularly where surgical skills and implants are not available for intramedullary nailing.

Ankle fractures

Ankle fractures are very common. As with all intra-articular fractures one should strive for an anatomical reduction. Because of the biconvex saddle shape of the articular surface, small amounts of talar shift significantly increase joint surface contact pressures.

It is useful to think of the ankle mortise as having three columns: medial, lateral and posterior. Each column has a bony and a soft-tissue component. On the lateral side there are the lateral malleolus, lateral collateral ligament and syndesmotic ligaments. On the medial side there are the medial malleolus and medial collateral ligament (deltoid ligament). The posterior column has the posterior syndesmotic ligaments attached from the lateral part of the posterior malleolus to the posterior lateral malleolus.

If only one column (either the bony or soft-tissue component) has been injured, then it is considered a stable injury and can be treated non-operatively with cast or splint protection for 6–8 weeks.

If both or all three columns are involved or there is evidence of talar shift, it is an unstable injury. Depending on the patient's age and risk factors for wound complications, in general unstable fractures are treated with open reduction and rigid fixation to hold the fracture anatomically.

Non-operative treatment may be used for unstable fractures in elderly patients or patients with poor skin and unfavourable soft tissues, but this approach requires close observation and careful attention to casting technique.

Calcaneal fractures

The os calcis injury is most frequently caused by a fall from a height. It is important to exclude associated injuries to the lumbar spine, which occur in 20% of cases. Most os calcis fractures involve the posterior facet of the subtalar joint. The severity of the injury is often best appreciated with CT scans (***Figure 32.27***). Treatment depends on the severity of the injury to the subtalar joint and widening of the heel leading to peroneal impingement. An os calcis fracture is a significant injury and outcomes following surgical or non-operative treatment are unpredictable. On occasion in severe injuries, primary fusion of the subtalar joint may be considered.

Talus fracture

The talus consists of a head, neck and body. The most common injury is a talar neck fracture. This is caused by forced dorsiflexion of the forefoot (aviator's astragalus). The blood supply to the body of the talus is interrupted in displaced talar neck fractures. In high-energy injuries the talus can not only be fractured but also dislocated, at either the talonavicular joint, subtalar joint or tibiotalar joint. These are very serious injuries to the foot that can affect the patient's long-term function through the development of either degenerative changes or avascular necrosis. To optimise outcome and reduce the possibility of avascular necrosis, anatomical reduction and stable fixation of the talar neck should be performed. Fixation of the talus to achieve compression can be technically very challenging. An operative issue with talus fractures is that there tends to be comminution that does not allow effective compression of the fracture fragments together, or when compression is achieved the shape of the talus is inadvertently altered, thereby affecting the shape of the foot. In addition, the injury to the blood supply from the initial trauma may result in avascular necrosis of the talus, non-union and later degeneration between it and the adjacent joints (tibiotalar, talocalcaneal and talonavicular).

Tarsometatarsal (Lisfranc) joint injuries

Injuries to the midfoot are associated with significant morbidity ranging from a midfoot sprain to complete rupture of the ligaments connecting the forefoot to the midfoot. Injury classically follows forced plantarflexion of the midfoot. An alternative mechanism of injury are crush injuries where the foot is forced flat by a heavy weight. Lisfranc's ligament connects the second metatarsal to the medial cuneiform. Poorly treated injuries to the midfoot lead to significant morbidity and, if suspected, a CT of the foot should be undertaken. Treatment options range from closed reduction and plaster cast application to open reduction and internal fixation. In severe cases primary tarsometatarsal fusion may be considered.

Achilles tendon rupture

Complete rupture of the Achilles tendon is a common injury; 20% of acute injuries are missed. Active plantarflexion of the

Jacques Lisfranc de St Martin, 1790–1847, Professor of Surgery and Operative Medicine, Paris, France.

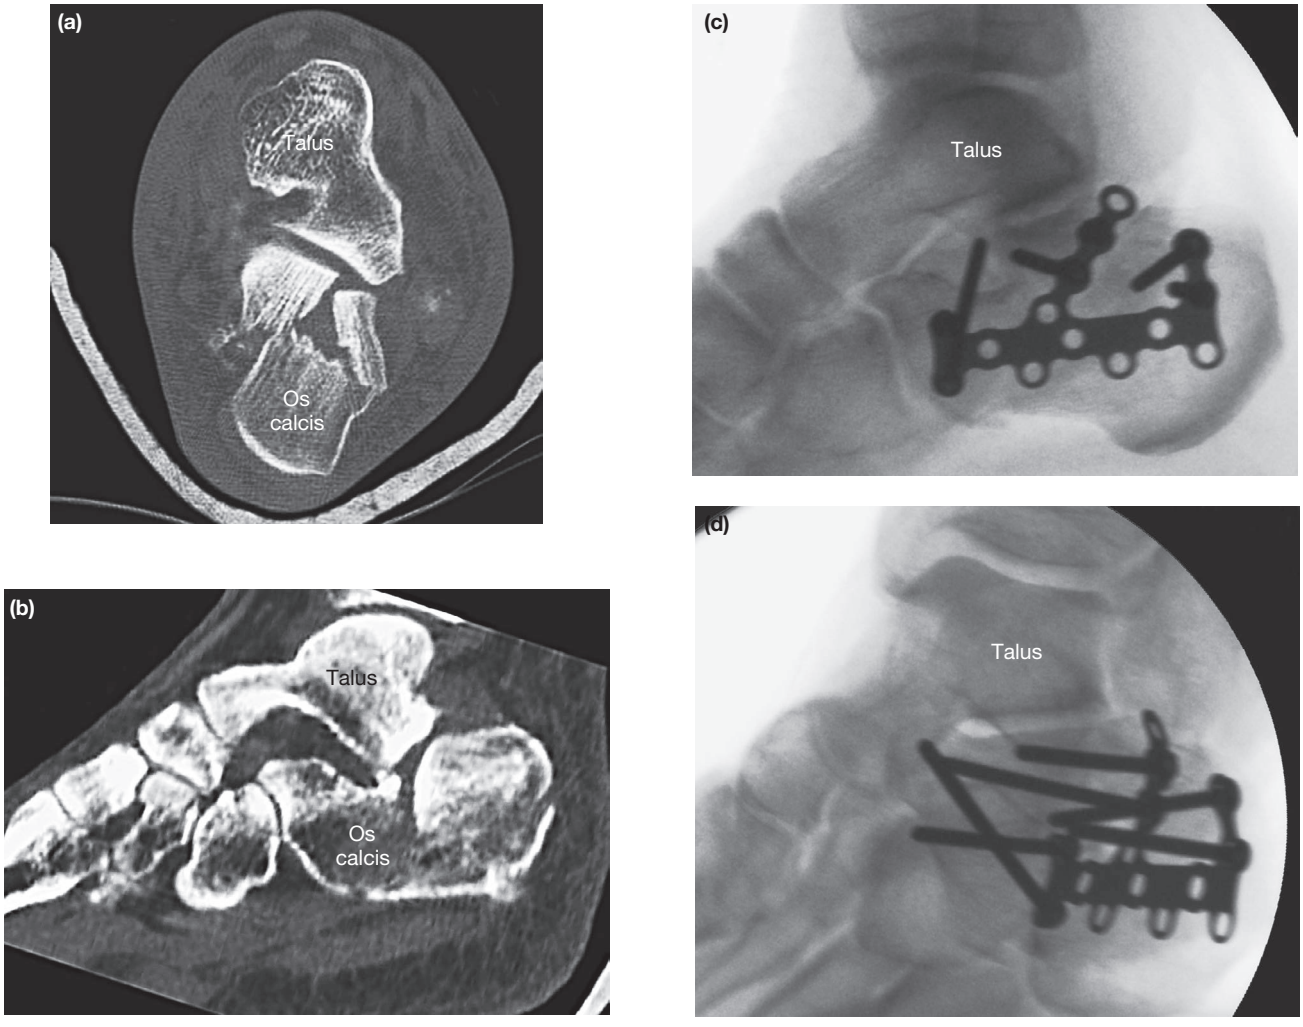

Figure 32.27 Axial **(a)** and sagittal **(b)** views of a displaced intra-articular fracture of the os calcis. **(c, d)** Intraoperative views of the reconstruction. Both the overall shape and the articular surface have been restored.

ankle is still possible, although weak, through the use of the toe plantarflexors.

A classic history is a feeling of being kicked in the heel and feeling something go. The most common activity leading to Achilles tendon rupture is badminton or squash following sudden forced contraction of the calf.

On examination a palpable gap may be felt. The diagnosis is confirmed by placing the patient prone on the examination couch, feet off the edge of the bed; squeezing the calf fails to elicit passive plantarflexion of the foot. If doubt exists, an ultrasound can confirm the diagnosis.

Treatment of acute Achilles tendon rupture involves surgical repair or functional management. There is an increasing trend to functional management as opposed to direct surgical repair.

TREATMENT OF FRACTURES IN THE SKELETALLY IMMATURE

The treatment principles that were described for the adult are equally applicable to the child (i.e. reduce, hold, heal, rehabilitate).

A major difference to consider is that in extra-articular fractures there is a remodelling potential, which means that increased degrees of deformity may be accepted. Remodelling happens best in the plane of the joint and the closer the injury is to the growth plate. Rotational and joint surface remodelling are poor. Fractures occurring near the site of greatest longitudinal growth will remodel the most (e.g. fractures around the distal femur have a greater remodelling potential than the proximal femur). The younger the patient, the greater the remodelling potential. Significant remodelling essentially ceases when the growth plates have closed.

A further difference is that paediatric fractures heal more rapidly and, as such, do not need to be held as long as in the adult counterpart. Similarly, fixation does not need to be as rigid, as fracture union is more rapid.

Growth plate injuries require special mention (*Figure 32.12*). In general, growth plate injuries should be anatomically reduced to minimise the potential for growth disturbance. However, in the process of reducing the fracture, further injury to the growth plate should be avoided.

Repeated manipulation of physeal injuries should be avoided. Injury to the perichondral ring and placing metal-

work across the physis (where possible) should similarly be avoided. If fixation necessitates crossing the physis, consider limited damage by using the smallest smooth K-wires with a single pass in the middle of the physis if possible.

The paediatric periosteum is often thick and very strong; this needs to be considered when reducing the fracture, requiring an exaggeration of the deformity and pushing the fracture back into place instead of just applying longitudinal traction. The periosteal hinge should be preserved as it also allows for better holding of the fracture if it remains intact, as previously described (***Figure 32.12***).

Always consider the possibility of non-accidental injury, as discussed in ***Chapters 26 and 44***.

SPECIFIC PAEDIATRIC INJURIES

Distal radial fractures

Fractures of the distal radius are very common in children. The bone either fails at the physis, leading to Salter–Harris type 2 fractures of the distal radius, or the metaphysis fails. The treatment principle of physeal fractures is to achieve an anatomical reduction. This can often be achieved with closed manipulation and the fracture held in position until healing with a below-elbow plaster cast. Growth arrest is rare after physeal fractures of the distal radius.

Complete metaphyseal fractures of the distal radius require close attention (***Figure 32.28***). In most cases an acceptable closed reduction can be achieved, but holding the distal fragment in an acceptable position can be challenging with cast immobilisation. Brachioradialis, which is attached to the radial styloid, is a continual deforming force. If non-operative treatment using a cast application is chosen, the position should be checked with radiographs weekly for the first 3 weeks; if re-displacement occurs, repeat manipulation and K-wire fixation may be required.

Distal humerus (supracondylar fracture)

Supracondylar humeral fractures are very common injuries in children. The distal humerus may go into flexion or extension, extension being by far the most common. Treatment depends on the degree of displacement. Undisplaced fractures may be protected in a collar and cuff or backslab for 3 weeks and then progressive mobilisation.

If displaced, the fracture can often be reduced with closed manipulation. If the dorsal periosteal hinge is intact, above-elbow cast immobilisation for 3–4 weeks is often sufficient to hold the fracture until union. If the periosteal hinge is broken, percutaneous K-wires are used to hold the fracture, supplemented with an above-elbow cast.

Figure 32.28 (a) Anteroposterior and lateral radiographs of a 10-year-old child showing a dorsally angulated metaphyseal fracture of the radius and undisplaced fracture of the ulna. **(b)** The injury was treated with closed manipulation and cast application. Eight weeks' postinjury radiograph out of the cast. The fracture is united, with residual 11° dorsal angulation. **(c)** Radiograph of the wrist following repeat injury 2 years later at age 12, showing complete remodelling. No residual deformity.

A very rare but feared complication of paediatric supracondylar fractures is Volkmann's ischaemic contracture. This is due to excessive swelling and missed compartment syndrome in the forearm. It is particularly important not to put the elbow into deep flexion if there is a lot of swelling. If deep flexion is the only way to hold the fracture, then K-wire fixation should be considered.

Neurovascular injury at the time of a supracondylar fracture is not uncommon. Careful attention should be paid to the neurovascular status of the limb. The white pulseless hand is a surgical emergency and requires immediate attention, assessment and urgent reduction. If the pulse does not return with reduction, then the vessels should be explored by appropriately trained surgeons.

The pink pulseless hand is more controversial and requires early senior decision making. If there is satisfactory perfusion of the limb, no suggestion of compartment syndrome and no neurological injury, then reduction and stabilisation of the fracture is warranted and a more expectant approach to the vascular injury can be taken. Often the pulse will return within 24–48 hours.

Neurological injury is common, most often a neuropraxia. They often resolve on fracture reduction, stabilisation and resolution of the swelling.

Malunion in varus or valgus remains a problem. Often the elbow will remodel the deformity in the anteroposterior flexion–extension plane, but varus and valgus malunion remodels less. Careful attention needs to be paid to the adequacy of the reduction and K-wire placement to hold the fracture to avoid angular malunion.

Lateral condylar mass fracture of the elbow

Lateral condylar mass fractures of the elbow are easily missed and often considered benign as there is often only a small flake of bone visible. This thin sliver of metaphyseal bone on the lateral side of the elbow is very deceptive. Do not underestimate the significance of this injury (***Figure 32.29***).

Treatment depends on the stability of the lateral mass fragment. If stable, non-operative treatment is acceptable. If unstable, anatomical reduction and fixation should be attempted to avoid complications.

Unstable fractures are suggested by significant soft-tissue swelling, by fracture displacement of more than 2 mm or by the fracture being visible on both anteroposterior and lateral views of the elbow.

Unstable fractures require anatomical reduction and rigid fixation with K-wires or screw fixation to avoid displacement and complications. Avascular necrosis of the capitellum and non-union of the lateral condyle lead to the so-called 'fish tail' deformity.

Slipped upper femoral epiphysis

A slipped upper femoral epiphysis classically occurs in a child approaching puberty. It is easily missed as symptoms may be mild and the predominant symptom may be knee pain referred from the hip. A history of trauma may be offered and the child may limp.

Examination of the limb reveals a hip that flexes into external rotation. Radiographs should include a good lateral view of the femoral head and neck (***Figure 32.30***). If the radiographs are normal, consider an MRI, looking for a preslip; if found, consider prophylactic fixation. If treated in the early stages, the prognosis is very good. A severely displaced slipped upper femoral epiphysis might lead to avascular necrosis of the femoral head and chondrolysis. This is a very difficult condition to treat effectively in young patients.

Femoral shaft fractures

Femoral shaft fractures in children are treated based on the age and size of the child:

- infants (0–18 months);
- toddlers and small children (18 months–4 years);
- children (4–12 years);
- older children/adolescents.

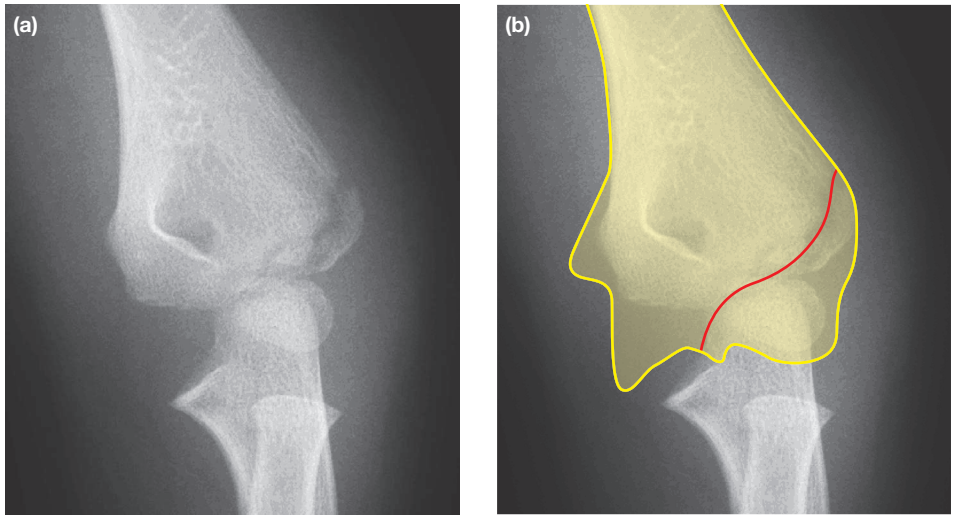

Figure 32.29 Lateral condylar mass fracture. **(a)** The metaphyseal fracture. **(b)** The yellow shows the shape of the distal humerus, including the cartilaginous analogue, and the red shows the true extent of the injury (i.e. a significant intra-articular fracture).

Richard von Volkmann, 1830–1889, Professor of Surgery, Halle, Germany.

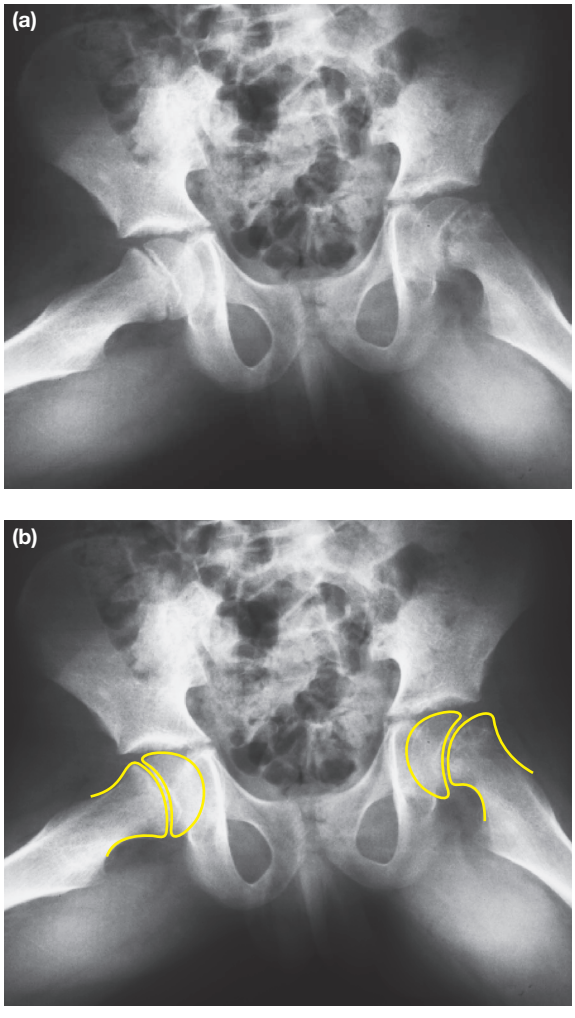

Figure 32.30 Slipped left upper femoral epiphysis. **(a)** Plain radiograph; **(b)** the injury highlighted.

In infants (0–18 months), ensure that there is no evidence of non-accidental injury. In infants under 12–15 kg, gallows traction is acceptable. This traction involves suspension of the legs vertically with the buttocks just off the bed. In toddlers and small children treatment is by traction initially followed by hip spica application. Shortening of up to 1 cm and angulation of 15–20° can be accepted depending on the age of the child because of extensive remodelling potential.

As the child gets older and time to union increases, the non-operative measures of traction and hip spica become more cumbersome.

In children from 4 to 12 years several treatment options exist: traction and hip spica, elastic stable intramedullary nailing (ESIN), external fixation or plate fixation. Definitive treatment depends on surgeon skills, facilities and patient and parent needs.

In older children and adolescents, non-operative treatment with traction and hip spica cast application becomes less tolerable. Depending on the size and build of the patient, operative treatment may include ESIN (*Figure 32.31*), external fixation

Figure 32.31 (a–c) Femoral shaft fracture in a child that has been stabilised with elastic nails.

or plate fixation. In larger overweight adolescents, titanium elastic nails may not be strong enough to resist bending forces and locked intramedullary nailing may be considered.

Summary box 32.6

Fractures in the skeletally immature

- Do not forget non-accidental injury
- Be reluctant to remanipulate a physeal injury
- Elastic nails are a significant step forward in fracture treatment in children
- Not many fractures require operative intervention in children

It is important, however, to remember that there is a small chance of avascular necrosis of the femoral head if an antegrade intramedullary nail is used prior to or just after physeal closure. This is a rare but devastating complication in this age group. Far lateral entry point nails on the greater trochanter have been developed to limit the effect on the blood supply to the femoral head; however, the risk of avascular necrosis persists.

Tibial shaft fractures

Tibial fractures in children are often very amenable to non-operative treatment, starting with an above-knee cast, followed by conversion to a Sarmiento patellar tendon

Augusto Sarmiento, b. 1927, Colombian orthopaedic surgeon, Professor and Chairman of the Department of Orthopedics, University of Southern California, Los Angeles, CA, USA.

below-knee cast at 4–6 weeks. Remodelling in the tibia is somewhat limited; as such, less angular deformity (only 10–15°) can be accepted and no rotational deformity. Some shortening of the tibia can be accepted as the tibia is expected to overgrow by 0.5 cm in response to injury. If it is not possible to hold the fracture in an acceptable position with a cast, then external fixation, elastic stable intramedullary nailing (ESIN)/titanium elastic nails (TENS; thin flexible nails inserted in the canal of a long bone to splint it) or plating is an option.

SPECIAL CONSIDERATIONS

Special consideration needs to be given to osteoporotic and pathological fractures, for example the ability to hold the fracture until union. Furthermore, open fractures require urgent appropriate treatment to ensure bone healing in the absence of infection.

Osteoporotic fractures

Osteoporosis is a condition characterised by low bone mineral density and reduced strength. Osteoporotic bone is liable to fracture with low-energy injuries (e.g. a fall from standing height). Treatment of lower limb osteoporotic fractures in older patients is challenging. As there may be additional and pre-existing mobility problems, such patients are unable to partially weight-bear and so fixation should be strong enough to allow immediate weight-bearing and to hold the position until union. Locking plate technology improves fixation in osteoporotic bone, and bone void fillers can be utilised (***Figure 32.32***).

Pathological fractures

When abnormal bone fails under normal load this is referred to as a pathological fracture. Depending on the cause of the pathological fracture the bone may not heal and consideration should be given to a load-bearing device not load-sharing. If involving the joint surface or close to the joint surface, the affected area may be excised en bloc and a joint replacement performed.

The bone may be weakened by a primary bone tumour, secondary metastatic deposits, haematological malignancy (myeloma, lymphoma, leukaemia), osteomyelitis and metabolic bone disease (osteomalacia, Paget's disease, osteoporosis).

A pathological fracture should be suspected if the history is not consistent with the severity of the injury. The patient may give a history of low-energy injury that normally would not cause a fracture. If a pathological fracture is suspected, the cause should be actively sought. Where a primary bone tumour is suspected, treatment should be planned to prevent disseminating the disease (see ***Chapter 42***).

In patients with metastatic bone disease, the primary source should be sought if multiple metastatic deposits are identified. If life expectancy is poor, then stabilisation with a load-bearing device may be considered. If an isolated metastasis is identified and an overall good prognosis is offered by the oncologists, a more aggressive curative approach may be taken with en bloc excision of the primary and the isolated secondary deposit.

If a metastatic deposit is identified prior to fracture, prophylactic fixation should be considered if impending fracture is likely. Prophylactic stabilisation with a load-bearing device is once again advocated. If life expectancy is good and the deposit periarticular, an en bloc excision and joint arthroplasty may be considered to optimise return to near normal function as soon as possible.

Open fractures

Any fracture with an overlying wound should be considered an open fracture. The term previously used was a compound fracture. Open fractures require particular mention because adequate stabilisation of the bony injury and appropriate management of the soft-tissue injury are paramount to ensure a good outcome with a low complication rate. The treatment of bone and joint infection is expensive, laborious and time-consuming for the professional as well as the patient. An infected femoral shaft fracture following intramedullary nailing will typically take 3 years and five operations to clear the infection and achieve union.

The Gustilo and Anderson classification of open fractures is the most frequently used classification (***Table 32.2***). The definitive grade is determined intraoperatively after thorough debridement. It is not based on size of wound alone but takes into account several factors; for example, a farmyard or heavily contaminated wound of under 1 cm may still be considered a grade III injury.

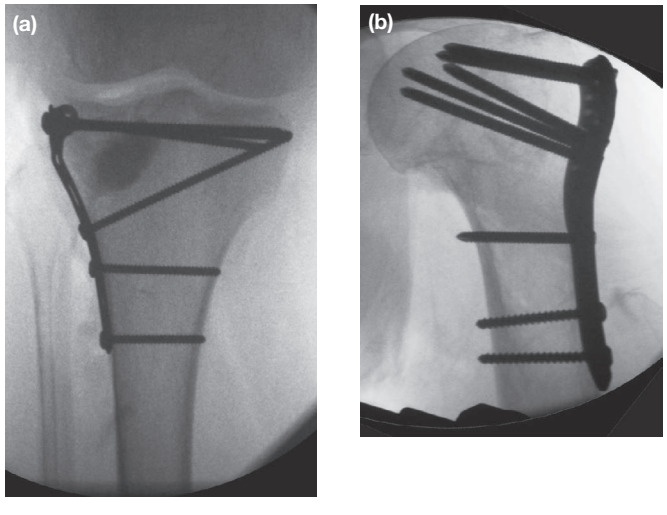

Figure 32.32 Variations in fixation technique suited to osteoporotic bone. **(a)** Norian bone substitute has been injected to support the lateral tibial plateau in the partial articular fracture. **(b)** A locking plate in a proximal humerus. The screws are threaded into the plate to make a fixed-angle device.

Sir James Paget, 1814–1899, surgeon, St Bartholomew's Hospital, London, UK.

The aim of open fracture management is to achieve bony union, optimise function and avoid infection. The treatment of open fractures should be considered in two phases: the emergency department presurgical phase and the surgical phase.

Presurgical phase

1. Take a photograph to document the severity of the injury and limit the need for repeated opening of dressings. (Do not delay steps below unduly.)
2. Assess neurovascular status; if compromised and the fracture is displaced, quickly remove any macroscopic dirt and reduce the fracture/dislocation. It is not essential to achieve an anatomical reduction; simply remove the pressure from the soft tissues (make a leg look like a leg and an arm look like an arm). If the bone was out of the skin and is reduced under the skin, then document clearly and inform the surgical team.
3. Once overall alignment is achieved, splint the affected limb; treatment of an open fracture is treatment of the soft tissues.
4. Apply a moist saline dressing to the wound. It is acceptable to irrigate the wound with saline in the emergency department to remove any macroscopic dirt, but definitive debridement and washout of the wound should be undertaken in a theatre environment.
5. Administer intravenous antibiotics according to local protocols. It has been shown that early administration of intravenous antibiotics is one of the most important steps. A broad-spectrum antibiotic should be chosen covering Gram-positive, Gram-negative and, if there is severe contamination, anaerobic organisms.
6. Obtain a tetanus immunisation history and treat accordingly.
7. Inform a senior orthopaedic surgeon of the injury as soon as possible and make preparations for the surgical phase.

Surgical phase

In the past an open fracture was considered a contraindication to internal fixation. It is increasingly evident that stable fixation of the bony injury is very important to prevent deterioration of the soft tissues, allowing recovery and healing.

Fracture stabilisation may come in the form of external fixation or internal fixation with screws/plates/intramedullary nails, depending on the setting.

Summary box 32.7

Special considerations

- Osteoporotic fractures in older patients may require specialised fixation techniques with locking screw/plate technology and injectable bone cement augmentation
- Pathological fractures may not heal and require load-bearing not load-sharing implants
- Arthroplasty in suitable patients bypasses the problems of blood supply and weak bone and allows early full weight-bearing and return to function
- Open fractures require prompt debridement, stabilisation and adequate soft-tissue cover to prevent infection

Management of the soft tissues is critical to prevent the zone of injury spreading. Thorough debridement of any contaminated or non-vital soft tissue is important. Any loose or devitalised bone fragments should be discarded. Bone defects are easier to deal with than an infected non-union.

Soft-tissue reconstruction may involve primary or delayed primary closure of the wound, or more sophisticated soft-tissue reconstruction options including microvascular free tissue transfer.

Continue intravenous antibiotics until 48 hours after definitive wound closure.

COMPARTMENT SYNDROME

Compartment syndrome is raised pressure in a fascial compartment to a level that compromises tissue perfusion. There are several causes of compartment syndrome, fractures being the most common (70%), followed by soft-tissue contusions (23%). Rarer causes include: bleeding disorders, including anticoagulation; burns (particularly circumferential third-degree burns); postischaemic swelling (reperfusion injury); tight casts/dressings; and extravasation of intravenous infusions (contrast under pressure).

The pathophysiology involves increased tissue pressure, which leads to reduced microperfusion, resulting in tissue ischaemia and irreversible muscle damage from cellular anoxia.

Compartment syndrome is a clinical diagnosis characterised by pain out of proportion, increasing pain, and pain on passive stretch, with paraesthesia possible. Paralysis, numbness and pallor are late signs and pulselessness is an extremely late sign.

Compartment pressure monitoring may be useful in cases of diagnostic uncertainty and in patients with altered levels of consciousness (intubated, head injury).

Measure multiple sites near but not in the fracture site, in all the compartments of the affected limb. Generally accepted pressure thresholds include an absolute pressure greater than or equal to 30 mmHg or pressure difference (diastolic pressure – compartment pressure) less than or equal to 30 mmHg.

Emergency treatment involves splitting casts and/or dressings to the skin and elevating the extremity. Senior input should be sought and arrangements put in place to perform definitive treatment with fasciotomies.

There are some common pitfalls to remember. The incidence of compartment syndrome associated with high- and low-energy injuries is nearly equal. Compartment syndrome can occur in open fractures. Have a high index of suspicion and be particularly vigilant in patients with an altered level of consciousness.

CONCLUSION

The correct identification of extremity trauma, combined with timely and appropriate treatment, is essential to return patients to normal function as safely and as quickly as possible. The same injury may be treated in different ways based on patient factors, age, functional demands and comorbidities. Surgeon and resource-based factors also need to be considered.

Summary box 32.8

Summary of extremity trauma

- Realise that an injury exists
- Find the characteristics of the injury, describe it and classify it
- Consider the natural history of the injury
- Treatment is guided by outcome if known or by principle if not
- Beware of injuries that are 'easily missed'

CHAPTER 33

Disaster surgery

Learning objectives

To recognise and understand:

- The common features of various disasters
- The principles behind the organisation of the relief effort and of triage in treatment and evacuation
- The role and limitations of field hospitals in disaster
- The features of conditions peculiar to disaster situations and their treatment

INTRODUCTION

Natural disasters provide a constant reminder of the power and capricious nature of our planet. The depletion of the ozone layer and global warming mean that the future may hold in store calamitous events with even greater magnitude than those experienced before. National conflicts and ideological differences have not lessened and the resultant 'unnatural disasters' have the potential to rival the natural ones in enormity (see ***Chapter 34***). Disasters by their very nature are unpredictable and no two are alike. Nevertheless, there are numerous common elements and it has been shown that countries that invest in disaster preparedness are better equipped to cope with such catastrophes. Recent wars and disasters have highlighted the increasingly crucial role of surgeons in these scenarios.

COMMON FEATURES OF MAJOR DISASTERS

Any event that results in the loss of human life is disastrous, but most accidents, such as aeroplane and train crashes, are limited in the number of people involved. Conversely, natural disasters, such as earthquakes and tsunamis, leave in their wake massive destruction over large areas that can transcend national boundaries. All the apparatus of a society that responds to such disasters (the civil administration, emergency services, fire brigades and hospitals) may itself be involved and unable to respond (***Figure 33.1***). Large numbers of people may require immediate shelter, clean water and food, in addition to any medical needs.

A breakdown of communication is inevitable and can be accompanied by widespread panic and disruption of civil order. Access to the disaster area may be limited because of the destruction of bridges, affecting road and rail links.

Figure 33.1 Damage to emergency medical services.

Summary box 33.1

Common features of major disasters

- Massive casualties
- Damage to infrastructure
- A large number of people requiring shelter
- Panic and uncertainty among the population
- Limited access to the area
- Breakdown of communication

FACTORS INFLUENCING RELIEF EFFORTS AND PROVISION OF MEDICAL AID

Good communication is critical for the authorities to respond quickly to a disaster. Wireless technology and satellite imagery have revolutionised the way in which real-time information can be obtained (***Figure 33.2***). Nonetheless, there is an inevitable lag period between the occurrence of the disaster and the response from the establishment.

The location of the disaster area has a bearing on relief efforts. In large cities emergency and medical services are better developed. However, these areas are densely populated and

Figure 33.2 Satellite image showing destruction of a bridge as a result of flooding.

may have limited access by road and air. Disasters in remote areas can be particularly difficult to manage because relief efforts are hampered by geographical isolation and the lack of infrastructure.

The time frame in which a disaster occurs also impacts on the relief efforts. Earthquakes can unleash havoc in seconds but floods and hurricanes may continue for several days. Another important factor is the state of resources of the country; disasters in poorer countries can seldom be managed without significant outside assistance

Summary box 33.2

Factors influencing rescue and relief efforts

- Status of communications
- Location, whether rural or urban
- Accessibility of the location
- Time frame in which disaster occurs
- Economic state of development of the area

SEQUENCE OF RELIEF EFFORTS AFTER A DISASTER

Establishing a chain of command

Many countries have dedicated organisations that deal with disasters. In other countries, an administrative hierarchy is established to coordinate the teams participating in relief efforts (*Figure 33.3*).

Damage assessment

The first objective in disaster management is an assessment of the damage and the number of casualties. All sources of information must be employed. The 24-hour news services are frequently the first on the scene and can be an important source of information. Drones are now a quick and inexpensive option for a rapid view of a disaster area.

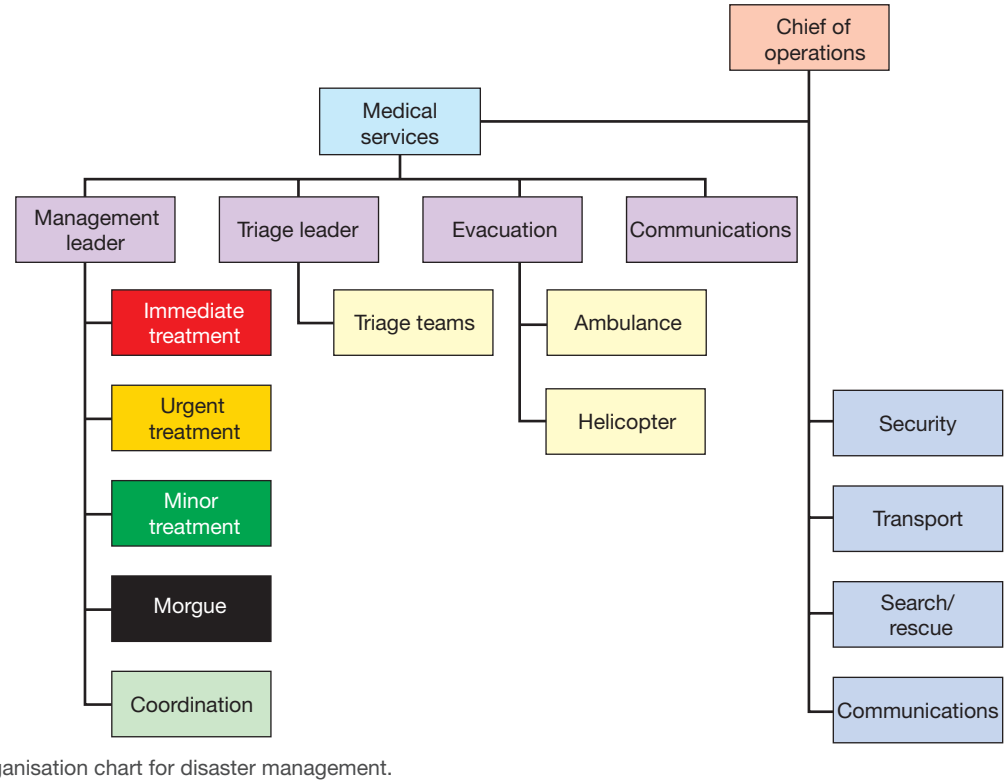

Figure 33.3 Organisation chart for disaster management.

Figure 33.4 Heli-evacuation.

Mobilising resources

The next step is mobilisation of human and material resources appropriate to the extent of the disaster. Although all modes of transport need to be considered, helicopters provide the quickest access for the first responders (*Figure 33.4*). The teams that make up the initial response must include experienced staff who can assess the situation and who have the authority to take immediate decisions.

Rescue operation

Early coordination of the rescue effort allows optimal use of resources. The first priority is to prevent further damage from occurring, both to people and to the infrastructure. The types of injuries encountered by rescue workers depend on the delay between the onset of the disaster and their arrival. Patients with head injuries and abdominal and thoracic trauma will either have been treated or have succumbed to their injuries within 48–72 hours of a disaster. After the first week, the only casualties requiring treatment are those with complex limb trauma and infected wounds (*Figure 33.5*).

Coordination with relief agencies

A laudable aspect of globalisation is the outpouring of help from governments and non-governmental organisations in response to a disaster. Some, such as Rescue And Preparedness In Disasters (RAPID), deal with search and rescue, whereas others, such as the International Committee of the Red Cross and Oxfam, provide general disaster-related relief (*Figure 33.6*). The various United Nations agencies deal with medical care, food provision and refugees. Coordinating the efforts of these organisations is essential for optimal results, as medical aid in isolation is inadequate without the simultaneous provision of safe drinking water, food, clothing and shelter.

Summary box 33.3

Sequence of the relief effort in major disasters

- Establish chain of command
- Set up lines of communication
- Carry out damage assessment
- Mobilise resources
- Initiate rescue operation
- Triage casualties
- Start emergency treatment
- Arrange evacuation
- Start definitive management

Dealing with the media

Disasters act like a magnet for the media. In today's world of 24-hour news coverage, this plays an important part in shaping public opinion. It is essential to establish a working relationship between the media and the rescue teams. With careful handling the media can become a powerful ally and play a constructive role in identifying problems, galvanising aid and keeping the public informed.

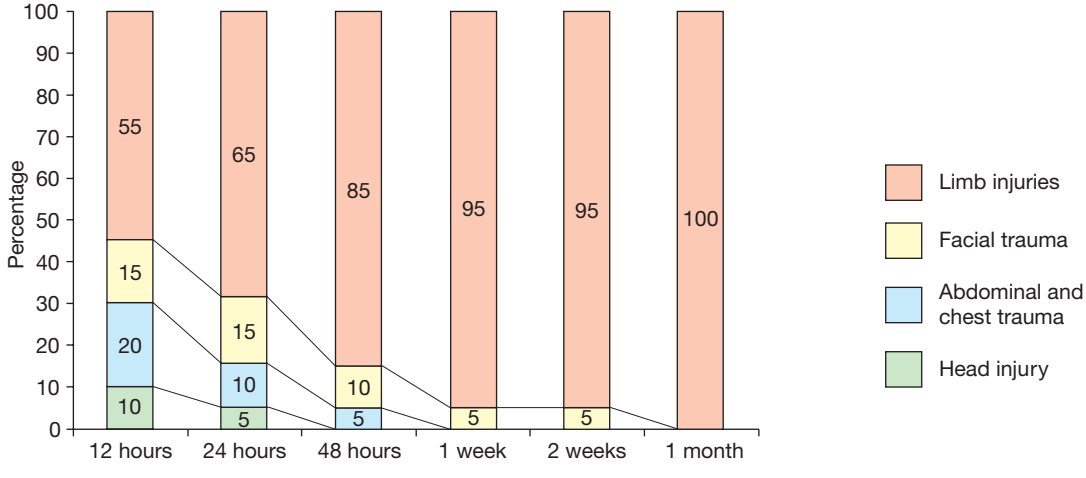

Figure 33.5 Time line showing the type of injuries encountered at different times in a disaster.

Figure 33.6 Oxfam and the International Committee of the Red Cross provide generalised relief.

Triage

Derived from the French verb *trier*, triage means 'to sort' and is the cornerstone of the management of mass casualties. It aims to identify those patients who will benefit the most by being treated the earliest, ensuring 'the greatest good for the greatest number'. Numerous studies show that only 10–15% of disaster casualties are serious enough to require hospitalisation. By sorting out the minor injuries, triage lessens the immediate burden on medical facilities. Deciding who receives priority when faced with hundreds of seriously injured victims is a daunting prospect. Triage should be undertaken by someone senior, who has the experience and authority to make these critical decisions. To keep pace with the changing clinical picture of an injured person, triage needs to be undertaken in the field, before evacuation and again at the hospital.

Triage areas

For efficient triage the injured need to be brought together into any undamaged structures that can shelter a large number of wounded. A good water supply, good lighting and ease of access are useful. Separate areas should be reserved for patient holding, emergency treatment and decontamination (in the event of discharge of hazardous materials).

Practical triage

Emergency life-saving measures should proceed alongside triage and can actually help the decision-making process. The assessment and restoration of airway, breathing and circulation are critical and are discussed in ***Chapter 27***. Vital signs and a general physical examination should be combined with a brief history, taken by a paramedic or by a volunteer worker if one is available.

Documentation for triage

Accurate documentation is an inseparable part of triage and should include basic patient data, vital signs with timing, brief details of injuries (preferably on a diagram) and treatment given. A system of colour-coded tags attached to the patient's wrist or around the neck should be employed by the emergency medical services. The colour denotes the degree of urgency with which a patient requires treatment (***Figure 33.7***).

Triage categories

All methods of triage use simple criteria based on vital signs. A rapid clinical assessment should be made taking into account the patient's ability to walk, their mental status and the presence or absence of ventilation or capillary perfusion. A commonly used four-tier system is presented in ***Table 33.1***.

Evacuation of casualties

Decisions regarding the best destination for each patient need to be based on how far it is safe for them to travel and whether the facilities that they need for definitive treatment will be available. A quick retriage is very useful in this situation. The paramedics accompanying the casualties should be committed to preventing a 'second accident' (damage caused inadvertently by transport and treatment). An adequate supply of essentials such as intravenous fluids, dressings, pain medication and oxygen must be arranged (see ***Chapter 34***).

TABLE 33.1 Triage categories.

Priority	Colour	Medical need	Clinical status	Examples
First (I)	Red	Immediate	Critical, but likely to survive if treatment given early	Severe facial trauma, tension pneumothorax, profuse external bleeding, haemothorax, flail chest, major intra-abdominal bleed, extradural haematomas
Second (II)	Yellow	Urgent	Critical, likely to survive if treatment given within hours	Compound fractures, degloving injuries, ruptured abdominal viscus, pelvic fractures, spinal injuries
Third (III)	Green	Non-urgent	Stable, likely to survive even if treatment is delayed for hours to days	Simple fractures, sprains, minor lacerations
Last (0)	Black	Unsalvageable	Not breathing, pulseless, so severely injured that no medical care is likely to help	Severe brain damage, very extensive burns, major disruption/loss of chest or abdominal wall structures

Triage is the earliest example of clinical risk management. This is done on the basis of need so that resources can be allocated by good prioritisation. The process was first used in 1792 by Baron Dominique Jean Larrey, Surgeon in Chief to Napoleon's Imperial Guard. The concept of triage emerged from the French Service de Santé des Armées so that resources could be used to the optimum – 'most for the most'.

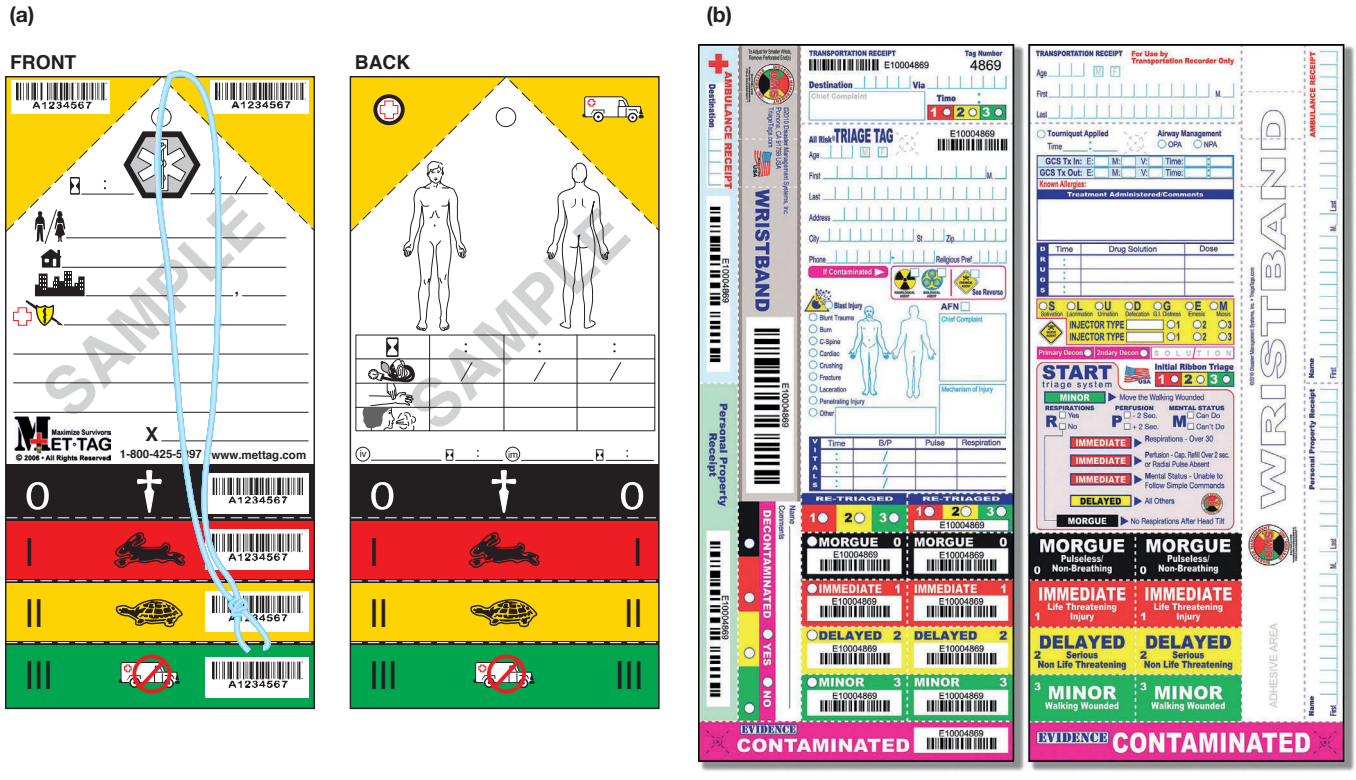

Figure 33.7 Triage tags (**(a)** courtesy of TACDA & METTAG products, The American Civil Defense Association; **(b)** courtesy of Disaster Management Systems).

Field hospitals

The decision to deploy field hospitals depends on the location, the number of casualties and the speed with which evacuation can be organised (***Figure 33.8***). Whether the traditional tented structure or the modular type, housed in containers, is employed, the facility must be equipped with radiograph capability, operating rooms, vital signs monitors, sterilising equipment, a blood bank, ventilators and basic laboratory facilities.

Management in the field

Field hospitals principally function in three main areas (***Table 33.2***).

Summary box 33.4

Essentials of casualty evacuation

- Retriage to upgrade priorities among the injured
- Select appropriate medical facilities for transfer
- Choose appropriate means of transport
- Prevent the 'second accident' during transfer
- Ensure an adequate supply of materials to accompany the patient

First aid

Care for patients with minor injuries involves cleaning and dressing wounds, suturing lacerations and splinting simple fractures. Most of these 'walking wounded' can be sent away with antibiotics and simple pain relief.

Damage control surgery

Damage control surgery (DCS) is the concept that only life- and limb-saving surgery should be performed in field hospitals to allow safe transfer of a patient to a definitive treating facility. This will include ensuring that the airway is secure, haemorrhage is under control and compartments are decompressed in the chest, skull, abdomen and the limbs. Devitalised tissue should be removed and any contamination prevented from developing into infection. DCS is explained in more detail, in the context of early management and other settings, throughout the chapters in Part 4.

Emergency care for immediate life-threatening injuries

There are many patients who may be saved by relatively simple measures, provided that these are taken urgently. Endotracheal intubation and tracheostomy may be needed to provide a secure airway. A needle thoracocentesis will relieve a tension pneumothorax and a chest drain will be needed before a patient with a significant chest injury is transferred by air. An open pneumothorax should be closed. Damaged major vessels

Figure 33.8 Field hospitals: **(a, b)** modular type; **(c)** tented structure; **(d)** interior of a tented field hospital.

TABLE 33.2 Type of treatment given in field hospitals.

	Examples	Further
First aid	Suturing cuts and lacerations, splinting simple fractures	Review at local hospital
Emergency care for life-threatening injuries	Endotracheal intubation, tracheostomy, relieving tension pneumothorax, stopping external haemorrhage, relieving an extradural haematoma, emergency thoracotomy/ laparotomy for internal haemorrhage	After damage control surgery, transfer patients to base hospitals once stable
Initial care for non-life-threatening injuries	Debridement of contaminated wounds, reduction of fractures and dislocations, application of external fixators, vascular repairs	Transfer patients to base hospitals for definitive management

to limbs should be repaired if possible. Fasciotomies will be needed for muscle compartments that are swelling from injury or from reperfusion. Amputation for clearly devitalised limbs and gas gangrene should be undertaken at field hospitals as delay will be fatal. Specific aspects of care are discussed in the relevant chapters elsewhere in this book.

Initial care for non-life-threatening injuries

Many patients sustain serious injuries that require prolonged care. These include compound limb fractures, degloving injuries, dislocations of major joints, major facial injuries and complex hand injuries. These patients will need specialised care requiring transfer to the appropriate facility. Replantations of amputated limbs and other extensive procedures should not

Summary box 33.5

Principles of DCS

- Do the minimum needed to allow safe transfer to a definitive facility
- Take actions that prevent deterioration of that patient during transfer
- Secure the airway – may require tracheostomy
- Control bleeding – may require craniotomy, laparotomy, thoracotomy, repair of major limb vessels
- Prevent pressure build-up – may require burr holes, chest drain, laparotomy, fasciotomy
- Prevent infection by extensile exposure and removing dead and contaminated tissue

be attempted in field hospitals as they are time-consuming and divert resources and personnel to the treatment of a few patients.

Debridement

Taken from the French, meaning to 'unleash or cut open', debridement plays a crucial part in the management of trauma. Wounds sustained in disasters are often heavily contaminated, containing foreign bodies and non-viable tissues (***Figure 33.9***). Debridement reduces the chances of anaerobic and necrotising infections and can prevent systemic sepsis. The following principles of debridement apply to all contaminated wounds:

- After the administration of anaesthesia, the injured area is copiously irrigated with normal saline. Lavage using a pressurised system is controversial, with concerns over tissue trauma and spread of debris (***Figure 33.10***). A water-jet based system that simultaneously clears the debris after debriding is very useful. The wound is palpated and all foreign matter removed. Dirt and debris enmeshed in soft tissues can only be removed by excision of those tissues. Open joints should be thoroughly irrigated and all foreign material removed.
- Wounds with extensive cavitation should be enlarged longitudinally to gain better access and allow full decompression of the underlying muscles. This should be carried out under tourniquet. This helps to visualise the damaged structures and allows the surgeon to gain proximal and distal control of vascular injuries and to identify severed ends of major nerves and tendons.
- The next step is excision of all dead and devitalised tissue. At this stage the tourniquet is let down to check the vascularity of the tissues. Skin excision is kept to a minimum and only the margins of the wound need be trimmed back to healthy bleeding edges. Excision of devitalised muscle should be undertaken generously. Muscle that is pale or dark in colour, that does not contract on pinching and that does not bleed on cutting must be removed. In patients with traumatic amputations, the bone ends are tidied, the skin and muscle edges trimmed to the lowest level possible and the wound left open.
- In patients with associated fractures, skeletal stabilisation should be obtained before embarking on any repairs. External fixators are invaluable for this and make wound management much easier (***Figure 33.11***).
- In the acute setting, only vascular repairs are justified. For lacerated vessels the ends are trimmed and an anastomosis performed. In the case of loss of substance of the vessel wall, a vein patch or reversed vein graft may be employed. Silicone tubing may be used as a temporary bypass (stent) while vascular repair is being carried out in patients with critically compromised distal circulation.
- Nerves and tendons should not be dissected out nor should any attempt be made at definitive repair in wounds with tissue devitalisation, as this leads to poor results. The key

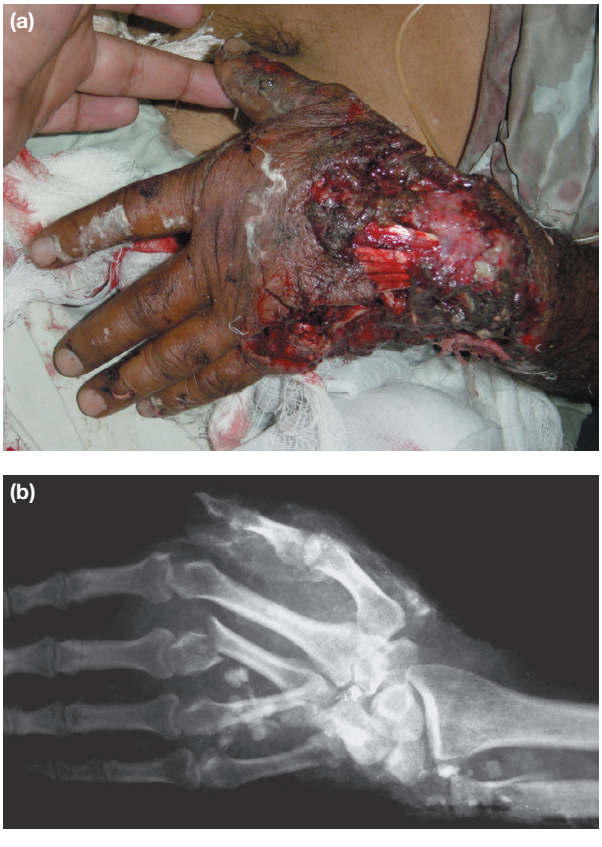

Figure 33.9 (a, b) Gross contamination typically seen in wounds sustained in disasters. The radiograph shows numerous radio-opaque foreign bodies in the soft tissues.

Figure 33.10 Lavage with normal saline to decontaminate a wound.

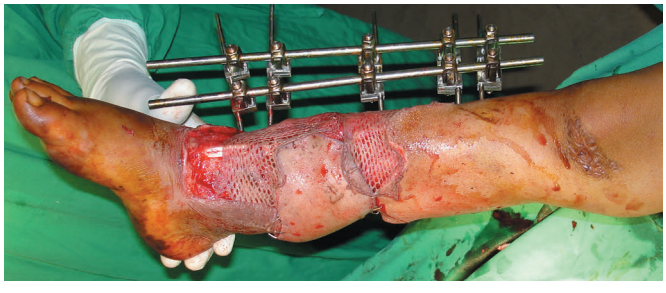

Figure 33.11 External fixators provide skeletal stabilisation and allow easy management of the soft tissues.

structures should be identified and the edges trimmed and tagged with non-absorbable sutures to facilitate repair during subsequent exploration.

- Wounds sustained in disasters are heavily contaminated and are not suitable for primary closure. However, blood vessels and exposed joint surfaces need to be covered. This can be achieved by loosely tacking adjoining muscle over the exposed area. The wound is then covered with fluffed gauze and sterile cotton and the extremity splinted with a plaster of Paris slab. For extremity injuries, elevation is critical to reduce oedema.
- Broad-spectrum antibiotics, such as third-generation cephalosporins, are started prophylactically and continued for 5–7 days.
- The wound is reinspected at 24–48 hours to assess the viability of the tissues. Wounds are closed between the fourth and sixth day if there is no infection. Tension should be avoided and one should not hesitate to use skin grafts to obtain cover.
- In wounds with gross infection no attempt at closure is made until infection is eradicated. These wounds are re-explored to make sure that there are no residual foreign bodies or devitalised tissue. Tissue should be taken for microbiological culture. Vacuum-assisted closure (Vac-Pac) has emerged as a very useful tool for deeply cavitating wounds. It utilises low-pressure suction to evacuate exudate, promote granulation tissue and reduce the size of the wound (***Figure 33.12***). Once the wounds are free from infection secondary closure can be undertaken.

Figure 33.12 (a, b) Use of low-pressure vacuum therapy in preparing a wound for secondary closure.

DEFINITIVE MANAGEMENT

The hospitals designated to undertake definitive management should be selected on the basis of the facilities available and the number of injured that they can handle. The resources required for trauma patients are more than the typical case mix of a hospital. A rule of thumb is that only half the bed strength of a hospital can be utilised to provide optimum trauma care in an emergency situation.

Hospital reorganisation

In hospitals receiving mass casualties some reorganisation of services is unavoidable. This includes transferring patients with non-urgent conditions to other facilities, augmenting surgical services, reorganising the specialist rota and redesignating medical wards as surgical care areas. An appeal for blood donations should be broadcast.

SPECIFIC ISSUES

There is no injury that is peculiar to disasters and the whole spectrum of external injuries from minor cuts and compound fractures to amputations is seen. Internal organ damage is frequent and, unless immediate help is available, this accounts for the majority of early mortality figures. People trapped under fallen buildings may suffer crush injuries and crush syndrome if the duration is prolonged. Crush injuries and missile injuries cause extensive tissue damage and gross contamination, both favourable conditions for anaerobic and microaerophilic infections.

Summary box 33.6

Principles of debridement and initial wound care

- Obtain generous exposure through skin and fascia
- Identify neurovascular bundles
- Excise devitalised tissue
- Remove foreign bodies
- Repair major vessels
- Obtain skeletal stabilisation with external fixators
- Only tag tendons and nerves that have been cut
- Leave the wound open and delay primary closure
- Avoid tight dressings
- Elevate the injured limb

Limb salvage

The Mangled Extremity Severity Score (MESS) and its modifications are useful in deciding about limb salvage. Extensive tissue loss, neurovascular damage and loss of long fragments of bone are traditionally indications for amputation. Currently, wounds of any dimension can be covered with microvascular flaps and distraction osteogenesis and vascularised bone can be used to restore bony continuity. If performed in time, vascular repairs can salvage most acutely ischaemic limbs. Because of these developments the indications for amputation in trauma have undergone a paradigm shift and the majority of patients who reach a tertiary-care facility within 24 hours are candidates for limb salvage (***Figure 33.13***). This assumes

Plaster of Paris is a white crystalline powder, calcium sulphate hemihydrate $CaSO_4 \cdot 0.5H_2O$, which sets hard when water is added to it.

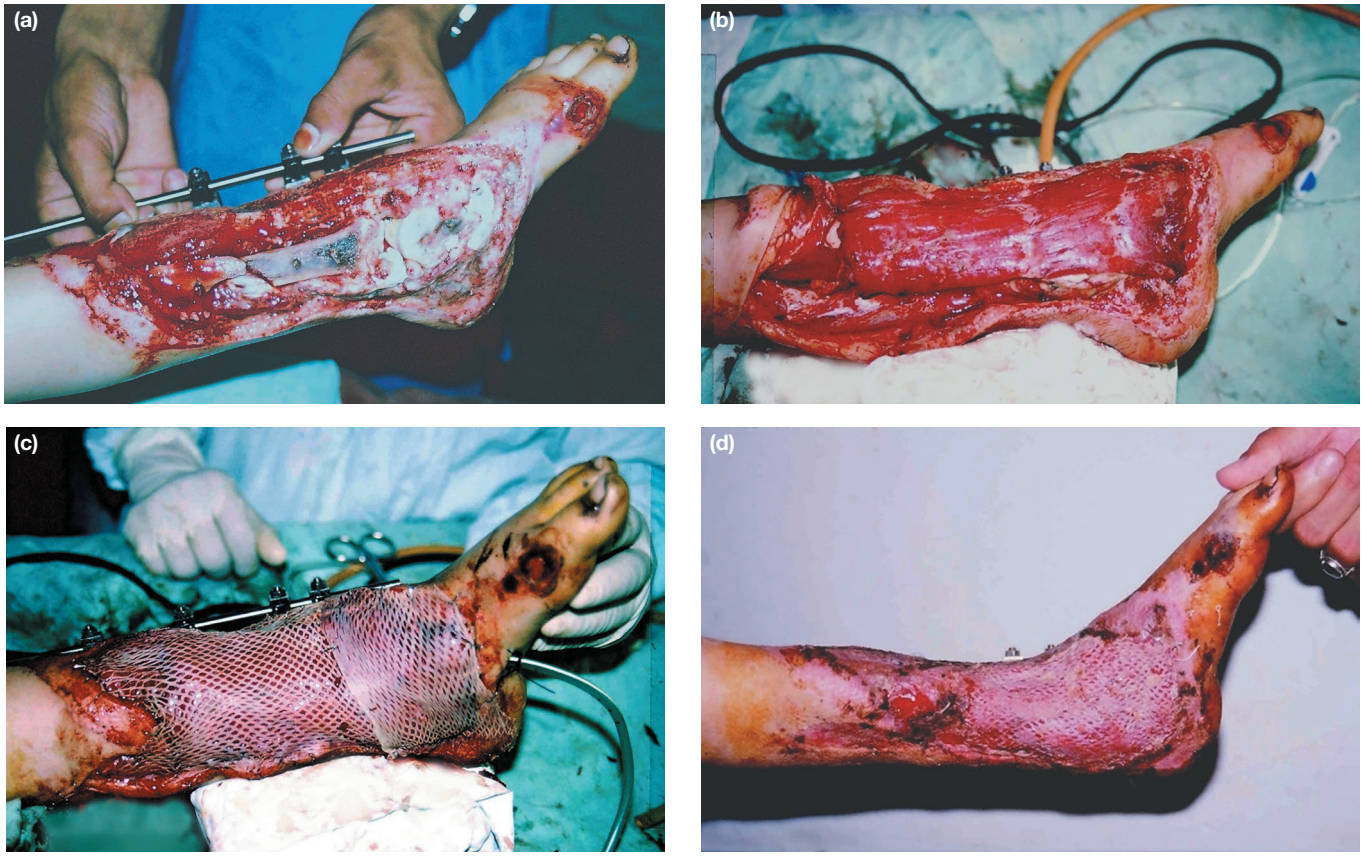

Figure 33.13 (a–d) Badly traumatised lower limb. Reconstruction has been performed using a microvascular rectus abdominis flap covered with a skin graft.

that debridement and, if required, vascular repairs have been performed in a field medical facility. A limb is unlikely to survive if the vascular repair of major limb vessels has been delayed for more than 4–6 hours.

Facial injuries

The management of facial injuries follows the same general principles of debridement and delayed closure as already outlined. Because of the functional and cosmetic importance of facial structures, skin and soft-tissue excisions are kept to a minimum. The face has a robust vascularity and a high ability to counter infection. Even in patients who present late with gross contamination, careful debridement followed by delayed primary closure can lead to good results (***Figure 33.14***).

Tetanus

This potentially fatal condition, also called 'lockjaw', is caused by *Clostridium tetani*, a Gram-positive spore-forming bacillus occurring naturally in the intestines of humans and in the soil. It enters the body through a wound and replicates, thriving on the anaerobic conditions present in devitalised tissues. It produces tetanospasmin, an exotoxin that binds to the neuromuscular junctions of the central nervous system neurones, rendering them incapable of neurotransmitter release. This leads to failure of inhibition of motor reflex responses to sensory stimulation and generalised contractions of agonist and antagonist muscles produce tetanic spasms. The median incubation period is 7 days, ranging from 4 to 14 days.

Early symptoms are painful spasms of the facial muscles, resulting in risus sardonicus (***Figure 33.15***). The spasms spread to involve the respiratory and laryngeal musculature. Spasms of the paravertebral and extensor limb musculature produce opisthotonus, an arching of the whole body. Laryngeal muscle spasm leads to apnoea and, if prolonged, to asphyxia and respiratory arrest. The spasms can be brought on by the slightest of sensory stimulus.

The diagnosis is obvious once it is fully manifest. There are three aspects of management:

- **Prevention**. Wounds contaminated with soil can harbour tetanus spores, and active immunisation is indicated by administering 0.5 mL of tetanus toxoid intramuscularly. Patients with gross contamination of cavitating wounds should also receive 250–500 U of human anti-tetanus globulin (ATG) intramuscularly to provide passive immunisation and to neutralise the circulating toxin. In full-blown

Hans Christian Joachim Gram, 1853–1938, Professor of Pharmacology (1891–1900) and of Medicine (1900–1923), Copenhagen, Denmark, described this method of staining bacteria in 1884.

Figure 33.14 (a–d) Late-presenting facial injury with gross contamination. A thorough debridement followed by delayed primary closure has yielded good results.

Figure 33.15 Risus sardonicus of 'lockjaw' (courtesy of Dr Samira Ajmal, FRCS).

clinical tetanus, 3000–10 000 U of ATG should be administered. Wound manipulation should be avoided for 2–3 hours after ATG administration to minimise tetanospasmin release.

- **Local wound care**. This includes a thorough wound debridement to eliminate the anaerobic environment. Intravenous administration of 10–24 × 10^6 U per day of penicillin G should be continued for 10–14 days. The wound should be closed using the delayed primary or secondary closure techniques.
- **Supportive care for established disease**. These patients are nursed in an intensive care unit (ICU) environment, free from strong sensory stimuli. Diazepam is useful in preventing the onset of spasms but, if these become sustained, the patient is paralysed, intubated and placed on a ventilator. The patient is then gradually weaned off the ventilator under cover of anticonvulsants. The overall mortality rate is around 45%, prognosis being determined

by the incubation period and the time from the first symptom to the first tetanic spasm. In general, shorter intervals indicate a poorer prognosis. Recently, intrathecal antitoxin administration has been used for spasm control to avoid ventilatory support. Nevertheless, without access to mechanical ventilation the mortality remains high and even those who survive may require several weeks of hospitalisation.

Summary box 33.7

Tetanus

- Caused by *C. tetani*
- Spores are present in the soil
- Thrives in dead or contaminated tissue
- Produces tetanospasmin, an exotoxin
- Produces spasm of muscles
- Make sure patients are immunised
- For heavily contaminated wounds give ATG

Necrotising fasciitis

Necrotising fasciitis is a rapidly spreading infection that produces necrosis of the subcutaneous tissues and overlying skin. It is caused by β-haemolytic streptococci and, occasionally, *Staphylococcus aureus*, but may take the form of a polymicrobial infection associated with other aerobic and anaerobic pathogens, including *Bacteroides*, *Clostridium*, *Proteus*, *Pseudomonas* and *Klebsiella*. It is termed Fournier's gangrene when it affects the perineal area and Meleney's gangrene when it involves the abdominal wall. The underlying pathology includes acute inflammatory infiltrate, extensive necrosis, oedema and thrombosis of the microvasculature. The area becomes oedematous, painful and very tender. The skin turns dusky blue and black secondary to the progressive underlying thrombosis and necrosis (***Figure 33.16***). The area may develop bullae and progress to overt cutaneous gangrene. It spreads contiguously but occasionally produces skip lesions that later coalesce. It is accompanied by fever and severe toxicity. Renal failure may occur as a result of hypovolaemia and cardiovascular collapse caused by septic shock. The rate of progression is dramatic and unless aggressively treated it leads to serious consequences with mortality approaching 70%.

The diagnosis is made on clinical grounds. Creatinine kinase levels may show enormous elevation and biopsy of the fascial layers will confirm the diagnosis. Patients should be admitted to the ICU and treated with careful monitoring of volume derangements and cardiac status. Oxygen supplementation is beneficial and endotracheal intubation is required in patients unable to maintain their airway.

High-dose penicillin G along with broad-spectrum antibiotics, such as third-generation cephalosporins and metronidazole, are given intravenously. The cornerstone of management is surgical excision of the necrotic tissue. The devitalised tissue is removed generously, going beyond the area of induration. The wound is lightly packed with gauze and dressed.

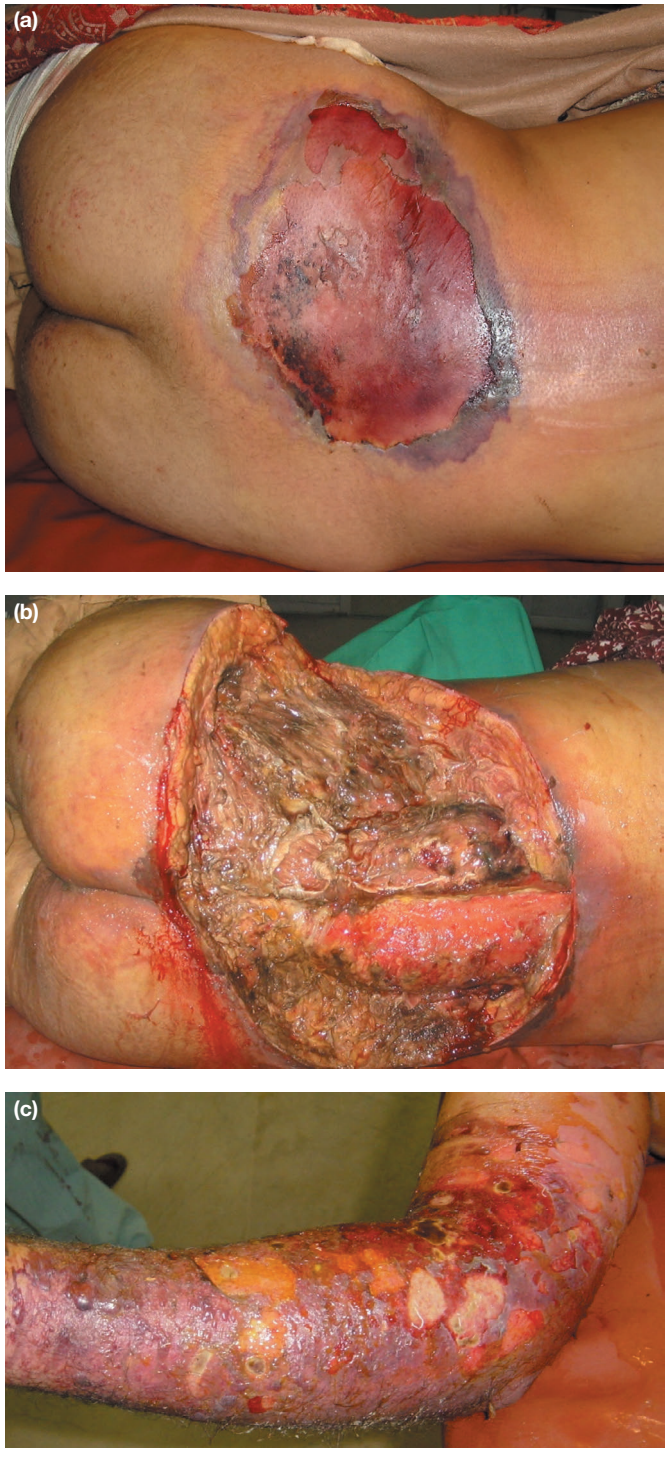

Figure 33.16 (a) Necrotising fasciitis at presentation and **(b)** rapid progression seen after 24 hours. **(c)** Typical bullae and induration.

Theodor Albrecht Edwin Klebs, 1834–1913, Professor of Bacteriology, successively at Prague, Czechoslovakia; Zurich, Switzerland; and then the Rush Medical College, Chicago, IL, USA.
Jean Alfred Fournier, 1832–1915, syphilologist, the Founder of the Venereal and Dermatological Clinic, Hôpital St Louis, Paris, France.
Frank Lamont Meleney, 1889–1963, Professor of Clinical Surgery, Columbia University, New York, NY, USA.

This process is repeated daily as the necrosis is prone to spread beyond the edges of the excised wound. In patients who survive, this results in a large wound, which will require skin grafting or flap coverage.

Summary box 33.8

Necrotising fasciitis

- Caused by β-haemolytic *Streptococcus* or is polymicrobial
- Also called Fournier's or Meleney's gangrene
- Progress is rapid and renal failure is an early complication
- Treat with radical surgical excision repeated every 24 hours
- Give oxygen and penicillin

Recently, the role of hyperbaric oxygen (HBO) has become more established with a reduction in mortality in patients treated with HBO (9–20%) compared with patients who did not receive HBO (30–50%).

Gas gangrene (clostridial myonecrosis)

Gas gangrene is a dreaded consequence of late-presenting missile wounds and crushing injuries. It is a rapidly progressive, potentially fatal condition characterised by widespread necrosis of the muscles and soft-tissue destruction. The common causative organism is *Clostridium perfringens*, a spore-forming, Gram-positive saprophyte that flourishes in anaerobic conditions. Other organisms implicated in gas gangrene include *Clostridium bifermentans*, *Clostridium septicum* and *Clostridium sporogenes*. Non-clostridial gas-producing organisms such as coliforms have also been isolated in 60–85% of cases of gas gangrene.

C. perfringens produces many exotoxins but their exact role is unclear. Alpha-toxin, the most important, is a lecithinase that destroys red and white blood cells, platelets, fibroblasts and muscle cells. The phi-toxin produces myocardial suppression while the kappa-toxin is responsible for the destruction of connective tissue and blood vessels.

Devitalised tissue or premature wound closure provides the anaerobic conditions necessary for spore germination. The usual incubation period is <24 hours but ranges from 1 hour to 6 weeks. A vicious cycle of tissue destruction is initiated by rapidly multiplying bacteria and locally and systemically acting exotoxins. This causes spreading necrosis of muscle and thrombosis of blood vessels. The typical feature of this condition is the production of gas that spreads along the muscle planes. Systemically, the exotoxins cause severe haemolysis and, combined with the local effects, this leads to the rapid progression of the disease, hypotension, shock, acute kidney injury and acute respiratory distress syndrome.

Pain that rapidly increases in severity is the earliest symptom. The limb swells up and the wound exudes a serosanguineous discharge. The skin is involved secondary to muscle necrosis, turning brown and progressing to a blue–black colour with haemorrhagic bullae (***Figure 33.17***). The characteristic sickly sweet odour and soft-tissue crepitus appear with established infection but their absence does not exclude the diagnosis.

Figure 33.17 Typical picture of spreading gas gangrene caused by a crush injury.

These local signs are accompanied by pyrexia, tachycardia, tachypnoea and altered mental status.

The diagnosis is made on the basis of history and clinical features. A peripheral blood smear may suggest haemolysis and a Gram stain of the exudate reveals large Gram-positive bacilli without neutrophils. The biochemical profile may show metabolic acidosis and renal failure. Radiography can visualise gas in the soft tissues and is particularly useful in patients with chest and abdominal involvement.

Patients should be admitted to the ICU and treated aggressively with careful monitoring. High-dose penicillin G and clindamycin, along with third-generation cephalosporins, should be given intravenously. Surgical treatment is the same as for necrotising fasciitis (see ***Necrotising fasciitis***). In established gas gangrene with systemic toxicity, amputation of the involved extremity is life-saving and should not be delayed. No attempt is made at closure; amputation stumps are left open and the wound is lightly packed with saline-soaked gauze and then dressed.

The role of HBO is not as clear as in necrotising fasciitis. However, considering the frequent catastrophic outcomes, it is recommended in severe cases if the facilities are available.

Summary box 33.9

Gas gangrene

- Caused by *C. perfringens*
- Spores are present in the soil
- Thrives in anaerobic conditions and produces many exotoxins
- Treat with radical and regular surgical excision
- Give oxygen and penicillin
- Early amputation may be life-saving

Crush injury and syndrome

A crush injury occurs when a body part is subjected to a high degree of force or pressure, usually after being squeezed between two heavy or immobile objects. Damage related to a crush injury includes lacerations, fractures, bleeding, bruising, compartment syndrome and crush syndrome (***Figure 33.18***).

Figure 33.18 (a–c) Extensive crush injury in a man trapped in a fallen house. The depth to which the soft tissues have been devitalised is seen clearly.

Crush syndrome

The association between crush injury, rhabdomyolysis and acute kidney injury was first reported in victims trapped during the 'London Blitz'. It is seen in earthquake and mining accident survivors and in battlefield casualties. Prolonged crushing of muscle leads to a reperfusion injury when the casualty is rescued. This releases myoglobin and vasoactive mediators into the circulation. It also sequesters many litres of fluid, reducing the intravascular volume and resulting in renal vasoconstriction and ischaemia. The myoglobinuria leads to renal failure from tubular obstruction.

The treatment of crushed casualties should begin as soon as they are discovered. Rescuers must be alert to the presence of associated injuries (***Figure 33.19***). Aggressive volume-loading of patients, preferably before extrication, is the best treatment. After provision of first aid and starting intravenous fluids the patient should be catheterised to measure urine output. In adults, a saline infusion of 1000–1500 mL/h should be initiated. This should be continued until myoglobin is no longer detectable in the urine. Mannitol administration can reduce the reperfusion component of this injury. Once a flow of urine is observed, a mannitol–alkaline diuresis of up to 8 litres per day should be maintained, keeping the urinary pH greater than 6.5. An early fasciotomy can decompress muscle compartments and prevent severe loss of limb function. A late fasciotomy, when it is obvious that the muscles of that compartment must be dead, is only likely to cause a massive release of myoglobin, as well as potentially introducing infection into dead tissue. It is therefore best not to perform a fasciotomy in cases where entrapment has been for over 12 hours. Intensive care is required with close attention to fluid balance and renal dialysis if required.

Figure 33.19 Rescuers must be prepared for injuries to the spine. Treatment of crush syndrome should start before extrication.

The **London Blitz** is the name given to the German air raids on London between 7 September 1940 and 17 May 1941, during which it is estimated that more than 15 000 people were killed. Blitz is short for *Blitzkrieg*, which is German for 'lightning war'.

Summary box 33.10

Crush syndrome

- Arises as a result of reperfusion
- Acute kidney injury and renal failure from myoglobinuria is a complication
- A late fasciotomy may make things worse not better

Compartment syndrome

A compartment syndrome develops when the pressure within a muscle compartment starts to rise as a result of trauma (see ***Chapter 32***). This occurs in muscles enclosed in a fascia such as the calf and forearm muscles and the intrinsic muscles of the hand and foot. A tight bandage or plaster, haemorrhage from a fracture or severe blunt trauma leads to a rise in pressure in the compartment until it exceeds venous drainage pressure. If the pressure rises further, it will cut off perfusion of the muscle. Passive stretching of the affected muscle will cause extreme pain and this is diagnostic of the condition. If the condition is left unrelieved, then nerves passing through the compartment will cease to function and the muscle will die and then undergo fibrosis and shortening, producing a Volkmann's ischaemic contracture. Removal of any constricting agent and, if necessary, a fasciotomy will relieve the pressure and muscle perfusion will restart. Pressure studies are not reliable; if in doubt, perform a fasciotomy.

Summary box 33.11

Compartment syndrome

- Commonest in a closed fracture or soft-tissue crush injury
- Pain on passive extension of the muscles is diagnostic
- Intracompartmental pressure studies are not reliable
- If there is any suspicion, then fasciotomy must be performed early

Frostbite and immersion injuries (trench foot)

Frostbite occurs when a part of the body freezes. The cells are disrupted and the tissue dies. It is in effect a 'cold' burn and can be categorised according to the depth that it affects in the same way as a conventional burn. Other mechanisms at play include vasoconstriction caused by cold, capillary sludging and reperfusion injury with the release of free radicals, which occurs on rewarming the part. It commonly involves the fingers, toes, cheeks, the tip of the nose and the ears. When frozen the tissue feels hard and cannot be indented. Immersion injury is a cold injury that does not involve actual freezing of the tissue and is commonly caused by prolonged immersion in cold water (hence trench foot). The patient may also be hypothermic. Warming should be gentle as the heat used may actually cause a burn! Rehydration with warm fluids and use of non-steroidal anti-inflammatory drugs such as ibuprofen are beneficial. Demarcation will occur between dead and viable tissue and at this stage no surgery should be undertaken as there is often considerable deep recovery. The injured area should be kept clean and dry and efforts made to prevent further injury, as well as to prevent infection. Definitive surgery to excise dead tissue can be left for many months. Recent developments, such as the use of tissue plasminogen activator and nerve blocks, show promising results in reducing amputations, but have to be started within 24 hours and are seldom possible in the field.

Summary box 33.12

Frostbite

- Can be superficial or deep like a burn
- Rewarm gently
- Allow demarcation to occur naturally
- Protect against further trauma and infection

HANDING OVER

Follow-up and secondary problems

The medical aspect of disaster management does not involve a single short-term effort. It requires a long-term commitment and involvement of various disciplines. Because of the large numbers of casualties, the initial treatment is directed towards the anatomical restoration of damaged structures. There are therefore numerous patients who will need secondary procedures for functional restoration. This second wave of patients is encountered 3–6 months after a major catastrophe and arrangements should be made to deal with this.

Designated centres

Initially, the casualties may be scattered among many hospitals. After the first few weeks most of the acute problems have been dealt with and only those patients who require longer term treatment remain. At this point it is advisable to designate a particular hospital as a centre for these patients. This concentrates resources and expertise and makes follow-up easier.

DISASTER PLANS

Disasters are unforeseen events and planning for them may seem paradoxical. It has, however, been shown that disaster planning not only works but also saves lives. Disaster planning is a wide field but a résumé of the important aspects follows.

Establishment of a national disaster management organisation

This is the first step in the planning for disasters. Most resource-rich countries already have such an agency, which can formulate policy at the national level and has the infrastructure to react quickly when the need arises.

Richard von Volkmann, 1830–1889, Professor of Surgery, Halle, Germany.

Anticipating disasters

Areas near active volcanoes and geological fault lines are at risk from seismic disturbances, whereas regions along major rivers are liable to flooding. The urban centres of all countries are now potential targets for terrorist attacks. It is important to not only carry out threat assessments but also, if possible, set up an early warning system.

Evacuation planning

Evacuation of large population centres as a prelude to, or in the wake of, an impending disaster is a complex exercise. Yet it may be the most prudent course of action to remove as many people as possible from harm's way. Clear identification of exit routes must be determined and communicated to the populations at risk.

Organisation of emergency services

Emergency services such as the fire brigade, police and ambulance service must have defined roles and areas of responsibility to ensure a coordinated response during a crisis. Members of these teams must be included in the planning phase to ensure that the final plan is practicable and reflects the situation on the ground.

Summary box 33.13

Disaster planning

- Disaster can be anticipated and should be prepared for
- Evacuation of a whole population may be the best option
- Coordination between military, police, fire, ambulance and medical services is important

Medical planning

Identification of hospitals able to take large numbers of casualties and the location of areas that can be used for patient holding and triage in case of mass casualties is important. Hospitals that offer specialised services should be identified and their role during a major crisis defined. Suitable hospitals in the surrounding areas must be designated as overflow hospitals in the eventuality of a very large volume of patients.

CHAPTER 34

Conflict surgery

Learning objectives

To understand and appreciate:

- Fundamental differences of war surgery
- Injury patterns of modern warfare
- Principles of war surgical management
- Blast and ballistic injury

INTRODUCTION

> He who wishes to be a surgeon must first go to war.
>
> Hippocrates (*c*.460–377 BCE)

The treatment of war wounds is as ancient as warfare itself. The Edwin Smith papyrus has been dated to 1600 BCE and is the oldest known treatise on trauma surgery and anatomy.[1] The history of battlefield surgery is the history of surgical advancement and the importance of the medical lessons learned from war have long been recognised.

While almost every conflict has served to increase our knowledge of the treatment of war injuries, and many individuals have played significant parts in the development of war surgery, Dominque Jean Larrey is considered by many to be the first modern military surgeon. Larrey, a French battlefield surgeon and favourite of Napoleon, devised some of the first systems of triage and casualty care that still form the fundamentals of modern military medicine. These systems must be in place in order to overcome the difficulties and logistical challenges of providing medical care to a battlefield.

HOW IS WAR SURGERY DIFFERENT?

While civilian trauma surgery bears some of the hallmarks of the battlefield, there are fundamental contrasts in environment and injury pattern that must be appreciated:

- The environment of war is likely to be austere. While recent long-term deployment has led to the establishment of some well-equipped field hospitals, logistical and personnel restrictions mean that sophisticated diagnostic and therapeutic techniques may not be available.
- War is hostile and potentially dangerous. Necessary workforce protection must be considered to ensure the safety of medical personnel and patients alike. Modern fighting forces employ physician-led resuscitation, along with forward surgical teams. Moving medical personnel closer to the fighting may increase their personal risk.
- War injuries are different from civilian trauma. Modern weapons may deliver such amounts of energy that the tissue destruction and patterns of injury seen are unlike all but the most extreme of civilian trauma.
- War is a mass casualty situation. Although casualty numbers vary between treatment facilities, triage is an important aspect of military surgery. The dictum 'do the best for the most, not everything for everyone' is important and may require a change in thinking for many used to civilian practice.
- War surgery is usually delivered in stages. The principles of damage control are often applied to allow transfer of patients between echelons of care. Careful planning, coordination and communication are essential.

ETHICAL AND LEGAL CONSIDERATIONS

International Humanitarian Law (IHL) regulates humanitarian issues during armed conflict. Modern IHL is derived from a variety of sources, notably the Geneva Conventions and their additional protocols, along with further specific regulations from the United Nations and The Hague Conventions. IHL provides medical personnel with rights in times of armed war, but also assigns duties to them surrounding the rights of protected personnel under their care.

Importantly, medical personnel are bound by medical ethics and IHL to treat patients solely based on need and without regard for their nationality, race and class or their religious or political beliefs.

Along with providing medical support to deployed forces, treatment is offered to both home nation and enemy combatants. The treatment of such patients may require a change in the approach to their definitive care. Evacuation of these

The papyrus is named after Edwin Smith, the Egyptologist who discovered it in 1866; it is held at the New York Academy of Medicine, NY, USA.
Dominique Jean Larrey, 1766–1842, French surgeon in Napoleon's Grand Armée.

personnel to certain categories of subsequent facility (see *Medical support roles*) may not be possible and the staged approach to care may need modification. Transfer to host nation medical facilities may be possible but dependent on local capability.

This scenario may require an adaptation to clinical thinking. As an example, consider the ethical and logistical dilemma in performing revascularisation and orthoplastic procedures for a local patient in a country without rehabilitation facilities.

Medical personnel and facilities are protected under IHL and should not be attacked. However, the nature of modern conflict is unconventional; guerrilla warfare and the inability of deployed forces to define the enemy combatant requires the security of facilities and personnel to be of the highest priority.

MEDICAL SUPPORT ROLES

The term 'role' is used to designate the tiers of medical support that integrate into a modern military operation.[2] An appreciation of the capabilities and limitations of these roles is essential to improving the care of casualties at each stage. Different nations and forces will have medical support configured with some variability but, overall, systems are similar in order to ensure that the basic treatment, supply and evacuation needs that are essential for a military operation are available.

- **Role 1** medical support provides for routine primary health care, specialised first aid, triage, resuscitation and stabilisation. It is integrated within a small unit. The capabilities of role 1 care will depend greatly on the size of the unit and the training of the personnel within it.
- **Role 2** provides an intermediate capability for the reception and triage of casualties, as well as being able to perform resuscitation and treatment of shock to a higher technical level than role 1. It is prepared to provide evacuation from role 1 facilities. It has capability for damage control surgery (DCS) and may include a limited holding facility for the short-term holding of casualties until they can return to duty or be evacuated.
- **Role 3** medical support is deployed hospital care and the elements required to support it. This includes a mission-tailored variety of clinical specialties, including primary surgery and diagnostic support. In recent conflicts role 3 facilities grew and evolved into sophisticated hard-built hospitals.
- **Role 4** provides the full spectrum of definitive medical care that cannot be deployed to the area of operations or is too time-consuming to be conducted there. It is normally provided in the country of origin or an allied nation depending on the location of deployment and time-lines of transfer.

It is important to appreciate that these roles are highly variable both within and between different nations. The size and scale of the operations as a whole, along with predictions of both civilian and military medical requirements, will dictate the structure of the medical support.

Summary box 34.1

Medical support roles

- R1– unit-level medical care including first aid and primary health care
- R2 – intermediate unit for resuscitation, damage control and stabilisation
- R3 – deployed hospital care with multispecialty capability
- R4 – definitive hospital care within the home or allied nation

MEDICAL EVACUATION

Medical evacuation refers to the movement and en route care of casualties within a conflict zone. The evacuation may be the initial movement from a battlefield or between other more sophisticated echelons of care, up to and including repatriation to a home nation.

Aeromedical evacuation using either fixed or rotary wing aircraft has had a major impact on evacuation timelines. Certain considerations must be made prior to and during aeromedical evacuation:

- the patient should be sufficiently stabilised for the anticipated mode and duration of travel;
- the patient's airway and breathing are adequate for movement;
- intravenous access, surgical drains, urinary catheters and any other tubes should be firmly secured;
- patients at high risk for thoracic barotrauma should be considered for prophylactic chest tube placement before prolonged aeromedical evacuation;
- blankets and/or warmers should cover the patient securely to mitigate against hypothermia.

The capability of different evacuation platforms may vary from highly sophisticated mobile critical care units to the simple transportation of casualties by non-medical personnel. These capabilities, along with the timelines and distances involved in casualty movement, should be major considerations for the planning of medical support operations.

The 'golden hour' is an oft-quoted principle in trauma medicine and refers to the initial time period following injury during which a life is most likely lost or saved. Although the origins and applicability of the term are disputed,[3] the principle is ubiquitously understood. Within the military setting, death is certainly seen to occur most commonly within the prehospital environment and within a short period after injury, with better outcomes seen after rapid transport to surgical care.[4]

Improvement in outcomes from severe deployed trauma may rely upon either the shortening of time to damage control care or lengthening of the 'golden hour'. Shortening of timelines may be achieved with change in transport systems or deployment of surgical teams further 'forward', or even the use of telemedical technology to utilise remote expertise. Lengthening of the golden hour may perhaps be achieved by the use of novel prehospital haemorrhage control techniques or an increase in the availability of prehospital blood products.[5–8]

PATTERNS OF MODERN WAR SURGERY

Modern warfare has changed over recent decades. The causes of injury are particular to the individual conflict, nation and armed service.[9] Historically, penetrating trauma was predominantly sustained by combat infantry, whereas naval and air personnel sustained more blunt injuries (*Table 34.1*).

Improvements in trauma scoring systems and the development of a concise system for the recording of injuries and casualty care have increased the ability of modern armed services to analyse the injury patterns of their deployed personnel.

TABLE 34.1 Historical causes of injury among US service personnel.

	Service			
Mechanism	Infantry (%)	Armoured (%)	Sea (%)	Air (%)
Ballistic	90	50	25	5
Blunt	2–3	5	10	50
Blast	2–3	5	10	<10
Thermal	2–3	25	30	25
Combined	<5	15	25	10

Adapted from Champion *et al*.[9]

A cohort analysis of combat injuries incurred by US forces[10] showed significant differences in injury patterns sustained in the most recent Afghanistan and Iraq conflicts compared with those sustained in the Second World War and the Korean and Vietnamese Wars. Head and neck injuries were far more common in recent conflict whereas thoracic and extremity injuries were less so. This is probably because of the increased use of body armour and similar personnel protective equipment in more recent conflicts.

The mechanism of injury has also changed. Although ballistic injuries remain an important contributor to battlefield trauma, injuries due to explosions (which include improvised explosive devices [IEDs], landmines, mortars, grenades and rockets) have become increasingly common and are now the predominant mode of wounding and fatality. The relative proportions of injuries caused by explosive and ballistic weapons are shown in *Table 34.2*.

The emergence of explosive patterns of injury is due to the increasing use of IEDs within conflicts. IEDs have been the signature weapon within operations in Afghanistan and Iraq; however, their use has not been limited to these regions. The relative low cost, ease of production and widespread expertise means that IEDs are likely to play significant roles in most contemporary and future conflicts.

PRINCIPLES OF WAR SURGERY

Battlefield death occurs early (or immediately) because of devastating central nervous system injury and haemorrhage, or late because of infection. Some of the injuries causing immediate death (including brain, heart and great vessel injury) are non-survivable[11] and may only be managed with prevention.

TABLE 34.2 Relative proportion of injuries caused by gunshot wounds and explosions among US personnel.

	Gunshot (% of total injuries)	Explosion (% of total injuries)
US Civil War	91	9
First World War	65	35
Second World War	27	73
Korean War	31	69
Vietnamese War	35	65
Iraq/Afghanistan War	19	81

Adapted from Owens *et al*.[10]

Treatment of haemorrhage is therefore the mainstay of military trauma medicine. Bleeding should be recognised and managed from the point of wounding.[12] Tourniquets are indicated for the control of catastrophic extremity bleeding. Non-compressible torso haemorrhage carries a poor prognosis,[13] although it may be amenable to methods of endovascular control not yet commonly used.[14]

A damage control approach to surgery must be employed to stop bleeding, to remove necrotic tissue and foreign material and to reduce contamination. In addition to life-saving surgery, procedures to salvage limbs, including revascularisation (or temporary shunting) and fasciotomy, should be considered early, when physiology allows.

DAMAGE CONTROL SURGERY

DCS was first described by Rotondo *et al*.,[15] although the idea of an abbreviated laparotomy for the unwell patient was not totally novel. The concepts of DCS were initially applied to complex trauma patients with combined vascular and visceral injuries. Improved outcomes were seen following DCS principles compared with conventional definitive surgery.

The DCS approach is to restore physiology over anatomy and is typically divided into several phases:

- **Phase 1**. Recognition of injury severity and the need for damage control principles, both surgical and resuscitative. Features of phase 1 include rapid-sequence induction of anaesthesia and intubation, early rewarming and prompt movement to the operating theatre.
- **Phase 2**. Immediate laparotomy with rapid control of bleeding and contamination, abdominal packing and temporary wound closure.
- **Phase 3**. Movement to the intensive care unit (ICU) for ongoing resuscitation with normalisation of biochemical and physiological parameters.
- **Phase 4**. Re-exploration in the operating theatre to perform definitive repair of all injuries. Multiple procedures on multiple occasions may be required. Even at this stage, non-essential procedures may be truncated or delayed if physiology deteriorates.

The selection of patients for damage control management may not be straightforward. While various physiological and biochemical markers of injury have been suggested, there is no validated threshold. Hypothermia, coagulopathy, acidosis, blood loss and anticipated operative time should all be considered (see ***Chapters 26 and 27***).

The benefits of a DCS approach to those patients who need it has been repeatedly shown, but liberal, and perhaps overzealous, use of DCS is unlikely to be beneficial to those who would tolerate definitive repair. DCS puts a heavy toll on theatre and ICU resources. In addition, multiple trips to theatre may increase the likelihood of morbidity, including abdominal wall hernias, fistulae and infection.

Damage control resuscitation (DCR) should be concurrent with DCS. The principles of DCR include permissive hypotension, the avoidance of crystalloid with haemostatic resuscitation and the recognition and management of acute traumatic coagulopathy (ATC). The application of these principles to military patients is uncertain because of longer timelines. Prolonged periods of permissive hypotension are likely to be harmful,[16] whereas haemostatic resuscitation and management of ATC is ineffectual in the absence of haemorrhage control.[17]

MASSIVE TRANSFUSION

While haemorrhage control prior to the need for massive transfusion is ideal, this is often not the case. The degree of injury and associated massive blood loss associated with war injuries may necessitate large-volume transfusion. The use of crystalloids to resuscitate exsanguinating patients is strongly discouraged, but the optimal ratio of blood products has not yet been ascertained. Massive transfusion protocols exist within most deployed units. The use of such a protocol in a UK role 3 facility, along with aggressive resuscitation and use of blood products, has been associated with improved trauma outcomes.[18] The success of such a protocol is highly dependent on a steady stream of blood products and reflects the sophisticated transfusion infrastructure that should be woven into a deployed capability.

Blood transfusion is increasingly administered in a more forward location (within both role 1 and role 2 environments) with limited volumes of blood transported to the point of wounding by aeromedical response teams. Future resuscitative strategies are under much scrutiny. The use of whole blood (and the possibility of 'walking blood banks') may be combined with alternatives to conventional blood components, which can join adequate oxygen carriage with positive or neutral effects on patient coagulation.[19]

DECISION MAKING WITHIN THE DEPLOYED ENVIRONMENT

The damage control approach is vital in a proportion of war injuries, but thought must be given to available resources. Within a well-established role 3 unit, both DCS and definitive procedures are likely to be possible. Blood and blood products are also likely to be available and restocked regularly. In this scenario, patient physiology is the major determinant of the mode of care.

In contrast, decision making becomes more crucial within the austere environment. Theatre space, intensive care beds, equipment and blood products may be limited. Long evacuation times may contraindicate permissive hypotension.

Limited resources, such as blood, may need to be divided among casualties. Within a role 1 or role 2 facility, immediate evacuation may be undertaken in preference to more thorough stabilisation.

Decision making of this nature is complex and difficult and requires practice in the context of simulation, exercises and courses.

WEAPON EFFECTS

Ballistics

The ability to manage conflict injuries relies on an understanding of the underlying mechanism of wounding, which is likely to be different from that in civilian trauma. As stated, while ballistic injuries are no longer the most common cause of battlefield injury, firearms remain a common element in all conflict. Civilian trauma practice, depending on local firearm laws, may well encompass a significant volume of gunshot wounds, although patterns of injury with war wounds may well differ as a result of the weapons used. An understanding of the mechanism of ballistic wounding is required to treat these wounds effectively.

The earliest recorded depiction of a firearm is from 1326, but firearms became ubiquitous on the battlefield during the seventeenth century.[20] Ballistic weapons all work with the same principles – an explosion is used to propel a projectile along and out of a straight tube – but have evolved considerably from rudimentary cannons to sophisticated modern-day firearms. The explosive force within a modern firearm comes from propellant encased within a cartridge. The basic design of a cartridge is shown in ***Figure 34.1***.

Internal ballistics describes the characteristics of a projectile while inside the weapon. The hammer mechanism strikes a primer at the base of the cartridge, which ignites the propellant. Hot gas produced by the explosion expands and forces the bullet away from the cartridge and along the barrel. Spiral grooves, or rifling, impart spin on the bullet, which aids accuracy and stabilisation.

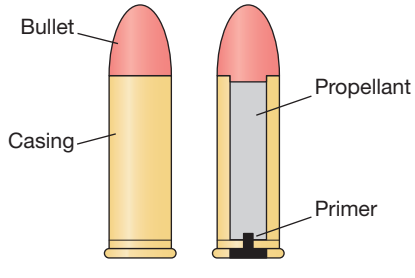

Figure 34.1 Diagram of basic cartridge structure.

While the basic principles apply to nearly all firearms, advances in firearm design have served predominantly to improve accuracy, reliability and rate of fire. Ammunition is normally held within a magazine or belt that loads directly into the chamber of the weapon. The loading mechanism determines the rate of fire. In a semiautomatic or fully automatic system, the recoil forces of the spent cartridge eject the cartridge while resetting the chamber and accepting a new cartridge from the magazine, such that the process may be repeated rapidly.

Shotguns utilise a similar mechanism except that a collection of smaller projectiles – 'shot' – are expelled rather than a single bullet. These smaller projectiles disperse away from one another after leaving the barrel. The degree of dispersal is dependent on the relative length of the barrel.

External ballistics describe the characteristics of a projectile in free flight. It may be influenced by ammunition type and ambient conditions. Ammunition differs widely with the most pronounced difference between pistol and rifle ammunition. Rifles are expected to be accurate at ranges up to and beyond 1000 metres, while pistols are intended for far shorter ranges. Rifle cartridges are longer and typically have a greater proportion of propellant to projectile. The characteristics of ammunition that determine wound effects are the size or calibre (which describes the internal diameter of the weapon barrel) and the material components of the bullet:

- Full metal jacket ammunition has an outer coating of harder metal around a softer core. This reduces breakdown of the bullet along the barrel and improves accuracy, reliability and target penetration.
- Soft tip and hollow point ammunition have a degree of exposed lead that flattens and deforms on impact. These bullets have less penetrating ability but rapidly transfer energy to the impacted tissue and cause large wounds.

Ballistic injuries

Terminal ballistics (or wound ballistics) describes the interaction between projectiles and target tissue. This interaction and subsequent transfer of energy cause injury. The kinetic energy of the bullet is related to the mass and velocity of the impacting projectile. Both the mass and velocity of military firearms may be considerably greater than those commonly seen in civilian trauma, leading to higher energies and more severe wounds. While the weapon and ammunition type may be a determinant in the potential injury caused, many other factors, including range, angle, clothing, armour and anatomical variation, will determine the actual wound pattern. Although an understanding of ballistic science may allow a surgeon to anticipate possible injuries, each should be evaluated and managed individually.

In consideration of the damage done, tissue may be described by the areas of disruption caused by the projectile and the permanent and temporary wound cavity, which are illustrated in ***Figure 34.2***.

The permanent cavity is the localised area of definitive tissue injury caused by contact with the projectile. This area of cell necrosis is the result of direct contact, crushing and laceration of tissues in the path of the projectile. The size and

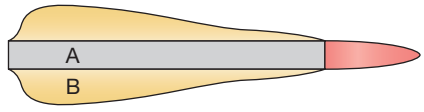

Figure 34.2 Diagram showing the permanent wound cavity (A) and the temporary wound cavity (B). This relatively large temporary cavity is more typical of a higher energy weapon.

trajectory of the projectile determines the cavity size. This type of cavity is the predominant wound effect of pistol bullets, which have relatively low energy. Higher energy projectiles, including military rifle and machine gun bullets, may be subject to greater degrees of deformation and tumbling as they travel through tissue. This increases the effective cross-sectional area of the projectile and may lead to a larger and less regular permanent wound cavity.

In contrast, the temporary wound cavity is created by lateral displacement of tissue that has not been in direct contact with the bullet. The degree of damage in this area is dependent on the amount of energy transferred by the bullet and the material properties of the tissue itself. Individual tissues have an elastic strength that resists the stretching caused by a projectile. As the energy increases, the tissue is no longer able to rebound and, above certain thresholds, contusion, laceration and permanent damage may occur. Skin, muscle, lung and bowel wall tissues have good elastic strength and may rebound well following stretch, with minimal damage within the temporary wound cavity. In contrast, liver, brain and spleen have poor elasticity and are more likely to shatter when stretched. The incompressibility of fluids within hollow organs (bowel and bladder) means that they are vulnerable to stretch despite favourable properties of the tissue wall itself.

Summary box 34.2

Ballistics

- Internal ballistics – characterise the projectile within the weapon during firing
- External ballistics – characterise the projectile in free flight
- Terminal ballistics – characterise the projectile/tissue interaction

MANAGEMENT OF GUNSHOT WOUNDS

The management of gunshot wounds in a conflict setting may differ from that in civilian practice. The typical low-energy wounds caused by pistols are sometimes managed conservatively in civilian trauma centres with adequate wound care, cleaning and antibiotics. Military wounds are associated with higher energies, higher rates of infection and more severe injury. The extent of these injuries, including the size of the wound cavities, may not be adequately assessed without thorough surgical examination (***Figure 34.3***). As such, most penetrating wounds in the military setting are explored under anaesthetic. The extent and capacity for recovery of the temporary wound

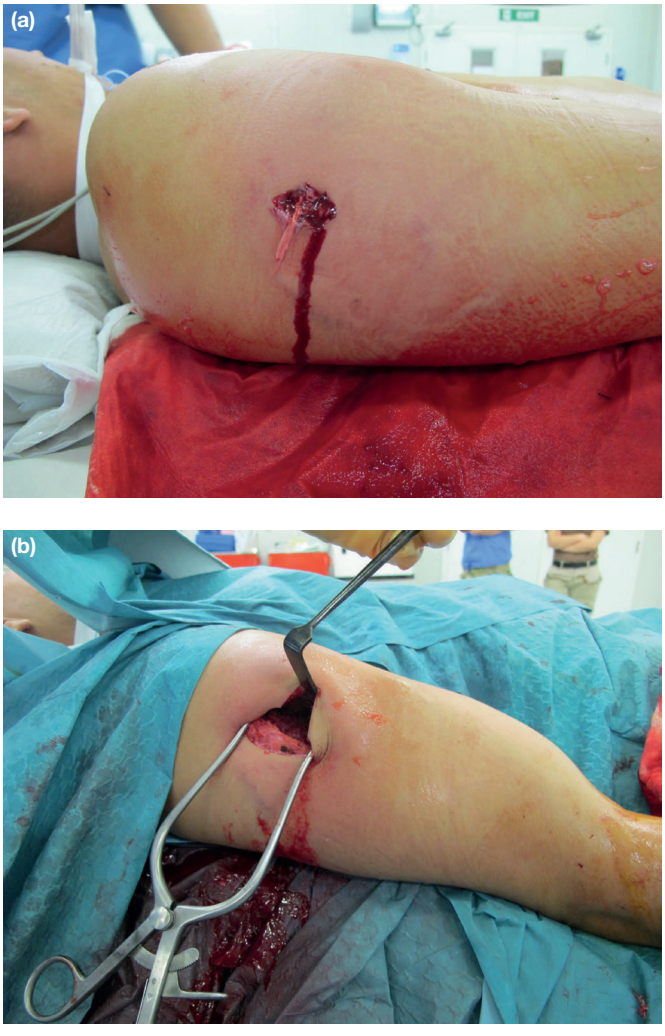

Figure 34.3 Entry wound to the right shoulder **(a)** with the wound extended in order to assess it adequately **(b)**.

cavity may not be appreciated at the time of the first operation. A damage control approach should be adopted if the physiology of the patient dictates it. An interval period may also allow for adequate appreciation of the permanent wound cavity, along with the response of the surrounding structures and demarcation of non-viable tissue.

BLAST

As already discussed, blast has become the predominant mechanism of injury in recent conflicts. Unfortunately, terrorist attacks within urban centres mean that these injuries are increasingly encountered within civilian practice.

While explosives come in many forms and their effects vary as a result, fundamental principles underlie all blast events.

An explosive may be defined as 'a substance that can be made to undergo a rapid chemical reaction that will transform a liquid or solid into gas, liberating a large amount of energy'.[21] The explosive properties of such a material are determined by the chemical composition of the material and the speed at which energy is expelled. Low explosives react by a process called deflagration, whereby the reaction is propagated by flame passing through the material at a rate significantly slower than the speed of sound. They are made up of a combustible material and an accompanying oxidant. Low explosives include gunpowder, gasoline and pyrotechnics such as fireworks and flares. Low explosives more commonly cause burns than typical blast injuries and will not be discussed further.

In contrast, high explosives degrade via detonation. Shockwaves are passed through the material at supersonic speeds and the resultant energy is expelled at very high rates. High explosives include plastic explosive and trinitrotoluene (TNT). The input of a relatively small amount of energy results in the production of a very large volume of gas, at high speed and pressure. The outward expansion causes a wave of compressed air that moves away from the point of detonation at supersonic speeds and in a uniform sphere (within a free field).

The change in surrounding pressure is described as the blast overpressure. Following detonation within a free field, there is a near instantaneous pressure rise, which falls exponentially. This is classically described by the Friedlander curve (***Figure 34.4***).

This characteristic pressure peak is only seen during a truly free (almost theoretical) scenario. Enclosure of the blast or reflection of blast waves by people, vehicles or buildings is likely to change the overpressure profile such that high pressures may be sustained for longer periods and have a greater propensity to cause injury. For this reason, blasts within enclosed spaces are notable for causing a greater range and severity of injury.

In addition to expanding gases, detonation of explosives may result in the expulsion of fragments. These fragments may be part of a device casing, separate material deliberately added with the intention of fragmentation or environmental material flung by the blast.

Blast winds are generated by the displacement of surrounding air. The direction of these winds may change as the blast

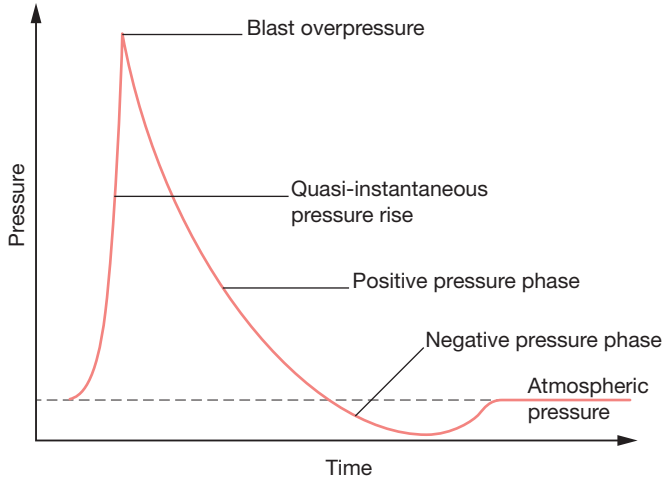

Figure 34.4 Theoretical blast overpressure changes within a free field.

Frederick Gerard Friedlander, 1917–2001, Austrian mathematician, lived and worked in the UK from 1934.

overpressure drops transiently beneath ambient pressure and creates a partial vacuum.

Improvised explosive devices

The characteristic weapon of modern warfare has been the IED, which was the leading cause of death among coalition troops during conflicts in Iraq and Afghanistan.[22] These devices may range from rudimentary homemade explosives to sophisticated devices containing high explosives. Within this broad range of devices are further categories including roadside explosives and blast mines, suicide bombers and explosive formed projectiles (EFPs). EFPs are a particular form of device with a deformable plate on the uppermost surface. The detonation of the device and expansion of the explosive products deforms this plate into a missile shape, while simultaneously accelerating it upwards to very high velocities. Alternatively, copper plates may melt to create a high-speed molten jet (a shaped charge). Upon contact with a target (typically a vehicle), the missile impacts the hull of the vehicle with a degree of penetration dependent on the device and vehicle armour. Huge amounts of kinetic energy are dispersed through the vehicle and occupants. Injuries may be caused by both direct impact of the deforming hull and gross upwards acceleration followed by downwards deceleration of the whole vehicle.

BLAST INJURIES

Blast injuries are classified by the blast mechanism (***Table 34.3***).

Primary blast injury

Primary blast injuries result from the overpressure and are, as such, unique to blast. The effect of blast overpressure is most marked at the interface between air and tissue or liquid.

Tympanic membrane (TM) rupture is the most common primary blast injury. Patients may be asymptomatic or have a degree of transient hearing loss and otorrhoea. Previously, the presence of TM rupture was used as a marker for other occult blast injuries. This has been challenged recently by findings that show TM injury is not ubiquitous in the presence of more severe primary blast injury. The blast environment and orientation of the ear canal to the shockwave are likely to determine the chance of injury.

TABLE 34.3 Classification of blast injuries.

Classification	Injury type	Examples
